Out of many experiments made with this instrument, I shall content myself with describing a few, very carefully performed at the breweries of Messrs. Trueman, Hanbury, and Buxton, and of Sir H. Meux, Bart., and at the machine factory of Messrs. Braithwaite; in the latter of which I was assisted by Captain Ericssen. In the first trials at the breweries, the end of the stop-cock attached to the differential barometer was lapped round with hemp, and made fast into the circular peep-hole of the furnace door of a wort copper, communicating with two upright parallel chimneys, each 18 inches square and 50 feet high. The fire was burning with fully its average intensity at the time. The adjustment of the level being perfect, the stop-cock orifice was opened, and the junction level of the oil and water rose steadily, and stood at $1\frac{1}{4}$ inches, corresponding to $\frac{1\cdot25}{8} = 0\cdot156$ of 1 inch of water, or a column of air 10·7 feet high. This difference of pressure indicates a velocity of 26 feet per second. In a second set of experiments, the extremity of the stop-cock was inserted into a hole, bored through the chimney stalk of the boiler of a Boulton and Watt steam-engine of twenty-horse power. The area of this chimney was exactly 18 inches square at the level of the bored hole, and its summit rose 50 feet above it. The fire-grate was about 10 feet below that level. On opening the stop-cock, the junction line rose $2\frac{1}{4}$ inches. This experiment was verified by repetition upon different days, with fires burning at their average intensity, and consuming fully 12 lbs. of the best coals hourly for each horse's power, or nearly one ton and a third in twelve hours. If we divide the number $2\frac{1}{4}$ by 8 the quotient 0·28 will represent the fractional part of 1 inch of water supported in the syphon by the unbalanced pressure of the atmosphere in the said chimney; which corresponds to $19\frac{1}{4}$ feet of air, and indicates a velocity in the chimney current of 35 feet per second. The consumption of fuel was much more considerable in the immense grate under the wort copper, than it was under the steam-engine boiler.

In my experiments at Messrs. Braithwaite's factory, the maximum displacement of the junction line was 1 inch, when the differential oil and water barometer was placed in direct communication with a chimney 15 inches square, belonging to a steam boiler, and when the fire was made to burn so fiercely, that, on opening the safety-valve of the boiler, the excess of steam beyond the consumption of the engine rushed out with such violence as to fill the whole premises. The pressure of one-eighth of an inch of water denotes a velocity of draught of 23·4 feet per second.

In building chimneys, we should be careful to make their area rather too large than too small; because we can readily reduce it to any desired size, by means of a sliding register plate near its bottom, or a damper plate applied to its top, adjustible by wires or chains passing over pulleys. Wide chimneys are not so liable as narrow ones to have their draught affected by strong winds. In a factory, many furnace flues are often conducted into one vertical chimney stalk, with great economy in the first erection, and increased power of draught in the several fires.

Vast improvements have been made in this country of late years in building stalks

for steam boilers and chemical furnaces. Instead of constructing an expensive, lofty scaffolding of timber round the chimney, for the bricklayers to stand upon, and to place their materials, pigeon-holes, or recesses, are left at regular intervals, a few feet apart, within the chimney, for receiving the ends of stout wooden bars, which are laid across, so as to form a species of temporary ladder in the interior of the tunnel. By means of these bars, with the aid of ropes and pulleys, every thing may be progressively hoisted for the building of the highest engine or other stalks. An expert bricklayer, with a handy labourer, can in this way raise, in a few weeks, a considerable chimney, 40 feet high, 5 feet 8 inches square outside, 2 feet 8 inches inside at the base, 28 inches outside, and 20 inches inside at the top. To facilitate the erection, and at the same time increase the solidity of an insulated stalk of this kind, it is built with three or more successive plinths, or recedures, as shown in *fig.* 348. It is necessary to make such chimneys thick and substantial near the base, in order that they may sustain the first violence of the fire, and prevent the sudden dissipation of the heat. When many flues are conducted into one chimney stalk, the area of the latter should be nearly equal to the sum of the areas of the former, or at least of as many of them as shall be going simultaneously. When the products of combustion from any furnace must be conducted downwards, in order to enter near the bottom of the main stalk, they will not flow off until the lowest part of the channel be heated by burning some wood shavings or straw in it, whereby the air syphon is set agoing. Immediately after kindling this transient fire at that spot, the orifice must be shut by which it was introduced; otherwise the draught of the furnace would be seriously impeded. But this precaution is seldom necessary in great factories, where a certain degree of heat is always maintained in the flues, or, at least, should be preserved, by shutting the damper plate of each separate flue, whenever its own furnace ceases to act. Such chimneys are finished at top with a coping of stone-slabs, to secure their brick-work against the infiltration of rains, and they should be furnished with metallic conducting rods, to protect them from explosions of lightning.

When small domestic stoves are used, with very slow combustion, as has been recently proposed upon the score of a misjudged economy, there is great danger of the inmates being suffocated or asphyxied, by the regurgitation of the noxious burned air. The smoke doctors who recommend such a vicious plan, from their ignorance of chemical science, are not aware that the carbonic acid gas of coke or coal must be heated 250° F. above the atmospheric air to acquire the same low specific gravity with it. In other words, unless so rarefied by heat, that gaseous poison will descend through the orifice of the ash-pit, and be replaced by the lighter air of the apartment. Drs. Priestley and Dalton have long ago shown the co-existence of these twofold crossing currents of air, even through the substance of stoneware tubes. True economy of heat and salubrity alike require vivid combustion of the fuel, with a somewhat brisk draught inside of the chimney, and a corresponding abstraction of air from the apartment. Wholesome continuous ventilation, under the ordinary circumstances of dwelling-houses, cannot be secured in any other way. Were these mephitic stoves, which have been of late so ridiculously puffed in the public prints, generally introduced, the faculty would need to be immediately quadrupled to supply the demand for medical advice; for headaches, sickness, nervous ailments, and apoplexy, would become the constant inmates of every inhabited mansion. The phenomena of the grotto of Pausilippo might then be daily realised at home, among those who ventured to recline upon sofas in such carbonated apartments; only instead of a puppy being suffocated *pro tempore*, human beings would be sacrificed, to save two penny worth of fuel *per diem*.

The figures upon the following page represent one of the two chimneys, recently erected at the Camden Town station, for the steam boilers of the two engines of 60 horse-power each, belonging to the London and Birmingham Railway company. These engines then drew their train of carriages up the inclined plane of Hampstead Hill. The chimneys were designed by Robert Stephenson, Esq., engineer to the Company, executed by William Cubitt, Esq., of Gray's Inn Road, — and do equal honour to both gentlemen, being probably among the most elegant and substantial specimens of this style of architecture in the world. In the section, *fig.* 348.,

A represents a bed of *concrete*, 6 feet thick, and 24 feet square.

B, brick footings set in cement; the lower course 19 feet square.

C, Bramley-fall stone base, with a chain of wrought iron let into it.

D, a portion, 15 feet high, curved to a radius of 113 feet, built entirely of Malm paviours, (a peculiarly good kind of bricks).

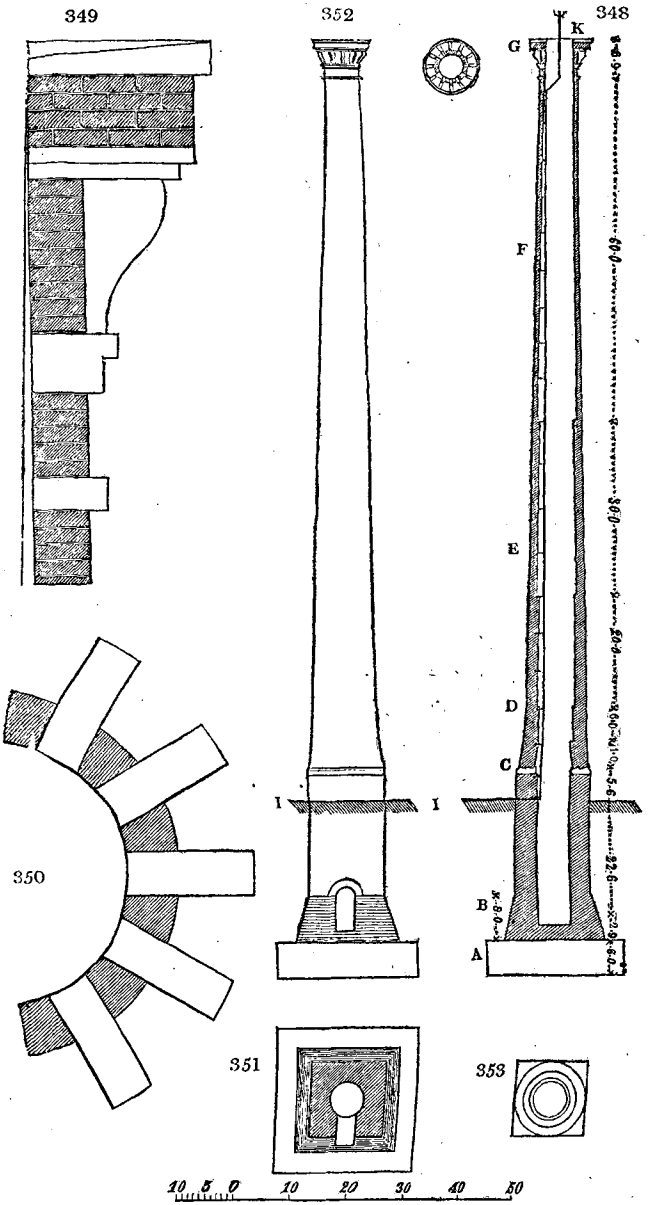
E, shaft built of Malm paviours in mortar.

F, ditto, built from the inside, without exterior scaffolding.

G, the cap ornamented, (as shown in the plan alongside,) with Portland stone, the dressings being tied together with copper cramps and an iron bond.

Fig. 349. represents the mouldings of the top, upon an enlarged scale.

Fig. 350., a plan of the foundation, upon an enlarged scale.
Fig. 351.; ditto, at the level of the entrance of the flue, as seen in
Fig. 352., the elevation of the chimney.
Fig. 353., plan at the ground level 1, in *fig.* 348. and 352.
K, *fig.* 348., the lightning conducting rod.



CHINA INK. (*Encre de Chine*, Fr.; *Chinesischer Tusch*, Germ.) The finest kind of this useful pigment is seldom met with in our markets. According to a description in a Japanese book, it is made from the condensed smoke or soot of burned camphor; and hence, when of the best quality, it has this odour. Most of the China

ink is made from oil-lampblack occasionally disguised as to smell, with musk, or with a little camphor black. The binding substance is gelatine, commonly made from parchment or ass' skin; but isinglass answers equally well. A good imitation may be made by dissolving isinglass in warm water, with the addition of a very little alkali (soda), to destroy its gelatinizing power; and incorporating with that solution, by levigation on a porphyry slab, as much of the finest lampblack as to produce a mass of the proper consistence. The minute quantity of alkali serves also to saponify the oil which usually adheres to lampblack; and thereby to make a pigment readily miscible with water.

CHINTZ is a peculiar style of fast-printed calico, in which figures of at least five different colours are impressed upon a white or light coloured ground.

CHLORATE OF POTASH, commonly called oxymuriate of potash. This interesting saline compound has become the object of a pretty extensive manufacture, in consequence of its application to make matches for procuring instantaneous light, and a detonating powder for fire-arms. It may be prepared both in the humid and dry way.

Having made a strong solution of purified potash, or carbonate of potash, with from two to three parts of water, we pass through it in a Woulfe's apparatus a current of chlorine gas, till it ceases to absorb any more. Chloride of potash and chloride of potassium alone are formed as long as there is an excess of alkali in the solution; but afterwards in the further reaction of the materials, the chloride passes into the state of a chlorate, and, as such, precipitates from the solution. During the first half of the operation, that is, till the potash be about one half saturated with chlorine, as indicated by litmus paper ceasing to be darkened and beginning to be blanched, only the chloride of potassium or muriate of potash falls. The process should be interrupted at this point in order to remove the salt, to wash it, to add the washings to the liquor, and then to transmit the gas freely through the solution. As the operation advances, less muriate of potash is formed, and at length nothing but the pure chlorate is separated in crystals. When finally the bubbles of gas pass through without being sensibly absorbed, the process is known to be completed; the liquid may then be allowed to settle, and be poured off from the crystals of chlorate of potash, which are purified from the muriate by dissolving them in three times their weight of boiling water, and filtering the solution while hot. On its cooling, the chlorate will separate in pearly-looking crystalline plates. It may be rendered quite pure by a second crystallization, in which state it does not affect solution of nitrate of silver.

The above potash lye usually gets a reddish tint in the course of the process in consequence of a little manganesic acid coming over with the chlorine, but it gradually loses this colour as the saturation becomes complete, and then the solution turns yellow. The tubes for conveying the gas should be of large diameter, if they be plunged into the saline solution, because the crystallization which takes place in it is apt to choke them up. This inconvenience may, however, be obviated by attaching to the end of the glass tube, a tube of caoutchouc terminated in a small glass funnel, or simply the neck of a caoutchouc bottle with a part of its body, whose width will not be readily closed with a saline crust. The residuary lixivium may be used against another operation, or it may be evaporated down to half its bulk and set aside to crystallize, whereby some more chlorate will be obtained, mixed indeed with muriate and carbonate, from which however it may be separated by a second crystallization. In general the pure chloride obtained does not exceed one tenth the weight of the potash employed; because in thus treating potash with chlorine, five-sixths of it are converted into muriate of potash and only one-sixth into chlorate, and a part of the latter adheres to the muriate, or is lost in the mother waters of the crystallizations.

The chlorate of potash may be more conveniently manufactured, like that of lime, in the dry way. St. Romer patented at Vienna the following method for that purpose in 1821: — Ten pounds of crystallized peroxide of manganese are to be finely pulverized, mixed with ten pounds of plumbago, and thirty pounds of common salt, and put into the leaden retort represented in *fig.* 354. p. 410. Vol. I. From the middle of the helmet-shaped lid of this vessel, a lead tube, two feet long, and two inches wide, conducts to the receiver, which is a square earthen pan, hard glazed both within and without, of the same capacity with the retort. The end of the tube must be made fast to a frame at the height of six inches above the bottom of the receiver. Upon its inner side, four inches apart, brackets are to be fixed for supporting a series of laths or shelves of white wood, on which a number of little paper or paste-board boxes are to be laid. In these boxes ten pounds of the purest carbonate of potash, prepared from tartar, are to be spread. The receiver must now be covered with a lid made tight by a water lute. Twenty pounds of concentrated sulphuric acid previously diluted with sixteen pounds of water, and then cooled, are to be poured upon the mixed materials in the retort, the lid immediately secured, with the tube adjusted in the receiver. The whole must be allowed to operate spontaneously without heat for twelve hours. At the end of this time the retort is to be surrounded with a water bath and steadily heated during twelve hours, and then left

to cool for six hours. The apparatus must now be opened, the cakes of chlorate of potash removed, and freed from muriate by solution and crystallization.

M. Liebig proposes the following process for obtaining chlorate of potash :—

Heat chloride of lime in water till it ceases to destroy vegetable colours. In this case a mixture of chloride of calcium and chlorate of potash is obtained. This is to be dissolved in hot water, and to the solution concentrated by evaporation, chloride of potassium is to be added, and then suffered to cool. After cooling, a quantity of crystals of chlorate of potash is obtained, which are to be redissolved and crystallized again to purify them. M. Liebig considers that this will be a cheap process for obtaining chlorate of potash. From 12 ounces of chloride of lime, of so bad a quality that it left 65 per cent. of insoluble matter, he obtained an ounce of chlorate of potash.

The only difficulty to overcome in this process is, from the chloride of lime not being so easily decomposed by heat as is generally supposed; a solution of it may be kept boiling for an hour without losing its bleaching power. The best method is to form a thin paste with chloride of lime and water, and then to evaporate it to dryness. If it be required to prepare it by passing chlorine into cream of lime, it is advantageous to keep it very hot.

The chlorate of potash which separates from the solution by crystallization has not the form of scales which it usually possesses, but is prismatic: whether this is occasioned by some admixture has not been ascertained; but on re-crystallizing, it is obtained in the usual form.

The solution ought not merely to be left to cool, in order to procure crystals, for the crystallization is far from being terminated even after complete cooling; crystals continue to be deposited for 3 or 4 days.

The following modification of the process for making chlorate of potash is that of M. Vée. A solution of chloride of lime marking 18° or 20° Baumé is to be set upon the fire in a lead or cast iron pot, and when it begins to get hot, there is to be dissolved in it a quantity of chloride of potassium sufficient to raise the hydrometer 3 or 4 degrees. It must be then concentrated as quickly as possible till it marks 30° or 31°, taking care that it does not boil over by the sudden extrication of oxygen. The concentrated liquor is set aside to crystallize in a cool place; where a deposit of chlorate of potash forms, mixed with chloride of potassium. The mother waters being evaporated to the density of 36°, afford another crop of crystals, after which they may be thrown away.

The salts obtained at the first crystallization are to be re-dissolved, and the solution being brought to 15° or 16° is to be filtered, when it will afford upon cooling pure chlorate of potash.

Chlorate, the old oxymuriate, of potash has a cooling, somewhat unpleasant and nitrous taste. It does not bleach. At 60° Fahr. 100 parts of water dissolve six parts of it, and at its boiling point, or 220°, sixty parts. When heated to dull ignition in a glass retort it gives out 39·15 per cent. of its weight of oxygen, and becomes thereby chloride of potassium. When strongly triturated in a mortar it crackles, throws out sparks, and becomes luminous. It deflagrates upon red-hot cinders like nitre: when triturated along with sulphur, or phosphorus, it detonates with great violence, not without danger to the hands of the operator, if they be not protected by a thick glove. Similar detonations may be produced with cinnabar or vermilion, sulphuret of potassium, sugar, volatile oils, &c.; but they can be effected only by the smart blow of a heated hammer and anvil. A mixture of sugar or starch with chlorate of potash is readily inflamed by a drop of sulphuric acid, and this experiment is the basis of the preparation of the oxygenated matches, as they have been commonly called. The following formula forms a good paste for tipping the said matches, made of narrow slips of either wood or card. Thirty parts of the chlorate in fine powder are to be mixed gently with a spatula upon paper with ten parts of flowers of sulphur well levigated, eight of sugar, five of gum arabic, and enough of vermilion to give the whole a rose tint. We begin by mixing tenderly together the sugar, the gum, and the salt previously pulverised; we then add as much water as shall reduce the mixture to a thin paste, and lastly introduce the sulphur; after which all must be well incorporated. The points of the matches, either previously tipped with sulphur or not, are to be dipped in that paste, so as to get coated with a little of it, and are lastly laid in a warm place till they become thoroughly dry. To kindle one of them, it must be touched with strong sulphuric acid, which for this purpose is usually kept in a small well-stoppered phial, and thickened with amianthus. Aspen is reckoned the best wood for matches.

Of late years a detonating priming for fire-arms has been much used with the percussion locks. The simplest formula for making it is to take ten parts of gunpowder, to lixiviate it with water, and to mix the residuum, while moist, with five parts and a quarter of chlorate of potash, reduced to an extremely fine powder. The paste may be made pretty thin, for the salt is sparingly soluble in the cold water, and it mixes best when tolerably fluid. This powder when dry is dangerous to handle, being very apt to

explode. But this danger is guarded against by letting fall a drop of the paste into each copper percussion cap, and leaving it to dry there. In the detonation of this powder, besides muriate of potash, there are generated a little sulphate of potash and chlorine gas, which rust the metal very fast. For which reason fulminate of mercury is now preferred by many sportsmen as a detonating powder. See FULMINATE.

The following ingenious and easy way of making this valuable chlorate has been lately suggested by Professor Graham: — Mix equal atomic weights of carbonate of potash and hydrate of lime (70 of the former, if pure, and 37 of slaked lime in powder), diffuse them through cold water, and transmit chlorine gas through the mixture. The gas is absorbed with great avidity, and the production of a boiling heat. When the saturation is complete, carbonate of lime remains, and a mixture of muriate and chlorate of potash, which latter salts are to be separated, as usual, by the difference of their solubility in water.

It has been remarked on the above process, that it effects no saving of potassa, and therefore is far inferior to the one long practised in several parts of Germany, especially at Giessen, and introduced into this country a good many years ago by Dr. Wagenmann, from Berlin. The chlorine is passed into a mixture of one equivalent of chloride of potassium (76), and 6 equivalents of hydrate of lime (222), previously stirred with water, to the consistence of a thin paste. Thus the calcium of the lime unites with the chlorine to form chloride of calcium, while the chloride of potassium is converted into chlorate of potassa, which salt is easily separated in crystals by its sparing solubility.

Chlorate of potash may also be made by saturating with chlorine a mixture of 74 parts of chloride of potassium (muriate of potash) and 168 parts of quicklime, brought to the consistence of a thin pap by the cautious addition of water. The mass being dissolved in warm water, and evaporated and cooled, yields crystals of chlorate of potash, while a mother water of chloride of calcium (muriate of lime) remains. The following process has likewise been prescribed: — Mix 10 parts of good chloride of lime with water into a pap, and evaporate to dryness, whereby it is converted into a mixture of chloride of calcium and chlorate of lime devoid of bleaching power; dissolve it in water, filter, concentrate the solution by evaporation, then add to it 1 part of chloride of potassium, and cool for crystallization. The salt which may thereby be separated from the chloride of calcium will afford 0·83 of pure chlorate of potash. By this process of Professor Liebig five sixths of the potash are saved, but much oxygen is wasted in the evaporation to dryness of the chloride of lime, and consequently, much chloric acid is lost towards the production of the salt. Vée mixes the chloride of lime pap, before heating it, with the chloride of potassium, boils the mixture smartly, whereby much oxygen is undoubtedly thrown off, and then sets the liquor *aside* to crystallize. L. Gmelin suggests that saturation of the liquor with chlorine before boiling might be advantageous. Gay Lussac has suggested to make this valuable salt by precipitating a solution of chloride of lime with carbonate (or sulphate) of potash, saturating the liquor after filtration with chlorine gas, evaporating, and crystallizing.

Professor Juch's process is to pass chlorine gas into a mixture of 1 pound caustic lime and 1 pound carbonate of potash, with 8 pounds of water. The resulting chloride of potash readily separates in the filtered liquid by crystallization from the very soluble chloride of calcium. By this method potash is not wasted in the useless production of chloride of potassium.

CHLORATES, compounds of chloric acid with the salifiable bases. The only acid belonging to this class of any manufacturing importance is the following:

CHLORIC ACID, the acid constituent of the preceding salt; it consists of one equivalent prime of chlorine = 35·476 and 5 of oxygen, = 40·065; the sum of which 75·541 is the prime equivalent of the acid.

CHLORINE, the most energetic of the undecompounded bodies, or chemical elements as they are usually called, exists, under ordinary circumstances, as a greenish yellow gas, but, when exposed to a pressure of 4 atmospheres, it becomes a yellow transparent liquid. In the first state, its density compared to air, reckoned 1·000, is 2·47: in the second, its density compared to water, 1·000, is 1·33. No degree of cold hitherto tried has liquefied the gas when dry. It is obtained by putting into a glass retort a mixture of 3 parts of common salt, with 2 parts of peroxide of manganese, and pouring upon it 2 parts of sulphuric acid diluted with its own weight of water; or, more conveniently, by pouring moderately strong muriatic acid upon peroxide of manganese in a retort; and in either case applying the gentle heat of a spirit lamp or a water bath, while the beak of the retort is plunged under brine upon the shelf of the pneumatic trough. The gas issues, and may be received in the usual way into inverted glass jars, or phials; but the first which comes over being mixed with the air of the retort must be rejected. It has a peculiar smell, and irritates the nostrils most violently when inhaled, as also the windpipe and lungs. It is eminently noxious to animal life, and, if breathed in its undiluted state, would prove instantly fatal. It supports the combustion of many bodies,

and indeed spontaneously burns several without their being previously kindled. The resulting combinations are called chlorides, and act most important parts in many manufacturing processes.

Water absorbs, at the ordinary temperature of the atmosphere, about double its volume of chlorine, and acquires the colour, smell, and taste of the gas, as well as its power of destroying or bleaching vegetable colours. When this aqueous chlorine is cooled to 36° Fahr. dark yellow crystalline plates appear in it of the hydrate of chlorine, which are composed in 100 parts of 27·7 chlorine, and 72·3 water. If these crystals be heated to about 45° they liquefy, and the gas flies off.

Chlorine has a powerful affinity for hydrogen, not only combining with it rapidly in the gaseous, but seizing it in many of its liquid and solid combinations, as in volatile oils, which it inflames, and in yellow wax, cotton, and flax, which it whitens. The compound of chlorine and hydrogen gases is muriatic acid gas. Manganese, when mixed with liquid muriatic acid, as in the above process, abstracts the hydrogen, and lets the chlorine gas go free. When chlorine is passed into water, it decomposes some of it, seizes its hydrogen to form a little muriatic acid, and enables its oxygen to unite either with the chlorine, into chlorous acid, or with the remaining water, and to constitute oxygenated water. Hence, aqueous chlorine, exposed to the sunbeam, continually evolves oxygen, and, ere long, becomes muriatic acid.

This watery compound acts in a powerful way upon coloured vegetable fibres, extracting their hydrogen or colouring element by the twofold affinities of the chlorine and oxygen for it.

Hence chlorine, as a bleaching agent, requires to be tempered by the quiescent affinity of some alkaline base, potash or lime. Malaria, or morbific and putrescent miasmata, consist chiefly of hydrogenous matter as their basis, and are best counteracted by chlorine, where it can be conveniently applied.

Chlorides of Potash, Soda, and Lime. — These are the most important preparations through which chlorine exercises its peculiar powers upon the objects of manufacture. When a weak solution of caustic potash or soda is saturated with chlorine it affords a bleaching liquor which is still used by some bleachers and calico-printers for their most delicate processes; but the price of the alkalis has led to the disuse of these chlorides as a general means, and has occasioned an extensive employment of chloride of lime. Upon the manufacture of this interesting compound I made an elaborate series of experiments several years ago, and published the results in the 13th volume of Brande's Journal, for April, 1822. I have no reason to suppose, from any thing that has been published since, that the processes there described have been essentially improved, or that any errors, either theoretical or practical, of any moment, exist in that memoir. I shall therefore first present my readers with a brief abstract of it, and then make such observations as subsequent inquiries suggest.

In the researches which I made, at many different times, upon the nature of the chloride of lime, I generally sought to combine the information flowing from both synthesis and analysis; that is, I first converted a known portion of hydrate of lime into bleaching-powder, and then subjected this chloride to analysis.

Two hundred grains of the atomic proto-hydrate of pure lime were put into a glass globe, which was kept cold by immersion in a body of water at 50°. A stream of chlorine, after being washed in water of the same temperature in another glass globe, connected to the former by a long narrow glass tube, was passed over the calcareous hydrate. The globe with the lime was detached from the rest of the apparatus from time to time, that the process might be suspended as soon as the augmentation of weight ceased. This happened when the 200 grains of hydrate, containing 151·9 of lime, had absorbed 130 grains of chlorine. By one analytical experiment it was found, that dilute muriatic acid expelled from 50 grains of the chloride, 20 grains of chlorine, or 40 per cent.; and by another, from 40 grains, 16·25 of gas, which is 40·6 per cent. From the residuum of the first 39·7 grains of carbonate of lime were obtained by carbonate of ammonia; from that of the second, 36·6 of ignited muriate of lime. The whole results are therefore as follows: —

	Synthesis.	1st Analysis.	2d Analysis.	Mean.
Chlorine	39·39	40·00	40·62	40·31
Lime	46·00	44·74	46·07	45·40
Water	14·60	15·26	13·31	14·28
	100·00	100·00	100·00	100·00

Though the heat generated by the action of the dilute acid had carried off in the analytical experiments a small portion of moisture with the chlorine, yet their accordance with the synthetic experiment is sufficiently good to confirm the general results. The above powder appears to have been a pure chloride, without any mixture of muriate. But it exhibits no atomic constitution in its proportions.

To 200 grains of that hydrate of lime 30 grains of water being added, the powder was subjected to a stream of chlorine in the above way, till saturation took place. Its increase of weight was 150 grains.

It ought to be remarked, that in this and the preceding experiment, there was no appreciable pneumatic pressure employed to aid the condensation of the chlorine. In the last case, we see that the addition of 30 grains of water has enabled the lime to absorb 20 grains more of chlorine, being altogether a quantity of gas nearly equal to that of the dry lime. Thus, an atom of lime seems associated with $\frac{7}{9}$ of an atom of chlorine. Analysis by muriatic acid confirmed this composition. It gave

Chlorine	-	39·5 = 51·8 cubic inches.
Lime	-	39·9
Water	-	20·6
		100·0

A great variety of apparatus has been at different times contrived for favouring the combination of chlorine with the slaked lime for the purposes of commerce. One of the most ingenious forms, is that of a cylinder, or barrel, furnished with narrow wooden shelves within, and suspended on a hollow axis, by which the chlorine was admitted, and round which the barrel was made to revolve. By this mode of agitation, the lime-dust, being exposed on the most extensive surface, was speedily impregnated with the gas to the requisite degree. Such a mechanism I saw at MM. Oberkampf and Widmer's celebrated *fabrique de toiles peintes*, at Jouy, in 1816. But this is a costly refinement, inadmissible on the largest scale of British manufacture. The simplest, and, in my opinion, the best construction for subjecting lime-powder to chlorine, is a large chamber 8 or 9 feet high, built of siliceous sandstone, having the joints of the masonry secured with a cement composed of pitch, resin, and dry-gypsum in equal parts. A door is fitted into it at one end, which can be made air-tight by strips of cloth and clay lute. A window on each side enables the operator to judge how the impregnation goes on by the colour of the air, and also gives light for making the arrangements within at the commencement of the process. As water lutes are incomparably superior to all others where the pneumatic pressure is small, I would recommend a large valve or door on this principle to be made in the roof, and two tunnels of considerable width at the bottom of each side wall. The three covers could be simultaneously lifted off by cords passing over a pulley, without the necessity of the workman approaching the deleterious gas, when the apartment is to be opened. A great number of wooden shelves, or rather trays, 8 or 10 feet long, 2 feet broad, and 1 inch deep, are provided to receive the riddled slaked lime, containing generally about 2 atoms of lime to 3 of water. These shelves are piled one over another in the chamber, to the height of 5 or 6 feet, cross bars below each keeping them about an inch asunder, that the gas may have free room to circulate over the surface of the calcareous hydrate.

The alembics for generating the chlorine, which are usually nearly spherical, are in some cases made entirely of lead, in others of two hemispheres, joined together in the middle, the upper hemisphere being lead, the under one cast-iron. The first kind of alembic is enclosed for two-thirds from its bottom, in a leaden or iron case, the interval of two inches between the two being destined to receive steam from an adjoining boiler. Those which consist below of cast-iron have their bottom directly exposed to a very gentle fire; round the outer edge of the iron hemisphere a groove is cast, into which the under edge of the leaden hemisphere fits, the joint being rendered air tight by Roman or patent cement. In this leaden dome there are four apertures, each secured by a water-lute. The first opening is about 10 or 12 inches square, and is shut with a leaden valve, with incurvated edges, that fit into the water channel at the margin of the hole. It is destined for the admission of a workman to rectify any derangement in the apparatus of rotation, or to detach hard concretions of salt from the bottom.

The second aperture is in the centre of the top. Here a tube of lead is fixed, which descends nearly to the bottom, and down through which the vertical axis passes. To its lower end the cross bars of iron, or of wood, sheathed with lead, are attached, by whose revolution the materials receive the proper agitation for mixing the dense manganese with the sulphuric acid and salt. The motion is communicated either by the hand of a workman applied from time to time to a winch at top, or it is given by connecting the axis with wheel work, impelled by a stream of water or a steam-engine.

The third opening admits the syphon-formed funnel, through which the sulphuric acid is introduced; and the fourth is the orifice of the eduction-pipe.

Manufacturers differ much from each other in the proportion of their materials for generating chlorine. In general, 10 cwt. of salt are mixed with from 10 to 14 cwt. of manganese, to which mixture, after its introduction into the alembic, from 12 to 14 cwt. of sulphuric acid are added in successive portions. That quantity of oil of vitriol must, however, be previously diluted with water, till its specific gravity becomes about 1·6. But, indeed, this dilution is seldom actually made, for the manufacturer of bleaching-powder almost always prepares his own sulphuric acid for the purpose, and therefore carries its concentration no higher in the leaden boilers than the density of 1·65, which, from my table of sulphuric acid, indicates $\frac{1}{4}$th of its weight of water, and therefore $\frac{1}{3}$rd more of such acid must be used.

The fourth aperture, I have said, admits the eduction-pipe. This pipe is afterwards conveyed into a leaden chest or cylinder, in which all the other eduction-pipes also terminate. They are connected with it simply by water-lutes, having hydrostatic pressure of 2 or 3 inches. In this general *diversorium* the chlorine is washed from adhering muriatic acid, by passing through a little water, in which each tube is immersed, and from this the gas is let off by a pretty large leaden tube, into the combination room. It usually enters in the top of the ceiling, whence it diffuses its heavy gas equally round.

Four days are required, at the ordinary rate of working, for making good marketable bleaching-powder. A more rapid formation would merely endanger an elevation of temperature, productive of muriate of lime, at the expense of the bleaching quality. But skilful manufacturers use here an alternating process. They pile up, first of all, the wooden trays only in alternate shelves in each column. At the end of two days the distillation is intermitted, and the chamber is laid open. After two hours the workman enters, to introduce the alternate trays covered with fresh hydrate of lime, and at the same time rakes up thoroughly the half-formed chloride in the others. The door is then secured, and the chamber, after being filled for two days more with chlorine, is again opened, to allow the first set of trays to be removed, and to be replaced by others, containing fresh hydrate, as before. Thus the process is conducted in regular alternation; thus, to my knowledge, very superior bleaching-powder is manufactured, and thus the chlorine may be suffered to enter in a pretty uniform stream. But for this judicious plan, as the hydrate advances in impregnation, its faculty of absorption becoming diminished, it would be requisite to diminish proportionately the evolution of chlorine, or to allow the excess to escape, to the great loss of the proprietor, and, what is of more consequence, to the great detriment of the health of the workmen.

The manufacturer generally reckons on obtaining from one ton of rock-salt, employed as above, a ton and a half of good bleaching-powder. But the following analysis of the operation will show that he ought to obtain two tons.

When a mixture of sulphuric acid, common salt, and black oxide of manganese are the ingredients used by the manufacturer of bleaching-powder, the absolute proportions are, upon the oxygen scale of equivalents; —

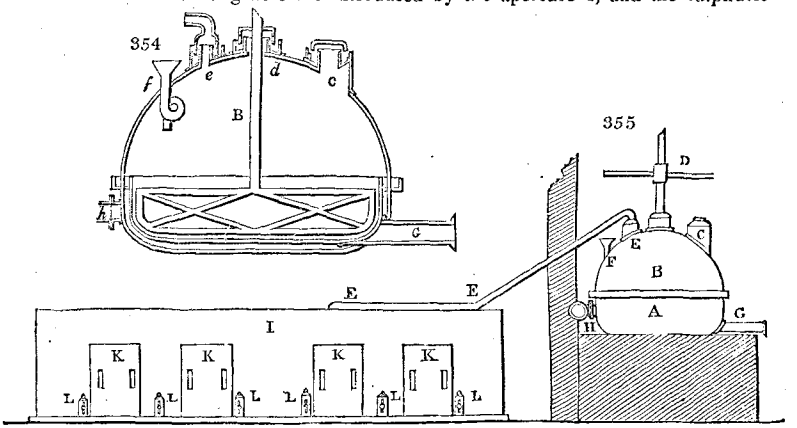
1 atom muriate of soda	7·5	29·70	100·0
1 atom peroxide of manganese	5·5	21·78	73·3
2 atoms oil of vitriol 1·846	12·25	48·52	163·3
	25·25	100·00	
And the products ought to be; —			
Chlorine disengaged	1 atom.	4·5	17·82
Sulphate of soda	1 —	9·0	35·64
Proto-sulphate of manganese	1 —	9·5	37·62
Water	2 —	2·25	8·92
		25·25	100·00

These proportions are, however, very different from those employed by many, nay, I believe by all manufacturers; and they ought to be so, on account of the impurity of their oxide of manganese. Yet making allowance for this, I am afraid that many of them commit great errors in the relative quantities of their materials.

From the preceding computation, it is evident that 1 ton of salt with 1 ton of the above native oxide of manganese, properly treated, would yield 0·59 of a ton of chlorine, which would impregnate 1·41 tons of slaked lime, producing 2 tons of bleaching-powder, stronger than the average of the commercial specimens; or allowing for a little loss, which is unavoidable, would afford 2 tons of ordinary powder, with a little more slaked lime.

Fig. 354. represents a retort of lead, well adapted to the evolution of chlorine from the mixture of salt, manganese, and sulphuric acid, or from manganese and muriatic acid.

The interior vessel is cast in lead, and it has round its bottom part a cast-iron steam case. The salt and manganese are introduced by the aperture c, and the sulphuric



acid by the syphon funnel F. The contact of these three substances is continually renewed by the agitator or stirrer B, which consists of wrought or cast iron sheathed with lead. *e* is the gas discharge pipe. The residuums are drawn off by the bottom discharge pipe G. The heating case receives its steam by the pipe *h*.

The chlorine gas, *fig.* 355. is conveyed from the retort B, into the chamber I, by the tube E E E. This chamber is divided into four compartments, to receive the gas disengaged from four retorts, like the above. The bottom of it is covered with a stratum three or four inches thick of quicklime, newly slaked and sifted, which is stirred about from time to time, by the rakes L L L L. When the saturation is sufficient, the [redacted]e of lime is taken out by the doors K K K K. The size of this apparatus allows 2 cwt. of manganese, and its equivalent quantity of salt and sulphuric acid, or of muriatic acid, to be introduced at once into the retort. D is the handle of the agitator.

The same form of retort will suit perfectly well to prepare chlorine for making liquid chloride of lime, which is preferred by many bleachers and calico-printers who have conveniences for preparing it themselves. The most concentrated solutions of the dry chloride of lime do not mark more than 6° B. (sp. grav. 1·04), and discolour only 50 volumes of Gay Lussac's solution of indigo, whilst the chloride made in the humid way marks from 8° to 9° B. (about 1·060), and discolours 80 volumes of the same solution.

In the chloride of lime apparatus, most generally used by the skilful calico-printers of Mülhausen, the mixture of muriatic acid and manganese is put into glass globes, with long necks, heated upon a sand-bath. The chlorine is conveyed by glass tubes into a cylindrical stone cistern, containing milk of lime. The furnace of the sand baths is made of cast iron, and has brick partitions, to give each retort its own fire. The smoke of all these fires goes off by a flue into sheet iron pipes. The cistern is made of siliceous sandstone. Its cover is of wood, coated with a resinous cement; and it fits at its edges into grooves cut in the stone. A wheel serves to agitate the liquid continually; its paddles being kept at two inches distance from the sides of the cistern. The milk of lime is introduced by a funnel, and the chloride is drawn off by a discharge pipe. I think the lead retort and agitator used in this country greatly preferable to the experimental laboratory plan described above. In all such apparatus we should avoid giving any pressure to the tubes or vessels, and should not therefore dip the extremities of the gas pipes beneath the surface of the liquid, but rather facilitate the combination of the chlorine and the lime, by enlarging the surfaces of contact and by agitating. Intermediate vessels containing water, or the chemical cascade of M. Clement, are very useful for absorbing any muriatic acid which may be disengaged along with the chlorine, and thereby preventing the needless formation of muriate of lime in the chambers or cisterns of impregnation.

When the solution of the chloride of lime is mixed with hydrate of lime, it bears, without decomposing, a pretty high temperature, provided it be not too long continued; it may even, in certain cases, be raised to near the boiling point without suffering a marked loss of its discolouring power; but when the chloride is deprived of that excess of lime, it is decomposed in a short time, even at a heat of 110° F.

When chlorine is admitted to milk of lime, it infallibly produces some muriate of lime; but the quantity is kept at a *minimum* by constantly presenting an excess of

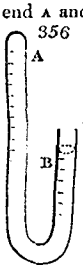
lime to the gas with the agitator, and by keeping the temperature as low as possible. Hence the influx of gas should not be so rapid as to generate much heat. An automatic agitator, moved by steam or water power, is therefore much better than one driven by the hand of the operator, who is apt to intermit his labours. If the liquor becomes hot at the end of the process, it should be immediately drawn off into large stone bottles, and cooled. The rose-colour which sometimes supervenes is due to a minute quantity of manganese. The strongest liquid chloride of lime that can be prepared will not discolour more than 80 times its volume of Gay Lussac's indigo test.

On acting upon cotton cloth with a concentrated solution of chloride of lime, at from 110° to 120° F., pure carbonic acid gas is disengaged, and the texture of the cloth is injured. Here the hydrogen of the water and the cotton being seized by the chlorine, the liberated oxygen combines with the carbon to form carbonic acid. In the discharge troughs, where printed calicoes are passed through strong solutions of chloride of lime, stalactitic crusts of carbonate of lime come to be formed in this way.

The *chlorometre* of Gay Lussac consists of a test solution of indigo and a graduated tube. One part of the best indigo, passed through a silk sieve, is to be dissolved in nine parts of concentrated sulphuric acid, by the aid of a water-bath heat applied for six hours. The sulphate of indigo is now to be diffused through such a body of water that one volume of chlorine gas shall discolour exactly ten times its volume of this dilute solution. The test liquor should be protected from the agency of light.

Mr. Crum, of Thorniebank, near Glasgow, has lately modified Dr. Dalton's copperas test for chloride of lime, and made it convenient to the practical man. The doctor justly considered that the more chlorine any bleaching powder contains, the more of the green sulphate of iron will it convert into the red sulphate, so that we have only to add successive portions of the chloride to a given weight of the dissolved copperas, and note the point at which all the iron gets peroxidized. See BLEACHING.

Besides the method of analysis already quoted from my memoir on the manufacture of the chloride of lime, another occurred to me long ago, which I often practised as an easy and expeditious test. Chlorine decomposes ammonia. If therefore water of ammonia, faintly tinged with litmus, be added slowly to a solution of a given weight of chloride of lime, the colour will continue to disappear till the chlorine be all neutralized by the reaction of the hydrogen of the ammonia. The quantity of liquid ammonia of a certain strength requisite to neutralize, in this way, a certain volume, say, one cubic inch, or a thousand grain measures, of chlorine gas, may be assumed as the standard of such a chlorometer. As chlorine or chloride of lime, when mixed with water of ammonia, causes the disengagement of azote, the quantity of this gas evolved may also be made the foundation of an accurate and convenient chlorometer. The two substances should be mixed over mercury, in a graduated syphon tube. The shut end A and the open end B are both graduated to one scale; for example, to hundredths of a cubic inch, or to grain or 10 grain measures. The tube is to be filled with mercury, and then 10 measures of it are to be displaced at the open end by inserting a wooden plug. This space being filled with the solution of chloride of lime, is to be turned up into the shut end by covering the open end with the finger, and inverting the tube; a few drops of water may be sent through to wash the mercury. The ammonia being now let up will cause a reaction, and evolve a quantity of azote, equivalent to the chlorine present. The action may be quickened by holding the sealed end of the tube obliquely over a lamp heat. The mercury is protected from the chlorine by the ammonia; and should any notion be entertained of such an action, the ammonia may be let up first. I have made innumerable researches over mercury with a detached apparatus of that kind, which combines precision with rapidity of result. It was by a similar mercurial syphon that I analyzed the carbonates, as described in the first edition of my Dictionary of Chemistry, 32 years ago.



M. Gay Lussac takes, as the basis of his indigo chlorometer, the fact, that one pound of pure crystallized peroxide of manganese is capable of affording, with muriatic acid, 0·7964 parts of a pound of chlorine; or one kilogramme yields 251¼ litres; that is, one pound yields 251¼ pound measures. Hence 3·98 grammes of that manganese are capable of affording 1000 gramme measures, or 1 litre of chlorine; or, in round numbers, 4 grains will yield 1000 grain measures. This quantity of gas being received into that volume of milk of lime, constitutes therefore Gay Lussac's primary standard. The small retort in which the manganese and muriatic acid are put ought to be heated to ebullition, to discharge every particle of chlorine. To prevent the manganese, in this experiment, from sticking to the bottom in a cake, it has been proposed to mix it previously with a little plumbago. See CHLOROMETRY.

For preparing the chlorides of potash and soda, the same apparatus may be employed as for the liquid chloride of lime. The alkaline solutions should be weak, containing not more than a pound to the gallon of water. Potash liquor, saturated

with chlorine, is much employed at Paris for whitening linen, under the name of the water of Javelle, the place where it was first made as a manufacture. One hundred parts of chlorine are said to saturate 133 parts of pure potash, and 195 of the carbonate; but the latter should not be used for preparing the bleaching fluid, as the carbonic acid resists the combination of the chlorine. A chloride of carbonate of soda has been lately recommended as a disinfecting substance against contagious miasmata or *fomites*. One hundred parts of chlorine will saturate 150 of the dry carbonate, and 405 of the crystallized. M. Payen prepares this medicinal chloride, by adding 138 parts of carbonate of soda to a liquid, consisting of water 1800, chloride of lime 100, at 98° of strength, by Gay Lussac's standard. The chloride of lime is to be dissolved, and the sediment well washed; the carbonate of soda, dissolved by heat, is to be poured into the solution, the precipitate allowed to subside, the clear fluid decanted, and the solid matter washed upon a filter. The collected solutions are neutral chloride of soda. Sixty-two parts of the carbonate of soda are then to be dissolved in the remainder of the water, and added to the preparation; the whole being thus filtered, a limpid liquor is obtained, indicating 5° by the hydrometer of Baumé.

The chloride of magnesia was long ago proposed by Sir H. Davy for bleaching linen, as being preferable to chloride of lime, because the resulting muriate of magnesia was not injurious to the fibre of cloth, as muriate of lime may be, under certain circumstances. I prepared a quantity of chloride of magnesia, by exposing a hydrate of that earth in the chlorine chamber of a large manufactory of chloride of lime at Glasgow, and obtained a compound possessed of considerable discolouring powers; but I found that the chlorine was so feebly saturated by the base, that it destroyed the colours of fast-dyed calicoes as readily as chlorine gas or chlorine water did, and was therefore dangerous for common bleaching, and destructive in clearing the grounds of printed goods, which is one of the most valuable applications of the calcareous and alkaline chlorides. The occasion of my making these experiments was the importation of a considerable quantity of magnesite, or native atomic carbonate of magnesia, from the district of Madras, by an enterprising friend of mine. Encouraged by the encomiums bestowed on the chloride of magnesia by many chemical writers, he expected to have benefited both the country and himself, by bringing home the earthy base of that compound, at a moderate price; but was disappointed to his cost.

Dr. Thomson is of opinion that the bleaching compound of lime and chlorine is not a chloride of lime, but a combination of chlorous acid with lime and of chlorine with calcium: consisting in its most concentrated state of

3 atoms of chloride of calcium	= 21
1 atom of chlorite of lime -	= 11
	32

So that about one third of the weight is chlorite of lime, to which alone the bleaching powers of the substance are owing. He admits a fact, rather inconsistent with this opinion, that bleaching powder does not attract moisture from the atmosphere with nearly so much rapidity as might be expected from a mixture containing two thirds of its weight of so deliquescent a salt as muriate of lime; unless this indeed be prevented by the chloride and chlorite being united into a double salt, which is a mere conjecture without either proof or analogy. And further, when dilute sulphuric or muriatic acid is poured upon bleaching powder, a profusion of chlorine is given out immediately, which he also admits to be inconsistent with the notion of its being a mixture of chloride of calcium and chlorite of lime, for no such evolution takes place when the above acids are mixed with solutions of chloride of calcium and chlorate of potash. Though I am of opinion that bleaching powder is simply a chloride of lime, in which the lime corresponds to the water in the aqueous chlorine, yet I cannot see the truth or appositeness of his last reason, because chlorine is certainly given out when chlorate of potash is acted upon by dilute muriatic acid, as any man may prove by adding to a mixture of these two substances a vegetable colour; for it will be speedily blanched. Dr. Thomson considers the chloride which is at present made in Mr. Tennant's great factory, as containing one atom of chlorine associated with one atom of lime, or, taking his numbers, as consisting of

Hydrate of lime	4·625
Chlorine -	4·5

or nearly equal weights of the chlorine and the base; indicating a surprising degree of excellence in the preparation. The average commercial samples of bleaching powder from different factories which I examined some years ago, did not possess nearly that strength; but varied in their quantity of chlorine from 20 to 28 per cent. In my synthetic experiments related above, the greatest quantity of chlorine that would combine with the atomic hydrate of lime was in the proportion of 130 to 200; but there is

no doubt that, if the lime contains additional water, it will condense more gas. I have never seen a chloride of lime of the strength mentioned by Dr. Thomson, and I should think there must be some fallacy in his statements. I have recorded in the paper above quoted an experiment which proves that, with additional moisture, a chloride of lime may be obtained of the following composition: —

Chlorine	39·5
Lime	39·9
Water	20·6
	100·0

In the article BLEACHING, of the Encyclopædia Britannica, Dr. Thomson deduces, from a test trial of Mr. Crum, that the best bleaching powder is a compound of 1 atom chlorite of lime = 11, 3 atoms chloride of calcium = 21, and 3 atoms of water = 9. "But," adds he, "in general the whole lime is not accurately saturated with chlorine. Accordingly, when the bleaching powder is dissolved in water a small residue almost always remains undissolved. Unless the powder be fresh made, a portion of chlorite is always converted into chloride of calcium. It is probable therefore that the best bleaching powder, as it comes into the hands of the bleachers, consists of

1 atom chlorite of lime	11
3 atoms chloride of calcium	21
6 atoms water	6·75
Impurity	2·25
	41·00

"If we consider the bleaching powder as a compound of chlorine and lime, our mode of calculating will not be altered. Instead of 1 atom chlorite of lime, and 3 atoms chloride of calcium, we shall have 4 atoms chloride of lime, 6 atoms water, and 2·25 of impurity as before." In such ambiguity does this able chemist place this interesting compound, for theoretical reasons, of which I cannot see the value. Surely there is no difficulty in conceiving chlorine to exercise a direct attractive force towards the hydrate of lime, as it is known to do towards each of its elementary constituents, the oxygen and the calcium. Such refinements as the preceding tend merely to mystify a plain matter. Even the chlorous acid here brought into play to form the ideal chlorite, is by his own admission a hypothetical being. "When chlorate of potash," says Dr. Thomson, "is mixed with sulphuric acid, and made into small balls the size of a pea, if we expose these balls to a heat somewhat lower than that of boiling water, a bright yellowish green gas separates, which may be received over mercury. Its smell is peculiar and aromatic. Water absorbs at least seven times its volume of it. It destroys vegetable blues. Its constituents are,

1 volume chlorine 2·5 or 4·5
2 volumes oxygen 2·222 or 4.

Thus this compound consists in weight of chlorine 4·5, oxygen 4 = 8·5. It has been called *quateroxide of chlorine*, but it is more probably a *teroxide*. It has been supposed by some to possess acid properties, and has therefore been called *chlorous acid*. But this is only as yet a hypothesis.

Surely this by the doctor's own showing is very slender authority for renouncing our long-received doctrines concerning the constitution of bleaching powder. I shall conclude by remarking that the ultra-atomists are now in a dilemma about this substance; M. Welter, and many French chemists, calling it a sub-chloride, of 1 atom of chlorine to 2 atoms of lime, and Dr. Thomson showing that Mr. Tennant, the greatest and best manufacturer of it, has produced it in the state of a chloride, or 1 atom of each. The fact is, in chloride of lime, as in water of ammonia, alcohol, and muriatic acid, there is no *sufficient reason* for definite proportion in any term short of saturation, and therefore we shall find *that* chloride in every gradation of strength from 1 per cent. of chlorine up to 40 per cent. — the strongest which I succeeded in preparing, though I passed a constant stream of chlorine in great excess over a pure hydrate of lime for upwards of 24 hours, with frequent renewal of the surface; indeed, till it refused to absorb any more gas, as indicated by its remaining stationary in weight.

CHLORINE AND ALKALI (*Manufacture of*). Mr. Tennant Dunlop of Glasgow obtained, in March, 1847, a patent for an improved method of producing chlorine. The process he usually adopts is to bring together common salt, nitrate of soda, or nitric acid and sulphuric acid, in suitable proportions; heat being then applied, chlorine or an oxide of azote and muriatic acid are evolved; these gases are caused to pass through a condenser charged with sulphuric acid of sufficient strength to absorb the oxide of azote; and then the chlorine and muriatic acid are separated by means of water.

In applying the product resulting from the above process, he obtains nitric acid from

the sulphuric acid charged with oxide of azote, which is true nitrous sulphuric acid. This is effected by the aid of atmospheric air, steam, and water. He introduces the nitrous sulphuric acid into a suitable vessel, and by the addition of water and heat, he effects the disengagement of oxide of azote, which being caused to traverse a condenser with a sufficient quantity of air and steam or water, is by this means transformed into nitric acid. This acid may be again used in the manufacture of chlorine, and again recovered, and so on. Sometimes, instead of treating the nitrous sulphuric acid as just described, the patentee causes the oxide of azote to be evolved, and to pass into a chamber into which a current of sulphuretted hydrogen is streaming; by which means sulphate of ammonia is obtained and sulphur deposited.

CHLOROMETRY (*Chlorometrie*) is the name given by the French to the process for testing the decolouring power of any combination of chlorine, but especially of the commercial articles, the chlorides of lime, potash, and soda. M. Gay Lussac proposed many years ago the following *graduated* method of applying indigo to this purpose. As indigo varies much in its dyeing quality, and of consequence in the proportion of chlorine required for its decoloration, he assumes, as the unity of blanching power, one litre of chlorine gas, measured at the mean pressure of 29·6 inches, and at the temperature of melting ice. This volume of gas, when combined with a determinate quantity of water, is employed to test the standard solution of indigo. For this purpose a solution in sulphuric acid of any sample of indigo is taken, and diluted with water to such a degree that 10 measures of it, in a graduated tube, are decoloured by that one measure of combined chlorine gas. Each measure of indigo solution so destroyed is called a degree, and, this measure being divided into 5 parts, the real test of chlorine is given to fiftieths, which is sufficiently nice. For the standard of the assays, a chloride of lime as pure and fully saturated as possible is taken, and dissolved in such a quantity of water, that the solution shall contain, or be equivalent to, one volume of chlorine gas. Calculation proves that this condition is exactly fulfilled by dissolving 4938 grammes of the said chloride in half a litre of water; or, in English measures, 5 gr. very nearly in 500 grain measures of water. This solution, which serves for a type, indicates 10° in the assay, or proof; that is to say, each single volume destroys the colour of 10 volumes of the dilute indigo solution. It may be remarked, that a greater degree of precision is in general attainable with a weak solution of chlorine or a chloride, for example at 4° or 5°, than with one much stronger; consequently if, after a preliminary trial, the standard considerably exceeds 10°, a given volume of water must be added to the solution, and then the above proof must be taken. If the volume of water added was double, the number of degrees afterwards found must be tripled, to obtain the true title of the chloride. It is, however, to be observed that the degree of decoloration varies with the time taken in making the mixture; the more slowly the chlorine is added to the indigo, the less of it escapes into the atmosphere, and the more effective it becomes in destroying the colour. The best mode of obtaining comparable results, is to pour suddenly into the test quantity of chlorine the whole volume of the indigo solution likely to be decoloured; but it is requisite to find approximately, beforehand, what quantity of indigo-blue will probably be destroyed. When it comes to the verge of destruction, it is green; but yellowish-brown when entirely decomposed.

I have tried the indigo test in many ways, but never could confide in it. The sulphuric solution of indigo is very liable to change by keeping, and thus to lead to erroneous results. The method of testing the chlorides by green sulphate of iron, described under bleaching, is in my opinion preferable to the above.

M. Gay Lussac has recently proposed another proof of chlorine founded on the same principle as that by green vitriol, namely, the quantity of it requisite to raise a metallic substance from a lower to a higher stage of oxidizement. He now prescribes as the preferable plan of chlorometry, to pour very slowly from a graduated glass tube a standard solution of the chloride, to be tested upon a determinate quantity of arsenious acid dissolved in muriatic acid, till the whole arsenious be converted into the arsenic acid. The value of the chloride is greater the less of it is required to produce this effect. It is easy to recognize, by a few drops of solution of indigo, the instant when all the arsenious acid has disappeared; for then the blue tint is immediately effaced, and cannot be restored by the addition of a fresh drop of the indigo solution.

In graduating the arsenical chlorometer, M. Gay Lussac takes for his unity the decolouring power of one volume of chlorine at 32° Fahr., and divides it into 100 parts. Suppose that we prepare a solution of chlorine containing its own volume of the gas, and an arsenious solution, such that, under a like volume, the two solutions shall reciprocally destroy each other. Let us call the first, the normal solution of chlorine, and the second, the normal arsenious solution. We shall fix at 10 grammes the weight of chloride of lime subjected to trial; and dissolve it in water, so that the total volume of the solution shall be a litre (1000 grammes measure), including the sediment. If we take a constant volume of this solution, 10 centimetres cube (10 gramme measures), for example, divided into 100 equal parts, and pour into it gradually the arsenious solution

(measured by like portions), till the chlorine be destroyed, the bleaching power will be proportional to the number of portions of the arsenious solution, which the chloride shall have required. If the chloride has destroyed 100 portions of the arsenious solution, its title will be 100; if it has destroyed 80 portions, its title will be 80, &c., and so forth.

On pouring the acidulous arsenious solution into the chloride of lime, this will become very acid; the chlorine will be emitted abundantly, and the proof will be quite incorrect. If, on the contrary, we pour the solution of the chloride of lime into the arsenious solution, this evil will not occur, since the chlorine will always find plenty of arsenious acid to act upon, whatever be the dilution of the one or the other; but, in this case, the standard of the chlorine is not given directly, as it is in the inverse ratio of the number of portions which are required to destroy the measures of the arsenious solution. If 50 portions of the chloride have been required, the proof will be $100 \times \frac{100}{50} = 200°$; if 200 have been required, the proof will be $100 \times \frac{100}{200} = 50°$, &c. This evil is not, however, very serious, since we have merely to consult a table, in which we can find the proof corresponding to each volume of the chloride employed for destroying the constant measure of the arsenious solution. The arsenious solution should be slightly tinged with sulphate of indigo, so as to show, by the disappearance of the colour, the precise point or instant of its saturation with chlorine, that is, its conversion into arsenic acid. If the arsenious acid be pure, the normal solution may be made directly by dissolving 4·439 grammes of it in muriatic acid (free from sulphurous acid), and diluting the solution till it occupies one litre, or 1000 grammes measure.—*Annales de Chimie et Physique*, LX. 225.

CHOCOLATE. Is an alimentary preparation of very ancient use in Mexico, from which country it was introduced into Europe by the Spaniards in the year 1520, and by them long kept a secret from the rest of the world. Linnæus was so fond of it, that he gave the specific name, *theobroma*, food of the gods, to the cacao tree which produced it. The cacao-beans lie in a fruit somewhat like a cucumber, about 5 inches long and 3½ thick, which contains from 20 to 30 beans, arranged in 5 regular rows with partitions between, and which are surrounded with a rose-coloured spongy substance, like that of water melons. There are fruits, however, so large as to contain from 40 to 50 beans. Those grown in the West India islands, Berbice, and Demerara, are much smaller, and have only from 6 to 15; their development being less perfect than in South America. After the maturation of the fruit, when their green colour has changed to a dark yellow, they are plucked, opened, their beans cleared of the marrowy substance, and spread out to dry in the air. Like almonds, they are covered with a thin skin or husk. In the West Indies they are immediately packed up for the market when they are dried; but in the Caraccas they are subjected to a species of slight fermentation, by putting them into tubs or chests, covering them with boards or stones, and turning them over every morning, to equalize the operation. They emit a good deal of moisture, lose the natural bitterness and acrimony of their taste by this process, as well as some of their weight. Instead of wooden tubs, pits or trenches dug in the ground are sometimes had recourse to for curing the beans; an operation called *earthing* (*terrer*). They are lastly exposed to the sun and dried. The latter kind are reckoned the best; being larger, rougher, of a darker brown colour, and, when roasted, throw off their husk readily, and split into several irregular fragments; they have an agreeable mild bitterish taste, without acrimony. The Guiana and West India sorts are smaller, flatter, smoother-skinned, lighter coloured, more sharp and bitter to the taste. They answer best for the extraction of the butter of cacao, but afford a less aromatic and agreeable chocolate. According to Lampadius, the kernels of the West India cacao beans contain, in 100 parts, besides water, 53·1 of fat or oil, 16·7 of an albuminous brown matter, which contains all the aroma of the bean, 10·91 of starch, 7¾ of gum or mucilage, 0·9 of lignine, and 2·01 of a reddish dye stuff somewhat akin to the pigment of cochineal. The husks form 12 per cent. of the weight of the beans; they contain no fat, but, besides lignine, or woody fibre, which constitutes half their weight, they yield a light brown mucilaginous extract by boiling in water. The fatty matter is of the consistence of tallow, white, of a mild agreeable taste, called butter of cacao, and not apt to turn rancid by keeping. It melts only at 122° Fahr., and should, therefore, make tolerable candles. It is soluble in boiling alcohol, but precipitates in the cold. It is obtained by exposing the beans to strong pressure in canvass bags, after they have been steamed or soaked in boiling water for some time. From 5 to 6 ounces of butter may be thus obtained from a pound of cacao. It has a reddish tinge when first expressed, but it becomes white by boiling with water.

The beans, being freed from all spoiled and mouldy portions, are to be gently roasted over a fire in an iron cylinder, with holes in its ends for allowing the vapours to escape; the apparatus being similar to a coffee-roaster. When the aroma begins to be well developed, the roasting is known to be finished; and the beans must be turned out, cooled, and freed by fanning and sifting from their husks. The kernels are then

to be converted into a paste, either by trituration in a mortar heated to 130° F., or by the following ingenious and powerful machine. The chocolate paste has usually in France a little vanilla incorporated with it, and a considerable quantity of sugar, which varies from one-third of its weight to equal parts. For a pound and a half of cacao, one pod of vanilla is sufficient. Chocolate paste improves in its flavour by keeping, and should therefore be made in large quantities at a time. But the roasted beans soon lose their aroma, if exposed to the air.

357

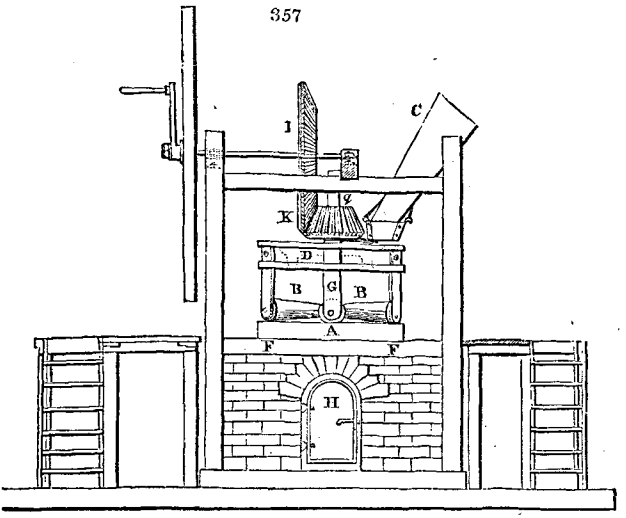


Fig. 357. represents the chocolate mill. Upon the sole A, made of marble, six conical rollers B B, are made to run by the revolution of the upright axis or shaft *q*, driven by the agency of the fly wheel E and bevel wheels I K. The sole A rests upon a strong iron plate, which is heated by a small stove, introduced at the door H. The wooden frame work F, forms a ledge, a few inches high, round the marble slab, to confine the cocoa in the act of trituration. C is the hopper of the mill through which the roasted beans are introduced to the action of the rollers, passing first into the flat vessel D, to be thence evenly distributed. After the cacao has received the first trituration, the paste is returned upon the slab, in order to be mixed with the proper quantity of sugar, and vanilla, previously sliced and ground up with a little hard sugar. When the chocolate is sufficiently worked, and while it is thin with the heat and trituration, it must be put carefully into the proper moulds. If introduced too warm, it will be apt to become damp and dull on the surface; and, if too cold, it will not take the proper form. It must be previously well kneaded with the hands to ensure the expulsion of every air bubble.

In Barcelona, chocolate mills on this construction are very common, but they are turned by a horse-gin set to work in the under story, corresponding to H in the above figure. The shaft G is, in this case, extended down through the marble slab, and is surrounded at its centre with a hoop to prevent the paste coming into contact with it. Each of these horse-mills turns out about ten pounds of fine chocolate in the hour, from a slab two feet seven inches in diameter.

Chocolate is flavoured with cinnamon and cloves, in several countries, instead of the more expensive vanilla. In roasting the beans the heat should be at first very slow, to give time to the humidity to escape; a quick fire hardens the surface, and injures the process. In putting the paste into the tin plate, or other moulds, it must be well shaken down to insure its filling up all the cavities, and giving the sharp and polished impression so much admired by connoisseurs. Chocolate is sometimes adulterated with starch; in which case it will form a pasty consistenced mass when treated with boiling water. The harder the slab upon which the beans are triturated, the better; and thence porphyry is far preferable to marble. The grinding rollers of the mill should be made of iron, and kept very clean.

About eight years ago, samples of chocolate were sent to me for analysis, by order of the Lords of the Admiralty. It was made at the victualling-yard, Deptford, for the use of the Royal Navy, by the government chocolate mills, where about

400 tons are annually prepared, to be distributed to the sailors and convicts at the rate of an ounce daily, and to be used at their breakfast. After taking the said chocolate for some time, men in several ships complained of its occasioning sickness, vomiting, purging, and more serious maladies, terminating in a few cases fatally. I examined it with great care, but could find no injurious ingredient in it, and no chemical alteration from the beans of the Guyaquil coco from which it was manufactured. But I observed that it consisted of gritty grains, from very imperfect trituration or milling; that these grains were quite immiscible with water, like so much fine gravel; that they contained many sharp spiculæ of the coco-bean husks, and that hence, when swallowed, they were calculated to form mechanically irritating lodgments in the villous coats of the stomach and bowels, whereby they could produce the morbid effects certified by several naval surgeons. It was, moreover, obvious that, from the insoluble condition of the chocolate, it could be of little use as an article of food, or as a demulcent substitute for milk, and that, in fact, three-fourths of it were, on this account, an ineffective article of diet, or were wasted.

Having reported these results and opinions to the Lords of the Admiralty, they were pleased, after a few weeks' consideration, to request me to go down to the victualling-yard at Deptford, and superintend the preparation of a quantity of chocolate in the best manner I could with the means there provided. I accordingly repaired thither on the 13th September, 1842, and experienced the utmost courtesy and co-operation from Sir John Hill, the Captain Superintendent, and his subordinate officers. The coco-beans had been heretofore milled, after a slight roasting upon the sole of an oat-kiln, along with their husks. As I was satisfied, from analysis, that the husks were no better food than sawdust, and that they might cause irritation by their minute spiculæ left after grinding between rotating millstones, I set about a plan for shelling them, but could find no piece of apparatus destined for the purpose. There was, however, a pea-shelling mill, which had been used only for one day some years before, and had stood ever since idle*, which, on being cleaned and having its millstones placed at a proper distance, was found to answer pretty well. The beans for experiment, to the amount of 6 cwt., had been previously roasted, under my care, at a well-regulated heat, with much stirring, in the oat-kiln; and, on being cold, were run through the shelling mill, which was put in communication with the fanners of the flour mill. By this arrangement, the coco-beans were tolerably shelled, and the kernels separated from their scaly husks. The weighings were accurately made.

6 cwt. of the Guyaquil coco	-	-	672 lbs.
Lost in roasting	-	43	117
shells	-	54	
waste	-	20	
Remained for milling	-	-	555

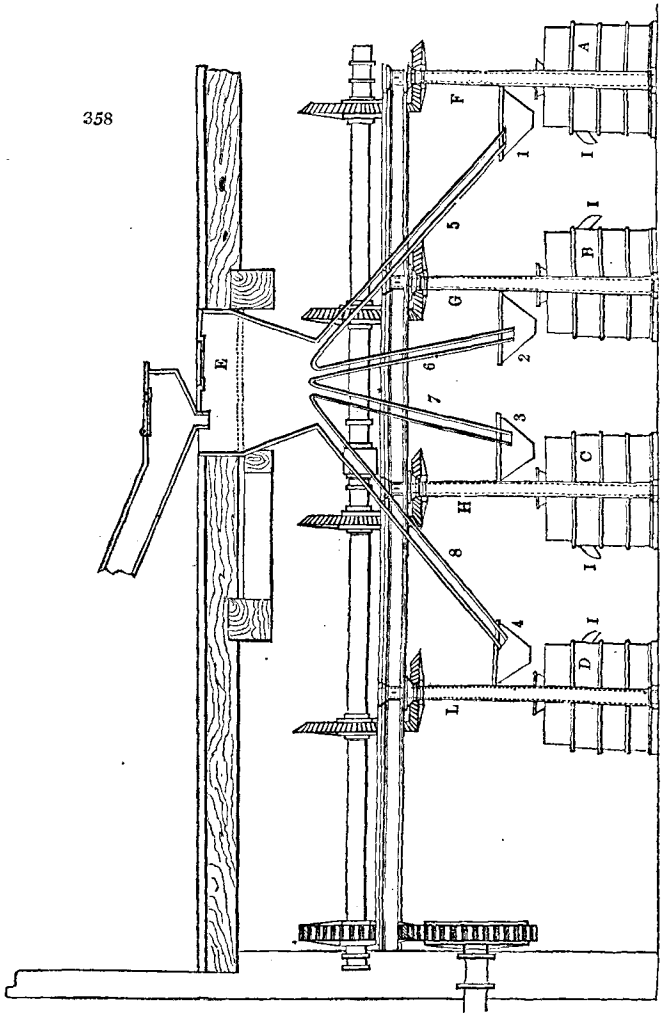
On the 14th September I made a report to the Lords of the Admiralty upon the experiments of the 13th, of which the following is an outline. After describing the pains taken to regulate the roasting temperature, and to equalize the effect upon the beans by moving them occasionally by a rake, I stated that the oat-kiln was not well adapted to the purpose of roasting the coco, because it was impossible to turn the beans regularly and continuously during the process, so that they could not be equally roasted, and because it was an unwholesome operation for the workmen, who must go into a chamber filled with noxious gases and fumes, to use the rakes. When the door of the kiln was shut, to allow the burned air from the fire below to draw up through it, mischief might be done to the stratum of coco on the sole, and when the door was again opened, to permit a person to go in and stir, time and heat were wasted in replenishing the chamber with fresh air. I understood that a revolving-cylinder-roasting machine had been made by Messrs. Rennie for the chocolate process at Deptford; but, for reasons unknown to me, it had never been employed.

The diminution of weight by roasting and shelling may be estimated at about 17 per cent. A part of this loss is moisture, which should be completely expelled, to prevent its causing the chocolate to become mouldy at sea. But a part of the defalcation was also due to some of the coco remaining in the crevices of the pea-splitting mill and the fanners, which would not be observable if these were in constant employment. I think, therefore, that the roasted kernels may be estimated in general at 85 per cent. of the raw beans.

Fig. 358. represents the chocolate mills at the victualling-yard, Deptford, as mounted

* It was found that peas in their skin kept better at sea than the split peas, and they were also preferred by the sailors in their natural state.

by the celebrated engineers, Messrs. Rennie. There are four double mill-stones, A, B, C, D, each three feet in diameter, of which the nether rests upon a bed of cast iron, like a drum-head, kept at the temperature of about 220° by the admission of steam to the case below. Over each mill there is a feeding-hopper 1, 2, 3, 4, in communication by the pipes 5, 6, 7, 8, with the general reservoir E, charged upon the floor above with cocoa through the funnel placed over it. The vertical shafts which turn these mills are marked F, G, H, L; they are moved by the train of bevel-wheels above, which are driven by an arm from the main shaft of the steam engine. Each mill can, of course, be thrown in and out of geer at pleasure. At I, I, I, I, the discharge-spout



is shown, which pours out the semi-fluid hot chocolate into shallow cylindrical tin pans, capable of containing about nine pounds of chocolate each. These four mills are capable of converting upwards of a ton of coco into good chocolate in a day, on the system of double trituration which I adopted, and two tons on the former rough plan. I found that the two stones of each mill had been placed so far asunder as would allow entire beans to pass through, as spurious chocolate, at one operation; but the chocolate thus discharged was in a very gritty state, whereas good chocolate in the liquefied state should

be smooth and plastic between the fingers, and spread upon the tongue without leaving any granular particles in the mouth. To obtain such a result, I divided the milling into two steps; for the first, two pairs of the stones, A and C, were set as close together as for a paint mill (which they closely resemble), and the other two pairs, B and D, were left at their ordinary distance. The paste obtained from the first set was transferred, while nearly liquid, into the hoppers of the second pairs, from which it issued at the spouts as thin and smooth as honey from the comb. In subserviency to these experiments, I made an analysis of the Guyaquil coco, which I found to be composed as follows:—

Concrete fat or butter of coco, dissolved out by ether	37
Brown extractive, extractible by hot water, after the operation of ether	10
Ligneous matter, with some albumine	30
Shells	14
Water	6
Loss	3
	100

The solid fat of the coco should be most intimately combined by milling with the extractive, albumine, and ligneous matter, in order to render it capable of forming an emulsion with water; and, indeed, on account of the large proportion of concrete fat in the beans, some additional substance should be introduced to facilitate this emulsive union of the fat and water. Sugar, gum, and starch or flour are well adapted for this purpose.

Under this conviction, I employed in the first of these trials at Deptford, made with one-half of the above roasted kernels $=277\frac{1}{2}$ lbs., 5 per cent. of sugar, which was first mixed upon a board with shovels, and the mixture was then put progressively into the hoppers of the two mills B and D. The paste which ran out of their spouts was immediately poured into the hoppers of A and C, from which it flowed smooth and very thin into the concreting pans. The sugar supplied to me was exceedingly moist, whereas it ought to be dry, like the bag sugar of the Mauritius. The other half of the coco kernels was milled alone once by the ordinary mills B and D. I subjected next day samples of these two varieties of chocolate to the following examination, and compared them with the sample of chocolate as usually made at Deptford, as also with a sample of chocolate sold by a respectable grocer in London. A like quantity of these four samples was treated with eight times its weight of boiling water, the diffusion well stirred, and then left to settle in a conical wineglass. Of the ordinary Deptford coco, four-fifths rapidly subsided in coarse grains, incapable of forming any thing like an emulsion with water, and therefore of little or no avail in making a breakfast beverage.

1. The single-milled chocolate made under my direction formed a smoother emulsion than the last, on account of the absence of the coco husks; but its particles were gritty, and subsided very soon.

2. The sugared double-milled chocolate, on the contrary, formed a milky-looking emulsion, which remained nearly uniform for some time, and then let fall a soft mucilaginous deposit, free from grittiness.

3. The shop chocolate formed a very indifferent emulsion, though it was well milled, because it contained evidently a large admixture of a coarse branny flour, as is too generally the case.

I have given small samples of the above No. 2. chocolate to various persons, and they have considered it superior to what is usually sold by our grocers. The presence of dry sugar in chocolate would also give it a conservative quality at sea, and prevent it from getting musty.

The Lords of the Admiralty, after seeing the above two samples of chocolate, and my report thereupon, were, about six weeks afterwards, pleased to request me to make at their victualling-yard further experiments in the preparation of chocolate; and they indicated two modes, one of milling twice with the husks, and another of milling twice without the husks; permitting me, at the same time, to mill a portion of the kernels with 10 per cent. of sugar, and a second portion of the kernels with 5 per cent. of sugar and 5 per cent. of the excellent flour used in making the biscuits for the royal navy. On the 24th October, 1842, I accordingly performed these experiments upon 12 cwt. of Guyaquil coco as carefully roasted as possible on the kiln.

The loss in drying and slightly roasting the 1344 lbs. of beans was 5 per cent.

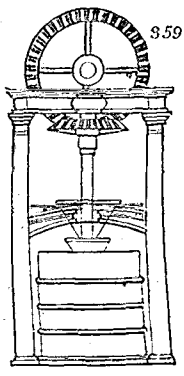
1st experiment, 212 lbs. of roasted coco, milled twice with the husks, produced, of chocolate — 209 lbs.

2d experiment, 191 lbs. ditto, milled twice without husks — 189

3d experiment, 191 lbs. kernels, milled once along with 19 lbs. of sugar =210 lbs. - - - - - - - - - - 212*

4th experiment, 573 lbs. of kernels, milled twice along with 68 lbs. of flour and 34 of sugar =675 - - - - - - - 669

Sample cakes of these four varieties of chocolate were subsequently sent to me for examination and report. I found that the chocolate milled twice with the flour and sugar formed a complete emulsion with hot water, bland and rich, like the best milk, but the other three were much inferior in this respect. Sugar alone, with proper milling, would serve to give the kernels of well roasted coco a perfect emulsive property. Instead of merely milling with rotatory stones, I would prefer, for the second or finishing operation, a levigating mill, in which rollers would be rolled either backwards and forwards, or, when slightly conical, in a circular direction, over a plane metallic, marble, or porphyry, slab, as is now, indeed, very generally practised by the trade. The coco-beans should be well selected, without musty taint, and possessed of a fine aroma, like the best of that imported from Trinidad. There is a great deal of very coarse coco and chocolate on sale in London and in the provincial towns of the United Kingdom.



359

Fig. 359. is an end view of one of the chocolate mills with its mitre-gearing. I consider the gritty chocolate hitherto made at Deptford as a very bad substitute for the chocolate which was made from coco by the sailors themselves with a pestle and mortar.

In 1840 the coco cleared for consumption in the United Kingdom was:—

British plantation - -	2,041,492 lbs.
Foreign - - -	186
Coco-nut husks and shells -	753,580
Chocolate and coco paste -	2,066

Of the coco-nut shells, 612,122 lbs. were consumed in Ireland! and less than 4000 lbs. of coco.

Of coco, 726,116 lbs. were consumed in Her Majesty's navy.

How scurvily are the people of Ireland treated by their own grocers! Upwards of 600.000 lbs. of worthless coco husks served out to them along with only 4000 lbs. of coco-beans!

The quantity of coco imported in 1850 amounted to 4,478,252 cwts., and in 1851 to 6,773,960 cwts.; the entries for home consumption were 3,103,926 and 3,024,338 cwts.; the re-exports were 1,443,363 and 1,543,455 cwts.; and the gross amount of duty 16,059*l.* and 15,778*l.* respectively.

CHROMATES, saline compounds of chromic acid with the basis. See CHROMIUM.

Messrs. Swindell and Co. obtained a patent in November, 1850, for obtaining copper, silver, and chrome, from their ores.

1st. To obtain copper and silver, or copper only, from their ores, according to this invention, the ores are first roasted to drive off the sulphur, and convert the metals to the state of oxides, after which the prepared ores are placed in tanks, and a solution of ammonia or its salts, of a strength of about 0·980, pumped on in sufficient quantity to saturate them. This solution is removed at the expiration of twelve to twenty-four hours, and will be found saturated with the metallic oxides, which are to be dissolved in boiling water and precipitated — the silver by hydrochloric, and the copper by hydrosulphuric acids or otherwise.

2nd. The ore from which zinc is obtained is the native sulphuret, which is mixed with about its own weight of common salt (for which muriate of potash, or of any earth, may be substituted), and exposed in a calcining furnace to a slow protracted heat, until all the sulphur present is converted into sulphuric acid. The products of this operation will be sulphate of soda, muriate of zinc, and muriate of iron, which are to be dissolved out in boiling water, and the two latter precipitated by lime, or other means after the sulphate of soda has been separated in the usual manner. The oxide of zinc, when thus precipitated, may be smelted in the usual way.

In treating chromium (chromite of iron), the ore is pulverized and mixed with common salt, muriate of potash, or hydrate of lime, and exposed in a reverberatory furnace to a red or even a white heat, the mixture being stirred every ten or fifteen minutes, and steam at a very elevated temperature introduced during the operation, until the desired effect is obtained, which may be ascertained by withdrawing a portion

* This small excess proceeded from a residue of the last experiment.

from the furnace and testing it, as customary. The products of this operation are finally treated in the manner usual for chromic and bichromic salts.

The mixture of chromium and common salt produces chromate of soda, the greater portion, or perhaps all of the iron contained in the chromium being absorbed by the hydrochloric acid evolved from the salt, and carried off in the form of sesquichloride of iron. From the first mixture is manufactured pure bichromate of soda, which, by the addition of hydrochloric acid, may be converted to chlorochromate; and from the last, or lime mixture, is produced a chromate of that earth, from which, by the addition of soda or potash, there may be obtained a compound salt, which, with those previously mentioned, may be advantageously employed in the operations specified in the title.

CHROMIC ACID. To a boiling saturated solution of bichromate of potash, add much oil of vitriol as will convert the potash into a bisulphate. Let the whole cool, and be then washed with a little water, and stirred, when the liquid decanted from the granular mass will be nearly pure chromic acid.

The solution of chromic acid in oil of vitriol is preferable as an oxidizing agent to every other at present known. See CHROMIUM.

CHROMIUM. The only ore of this metal, which occurs in sufficient abundance for the purposes of art, is the octohedral chrome-ore, commonly called chromate of iron, though it is rather a compound of the oxides of chromium and iron. The fracture of this mineral is uneven; its lustre imperfect metallic; its colour between iron-black and brownish-black, and its streak brown. Its specific gravity, in the purest state, rises to 4·5; but the usual chrome-ore found in the market varies from 3 to 4. According to Klaproth, this ore consists of oxide of chromium, 43; protoxide of iron, 34·7; alumina, 20·3; and silica, 2; but Vauquelin's analysis of another specimen gave as above, respectively, 55·5, 33, 6, and 2. It is infusible before the blowpipe; but it acts upon the magnetic needle, after having been exposed to the reducing smoky flame. It is entirely soluble in borax, at a high blowpipe heat, and imparts to it a beautiful green colour.

Chrome-ore is found at the Bare Hills, near Baltimore, in Maryland; in the Shetland Isles, Unst and Fetlar; the department of Var, in France, in small quantity; and near Portsoy, in Banffshire; as also in Silesia and Bohemia.

The chief application of this ore is to the production of chromate of potash, from which salt the various other preparations of this metal used in the arts are obtained. The ore, freed, as well as possible, from its gangue, is reduced to a fine powder, by being ground in a mill under ponderous edge-wheels, and sifted. It is then mixed with one-third or one-half its weight of coarsely bruised nitre, and exposed to a powerful heat, for several hours, on a reverberatory hearth, where it is stirred about occasionally. In the large manufactories of this country the ignition of the above mixture in pots is laid aside, as too operose and expensive. The calcined matter is raked out, and lixiviated with water. The bright yellow solution is then evaporated briskly, and the chromate of potash falls down in the form of a granular salt, which is lifted out from time to time from the bottom with a large ladle, perforated with small holes, and thrown into a draining-box. This saline powder may be formed into regular crystals of neutral chromate of potash, by solution in water and slow evaporation; or it may be converted into a more beautiful crystalline body, the bichromate of potash, by treating its concentrated solution with nitric, muriatic, sulphuric, or acetic acid, or, indeed, any acid exercising a stronger affinity for the second atom of the potash than the chromic acid does.

Bichromate of potash, by evaporation of the above solution, and slow cooling, may be obtained in the form of square tables, with bevelled edges, or flat four-sided prisms. They are permanent in the air, have a metallic and bitter taste, and dissolve in about one-tenth of their weight of water, at 60° F.; but in one-half of their weight of boiling water. They consist of chromic acid 13, potash 6; or, in 100 parts, 68·4 + 31·6. This salt is much employed in calico-printing and in dyeing; which see.

Chromate of lead, the chrome-yellow of the painter, is a rich pigment of various shades, from deep orange to the palest canary yellow. It is made by adding a limpid solution of the neutral chromate (the above granular salt), to a solution, equally limpid, of acetate or nitrate of lead. A precipitate falls, which must be well washed, and carefully dried out of the reach of any sulphuretted vapours. A lighter shade of yellow is obtained by mixing some solution of alum, or sulphuric acid, with the chromate, before pouring it into the solution of lead; and an orange tint is to be procured by the addition of subacetate of lead, in any desired proportion.

For the production of chromate of potash from chrome ore, various other processes have been recommended. The following formulæ, which have been verified in practice, will prove useful to the manufacturers of this important article:—

I. Two parts of chrome ore, containing about 50 per cent. of protoxide of chromium:
One part of saltpetre.

II. Four parts of chrome ore, containing 34 per cent. of protoxide of chromium.
Two parts of potashes.
One part of saltpetre.
III. Four parts of chrome ore, — 34 —
Two of potashes.
Four tenths of a part of peroxide of manganese.
IV. Three parts of chrome ore.
Four parts of saltpetre.
Two parts of argol.

Some manufacturers have contrived to effect the conversion of the oxide into an acid, and of course to form the chromate of potash, by the agency of potash alone, in a calcining furnace, or in earthen pots fired in a pottery kiln.

After lixiviating the calcined mixtures with water, if the solution be a tolerably pure chromate of potash, its value may be inferred, from its specific gravity, by the following table: —

At specific gravity 1·28	it contains about 50 per cent. of the salt.
1·21	33
1·18	25
1·15	20
1·12	16
1·11	14
1·10	12

In making the red bichromate of potash from these solutions of the yellow salt, nitric acid was at first chiefly used; but, in consequence of its relatively high price, sulphuric, muriatic or acetic acid has been frequently substituted upon the great scale.

There is another application of chrome which merits some notice here; that of its green oxide to dyeing and painting on porcelain. This oxide may be prepared by decomposing, with heat, the chromate of mercury, a salt made by adding to nitrate of protoxide of mercury, chromate of potash, in equivalent proportions. This chromate has a fine cinnabar red, when pure; and, at a dull red heat, parts with a portion of its oxygen and its mercurial oxide. From M. Dulong's experiments it would appear, that the purest chromate of mercury is not the best adapted for preparing the oxide of chrome to be used in porcelain painting. He thinks it ought to contain a little oxide of manganese and chromate of potash, to afford a green colour of a fine tint, especially for pieces that are to receive a powerful heat. Pure oxide of chrome preserves its colour well enough in a muffle furnace; but, under a stronger fire, it takes a dead-leaf colour.

The green oxide of chrome has come so extensively into use as an enamel colour for porcelain, that a fuller account of the best modes of manufacturing it must prove acceptable to many of my readers.

That oxide, in combination with water, called the hydrate, may be economically prepared by boiling chromate of potash, dissolved in water, with half its weight of flowers of sulphur, till the resulting green precipitate ceases to increase, which may be easily ascertained by filtering a little of the mixture. The addition of some potash accelerates the operation. This consists in combining the sulphur with the oxygen of the chromic acid, so as to form sulphuric acid, which unites with the potash of the chromate into sulphate of potash, while the chrome oxide becomes a hydrate. An extra quantity of potash facilitates the deoxidizement of the chromic acid by the formation of hyposulphite and sulphuret of potash, both of which have a strong attraction for oxygen. For this purpose the clear lixivium of the chromate of potash is sufficiently pure, though it should hold some alumina and silica in solution, as it generally does. The hydrate may be freed from particles of sulphur by heating dilute sulphuric acid upon it, which dissolves it; after which it may be precipitated, in the state of a carbonate, by carbonate of potash, not added in excess.

By calcining a mixture of bichromate of potash and sulphur in a crucible, chromic acid is also decomposed, and a hydrated oxide may be obtained; the sulphur being partly converted into sulphuret of potassium, and partly into sulphuric acid (at the expense of the chromic acid), which combines with the rest of the potash into a sulphate. By careful lixiviation, these two new compounds may be washed away, and the chrome green may be freed from the remaining sulphur, by a slight heat.

Liebig and Wöhler have lately contrived a process for producing a subchromate of lead of a beautiful vermilion hue. Into saltpetre, brought to fusion in a crucible at a gentle heat, pure chrome yellow is to be thrown by small portions at a time. A strong ebullition takes place at each addition, and the mass becomes black, and continues so while it is hot. The chrome yellow is to be added till little of the saltpetre remains undecomposed, care being taken not to overheat the crucible, lest the colour of the mixture should become brown. Having allowed it to settle for a few minutes, during which the dense basic salt falls to the bottom, the fluid part, consisting of

chromate of potash and saltpetre, is to be poured off, and it can be employed again in preparing chrome yellow. The mass remaining in the crucible is to be washed with water, and the chrome red being separated from the other matters, is to be dried after proper edulcoration. It is essential for the beauty of the colour, that the saline solution should not stand long over the red powder, because the colour is thus apt to become of a dull orange hue. The fine crystalline powder subsides so quickly to the bottom after every ablution, that the above precaution may be easily observed.

As *Chromic Acid* will probably ere long become an object of interest to the calico printer, I shall describe here the best method of preparing it. To 100 parts of yellow chromate of potash, add 136 of nitrate of barytes, each in solution. A precipitate of the yellow chromate of barytes falls, which being washed and dried would amount to 130 parts. But while still moist it is to be dissolved in water by the intervention of a little nitric acid, and then decomposed by the addition of the requisite quantity of sulphuric acid, whereby the barytes is separated, and the chromic acid remains associated with the nitric acid, from which it can be freed by evaporation to dryness. On re-dissolving the chromic acid residuum in water, filtering and evaporating to a proper degree, 50 parts of chromic acid may be obtained in crystals.

This acid may also be obtained from chromate of lime, formed by mixing chromate of potash and muriate of lime; washing the insoluble chromate of lime which precipitates, and decomposing it by the equivalent quantity of oxalic acid, or for ordinary purposes even sulphuric acid may be employed.

Chromic acid is obtained in quadrangular crystals, of a deep red colour; it has a very acrid and styptic taste. It reddens powerfully litmus paper. It is deliquescent in the air. When heated to redness, it emits oxygen and passes into the deutoxide. When a little of it is fused along with vitreous borax, the compound assumes an emerald green colour.

As chromic acid parts with its last dose of oxygen very easily, it is capable in certain styles of calico printing of becoming a valuable substitute for chlorine where this more powerful substance would not from peculiar circumstances be admissible. For this ingenious application, the arts are indebted to that truly scientific manufacturer, M. Daniel Kœchlin, of Mülhouse. He discovered that whenever chromate of potash has its acid set free by its being mixed with tartaric or oxalic acid, or a neutral vegetable substance (starch or sugar for example), and a mineral acid, a very lively action is produced, with disengagement of heat, and of several gases. The result of this decomposition is the active reagent, chromic acid, possessing valuable properties to the printer. Watery solutions of chromate of potash and tartaric acid being mixed, an effervescence is produced which has the power of destroying vegetable colours. But this power lasts no longer than the effervescence. The mineral acids react upon the chromate of potash only when vegetable colouring matter, gum, starch, or a vegetable acid are present, to determine the disengagement of gas. During this curious change carbonic acid is evolved; and when it takes place in a retort, there is condensed in the receiver a colourless liquid, slightly acid, exhaling somewhat of the smell of vinegar, and containing a little empyreumatic oil. This liquid heated with the nitrates of mercury or silver reduces these metals. On these principles M. Kœchlin discharged indigo blue by passing the cloth through a solution of chromate of potash, and printing nitric acid thickened with gum upon certain spots. It is probable that the employment of chromic acid would supersede the necessity of having recourse in many cases to the more corrosive chlorine.

The following directions have been given for the preparation of a *blue oxide* of chrome. The concentrated alkaline solution of chromate of potash is to be saturated with weak sulphuric acid, and then to every 8 lbs. is to be added 1 lb. of common salt, and half a pound of concentrated sulphuric acid; the liquid will now acquire a green colour. To be certain that the yellow colour is totally destroyed, a small quantity of the liquor is to have potash added to it, and filtered; if the fluid is still yellow, a fresh portion of salt and of sulphuric acid is to be added: the fluid is then to be evaporated to dryness, re-dissolved, and filtered; the oxide of chrome is finally to be precipitated by caustic potash. It will be of a greenish-blue colour, and being washed, must be collected upon a filter.

Chromate of Potash, adulteration of, to detect.—The chromate of potash has the power of combining with other salts up to a certain extent without any very sensible change in its form and appearance; and hence it has been sent into the market falsified by very considerable quantities of sulphate and muriate of potash, the presence of which has often escaped observation, to the great loss of the dyers who use it so extensively. The following test process has been devised by M. Zuber, of Mülhouse. Add a large excess of tartaric acid to the chromate in question, which will decompose it, and produce in a few minutes a deep amethyst colour. The supernatant liquor will, if the chromate be pure, afford now no precipitate with the nitrates of barytes or silver; whence the absence of the sulphates and muriates may be inferred. We must, however, use dilute solutions of the chromate and acid, lest bitartrate of potash be precipitated, which will take place if less than 60 parts of water be employed. Nor must

we test the liquid till the decomposition be complete, and till the colour verge rather towards the green than the yellow. Eight parts of tartaric acid should be added to one of chromate to obtain a sure and rapid result. If nitrate of potash (saltpetre) is the adulterating ingredient, it may be detected by throwing it on burning coals, when deflagration will ensue. The green colour is a certain mark of the transformation of the chromic acid partially into the chrome oxide; which is effected equally by the sulphurous acid and sulphuretted hydrogen. Here this metallic acid is disoxygenated by the tartaric, as has been long known. The tests which I should prefer are the nitrates of silver and baryta, having previously added so much nitric acid to the solution of the suspected chromate, as to prevent the precipitation of the chromate of silver or baryta. The smallest adulteration by sulphates or muriates will thus be detected.

CHROMIUM, OXIDE OF.—Mix intimately 45 parts of gunpowder with 240 parts of perfectly dry chromate of potash, and 35 parts of hydrochlorate of ammonia (sal ammoniac), reduce to powder, and pass through a fine sieve; fill a conical glass or other mould with this powder, gently pressed, and invert so as to leave the powder on a porcelain slab of any kind. When set on fire at its apex with a lighted match, it will burn down to the bottom with brilliant coruscations. The black residuum, being elutriated with warm water, affords a fine bright green oxide of chromium.

CHROMIUM, *green oxide of*.—Ignite bichromate of potash with a quarter of its weight of flowers of sulphur, by projecting the mixture into a red hot crucible in small successive portions, stirring the pasty mass till the excess of sulphur is burnt off; pulverize the cooled mass, and wash with water till it affords no precipitate with chloride of barium or acetate of lead. The powder which remains on being gently dried is of a beautiful green colour, and may be used as a pigment, or to prepare pure chromium.

CINNABAR; the native red sulphuret of mercury. It occurs sometimes crystallized in rhomboids; has a specific gravity varying from 6·7 to 8·2; a flat conchoidal fracture; is fine grained; opaque; has an adamantine lustre, and a colour passing from cochineal to ruby red. The fibrous and earthy cinnabar has a scarlet hue. It is met with disseminated in smaller or larger lumps in veins, which are surrounded by a black clay, and is associated with native quicksilver, amalgam with iron-ore, lead-glance, blende, copper-ore, gold, &c. Its principal localities are Almaden in Spain, Idria in the Schiefergebirge, Kremnitz and Schemnitz in Hungary; in Saxony, Bavaria, Bohemia, Nassau, China, Japan, Mexico, Columbia, California. It consists of two primes of sulphur = 32·240, combined with one of mercury, = 202,863; or in 100 parts, of 12·7 sulphur + 87·3 mercury. It is the most prolific ore of this metal; and is easily smelted by exposing a mixture of it with iron or lime to a red heat in retorts. Factitious cinnabar is called in commerce VERMILION, which see, as also, MERCURY.

CINNAMON. (*Cannelle*, Fr.; *Zimmt*, Germ.) Is the inner bark of the *laurus cinnamomum*, a handsome-looking tree, which grows naturally to the height of 18 or 20 feet, in Java, Sumatra, Ceylon, and other islands in the East Indian seas. It has been transplanted to the Antilles, particularly Guadaloupe and Martinique, as well as Cayenne, but there it produces a bark of very inferior value to the Oriental.

Cinnamon is gathered twice a year, but not till after the tree has attained to a certain age and maturity. The young twigs yield a bark of better quality than the larger branches. The first and chief harvest takes place from April to August; the second from November to January. After having selected the proper trees, all the branches more than three years old are cut off; the epidermis is first removed with a two-edged pruning knife, then a longitudinal incision is made through the whole extent of the bark, and lastly, with the bluntest part of the knife, the true bark is carefully stripped off in one piece. All these pieces of bark are collected, the smaller ones are laid within the larger, and in this state they are exposed to the sun, whereby in the progress of drying they become rolled into the shape of a quill. These convoluted pieces are formed into oblong bundles of 20 or 30 lbs. weight, which are placed in warehouses, sorted and covered with mats. Good cinnamon should be as thin as paper, have its peculiar aromatic taste, without burning the tongue, and leave a sweetish flavour in the mouth. The broken bits of cinnamon are used in Ceylon for procuring the essential oil by distillation. 700,095 lbs. of cinnamon were imported in the year 1850, and 527,777 lbs. in 1851, of which only 28,488 lbs. and 39,852 lbs., respectively, were retained for home consumption; the gross amount of duty received was 403*l.* and 542*l.*

CITRIC ACID. (*Acide citrique*, Fr.; *Citronensaure*, Germ.) Scheele first procured this acid in its pure state from lemon juice, by the following process. The juice put into a large tub, is to be saturated with dry chalk in fine powder, noting carefully the quantity employed. The citrate of lime which precipitates being freed from the supernatant foul liquor, is to be well washed with repeated affusion and decantation of water. For every 10 pounds of chalk employed, nine and a half pounds of sulphuric acid, diluted with six times its weight of water, are to be poured while warm upon the citrate of lime, and well mixed with it. At the end of twelve hours, or even sooner, the citrate will be all

decomposed, dilute citric acid will float above, and sulphate of lime will be found at the bottom. The acid being drawn off, the calcareous sulphate must be thrown on a canvass filter, drained, and then washed with water to abstract the whole acid.

The citric acid thus obtained may be evaporated in leaden pans, over a naked fire till it acquires the specific gravity 1·13; after which it must be transferred into another vessel, evaporated by a steam or water bath till it assumes a syrupy aspect, when a pellicle appears first in patches, and then over the whole surface. This point must be watched with great circumspection, for if it be passed, the whole acid runs a risk of being spoiled by carbonization. The steam or hot water must be instantly withdrawn, and the concentrated acid put into a crystallizing vessel in a dry, but not very cold apartment. At the end of four days the crystallization will be complete. The crystals must be drained, re-dissolved in a small portion of water, the solution set aside to settle its impurities, then decanted, re-evaporated, and re-crystallized. A third or fourth crystallization may be necessary to obtain a colourless acid.

If any citrate of lime be left undecomposed by the sulphuric acid, it will dissolve in the citric acid, and obstruct its crystallization, and hence it will be safer to use the slightest excess of sulphuric acid, than to leave any citrate undecomposed. There should not however be any great excess of sulphuric acid. If there be, it is easily detected by nitrate of barytes, but not by the acetate of lead as prescribed by some chemical authors; because the citrate of lead is not very soluble in the nitric acid, and might thus be confounded with the sulphate, whereas citrate of barytes is perfectly soluble in that test acid. Sometimes a little nitric acid is added with advantage to the solution of the coloured crystals, with the effect of whitening them.

Twenty gallons of good lemon juice will afford fully ten pounds of white crystals of citric acid.

Attempts were made both in the West Indies and Sicily, to convert the lime and lemon juice into citrate of lime, but they seem to have failed through the difficulty of drying the citrate for shipment.

The crystals of citric acid are oblique prisms with four faces, terminated by dihedral summits, inclined at acute angles. Their specific gravity is 1·617. They are unalterable in the air. When heated, they melt in their water of crystallization; and at a higher heat, they are decomposed. They contain 18 per cent. of water, of which one-half may be separated in a dry atmosphere, at about 100° F., when the crystals fall into a white powder.

Citric acid in crystals is composed by my analysis of carbon, 35·8, oxygen 59·7, and hydrogen 4·5; results which differ very little from those of Dr. Prout, subsequently obtained. I found its atomic weight to be 8·375, compared to oxygen 1,000. I cannot account for Berzelius's statements relative to the composition of this acid.

Citric acid in somewhat crude crystals is employed with much advantage in calico-printing. If adulterated with tartaric acid, the fraud may be detected by adding potash to the solution of the acid, which will cause a precipitate of cream of tartar.

The manufacture of citric acid so closely resembles that of tartaric acid, that the makers of one commonly fabricate the other. The raw material in this case is pretty generally a black fluid, like thin treacle, which comes from Sicily, and is obtained by inspissating the expressed juice of the lemon, — the rind having previously been removed from the lemon for the sake of its essential oil. This black juice is impure citric acid, and requires to be treated with chalk, as practised with respect to the first operation on tartar; by which means, an insoluble citrate of lime is formed; and this, after being well washed with cold water, is decomposed by sulphuric acid; and the solution, after undergoing the action of animal charcoal and proper evaporation, yields brownish crystals on cooling. These are re-dissolved, decoloured, and crystallized three or four times ere they can be sent into the market, for citric acid is more tenacious of colouring matter than most of the other vegetable acids. At Nice, and in the South of France, a portion of chloride of lime is digested upon the citrate of lime, to bleach it prior to decomposition by sulphuric acid. For this purpose, the washed citrate is exposed in shallow vessels to the action of the sun's rays covered by a weak solution of chloride of lime. In a few hours decolouration ensues; and it is moreover stated that the mucilage which hangs about the citrate of lime, and impedes the subsequent crystallization of the acid, is in this way destroyed, and the number of re-crystallizations requisite to give a saleable aspect to the citric acid thereby diminished. The use of chloride of lime for this purpose seems unknown, or, at least, is not practised in England. Of the samples of citric acid shown in the Great Exhibition, those from Howards and Kent, of Stratford, Pontifex and Wood, of Millwall, and J. Huskisson, of Gray's Inn Road, were extremely beautiful; and in respect to size and crystalline form surpassed anything exhibited in the French, Prussian, or Italian departments.

CIVET. (*Civette*, Fr.; *Zibeth*, Germ.) This substance approaches in smell to musk and ambergris; it has a pale yellow colour, a somewhat acrid taste, a consistence

like that of honey, and a very strong aromatic odour. It is the product of two small quadrupeds of the genus *viverra* (*v. zibetha* and *v. civetta*), of which the one inhabits Africa, and the other Asia. They are reared with tenderness, especially in Abyssinia. The civet is contained in a sac, situated between the anus and the parts of generation, in either sex. The animal frees itself from an excess of this secretion by a contractile movement which it exercises upon the sac, when the civet issues in a vermicular form, and is carefully collected. The negroes are accustomed to increase the secretion by irritating the animal; and likewise introduce a little butter, or other grease, by the natural slit in the bag, which mixes with the odoriferous substance, and increases its weight. It is employed only in perfumery.

According to M. Boutron-Chalard, it contains a volatile oil, to which it owes its smell, some free ammonia, resin, fat, an extractiform matter, and mucus. It affords by calcination an ash, in which there are some carbonate and sulphate of potash, phosphate of lime, and oxide of iron.

CLAY (*Argile*, Fr.; *Thon*, Germ.) is a mixture of the two simple earths, alumina and silica, generally tinged with iron. Lime, magnesia, with some other colouring metallic oxides, are occasionally present in small quantities in certain natural clays.

The different varieties of clay possess the following common characters: —

1. They are readily diffusible through water, and are capable of forming with it a plastic ductile mass, which may be kneaded by hand into any shape. This plasticity exists, however, in very different degrees in the different clays.

2. They concrete into a hard mass upon being dried, and assume, upon exposure to the heat of ignition, a degree of hardness sometimes so great as to give sparks by collision with hardened steel. In this state they are no longer plastic with water, even when pulverised. Tolerably pure clays, though infusible in the furnace, become readily so by the admixture of lime, iron, manganese, &c.

3. All clays, even when previously freed from moisture, shrink in the fire in virtue of the reciprocal affinity of their particles; they are very absorbent of water in their dry state, and adhere strongly to the tongue.

4. Ochrey, impure clays emit a disagreeable earthy smell when breathed upon.

Brongniart distributes the clays into: —

1. Fire-clays, (*argiles apyres*, Fr.; *feuerfeste*, Germ.)
2. Fusible, (*schmelzbare*, Germ.)
3. Effervescing (*brausende*, Germ.), from the presence of chalk.
4. Ochrey (*ocreuses*, Fr.; *ochrige*, Germ.)

Fire-clay is found in the greatest abundance and perfection for manufacturing purposes in,

1. *Slate-clay.* (*Thon-schiefer*, Germ.) Its colour is gray or grayish-yellow. Massive, dull, or glimmering from admixture of particles of mica. Fracture slaty, approaching sometimes to earthy. Fragments tabular. Soft, sectile, and easily broken. Sp. gr. = 2·6. Adheres to the tongue, and breaks down in water. It occurs along with *pit coal*; which see. Slate-clay is ground, and reduced into a paste with water, for making fire-bricks; for which purpose it should be as free as possible from lime and iron.

2. *Common clay or loam.* — This is an impure coarse pottery clay, mixed with iron ochre, and occasionally with mica. It has many of the external characters of plastic clay. It is soft to the touch, and forms, with water, a somewhat tenacious paste; but is in general less compact, more friable, than the plastic clays, which are more readily diffusible in water. It does not possess the property of acquiring in water that commencement of translucency which the purer clays exhibit. Although soft to the touch, the common clay wants unctuosity, properly so called. The best example of this argillaceous substance is afforded in the London clay formation, which consists chiefly of bluish or blackish clay, mostly very tough. Those of its strata which effervesce with acids partake of the nature of marl. This clay is fusible at a strong heat in consequence of the iron and lime which it contains. It is employed in the manufacture of bricks, tiles, and coarse pottery ware.

3. *Potter's clay, or Plastic clay.* — This species is compact, soft, or even unctuous to the touch, and polishes with the pressure of the finger; it forms, with water, a tenacious, very ductile, and somewhat translucent paste. It is infusible in a porcelain kiln, but assumes in it a great degree of hardness. Werner calls it *pipe-clay*. Good plastic clay remains white, or if gray before, becomes white in the porcelain kiln.

The geological position of the plastic clay is beneath the London clay, and above the sand which covers the chalk formation. The plastic clay of the Paris basin is described as consisting of two beds separated by a bed of sand. The lower bed is the proper plastic clay. The plastic clay of *Abondant*, near the forest of Dreux, analyzed by Vauquelin, gave —

Silica, 43·5; alumina, 33·2; lime, 0·35; iron, 1; water, 18.

This clay is employed as a fire-clay for making the bungs or *seggars*, or coarse earthenware cases, in which china ware is fired.

The plastic clay of Dorsetshire and Devonshire supplies the great Staffordshire potteries. It is gray coloured, less unctuous than that of Dreux, and consequently more friable. It becomes white in the pottery kiln, and is infusible at that heat. It causes no effervescence with nitric acid, but falls down quickly in it, and becomes higher coloured. Its refractoriness allows of a harder glaze being applied to the ware formed from it without risk of the heat requisite for making the glaze flow affecting the biscuit either in shape or colour. "Most of the plastic clays of France," says M. Brongniart, "employed for the same ware, have the disadvantage of reddening a little in a somewhat strong heat; and hence it becomes necessary to coat them with a soft glaze, fusible by means of excess of lead at a low heat, in order to preserve the white appearance of the biscuit. Such a glaze has a dull aspect, and cracks readily into innumerable fissures by alternations of hot and cold water." Hence one reason of the vast inferiority of the French stone-ware to the English.

4. *Porcelain clay or Kaolin earth.* — The Kaolins possess very characteristic properties. They are friable in the hand, meagre to the touch, and difficultly form a paste with water. When freed from the coarse and evidently foreign particles interspersed through them, they are absolutely infusible in the porcelain kiln, and retain their white colour unaltered. They harden with heat like other clays, and perhaps in a greater degree; but they do not acquire an equal condensation or solidity, at least when they are perfectly pure. The Kaolins in general appear to consist of alumina and silica in nearly equal proportions. Most of the Kaolin clays contain some spangles of mica which betray their origin from disintegrated granite.

This origin may be regarded as one of their most distinctive features. Almost all the porcelain clays are evidently derived from the decomposition of the felspars, granites, and principally those rocks of felspar and quartz, called graphic granite. Hence they are to be found only in primitive mountain districts, among banks or blocks of granite, forming thin seams or partings between them. In the same partings, quartz and mica occur, being relics of the granite; while some seams of Kaolin retain the external form of felspar.

The most valuable Kaolins have been found: —

In China and Japan. The specimens imported from these countries appear pretty white; but are more unctuous to the touch, and more micaceous than the porcelain clays of France.

In Saxony. The Kaolin employed in the porcelain manufactories of that country has a slight yellow or flesh colour, which disappears in the kiln, proving, as Wallerius observed, that this tint is not owing to any metallic matter.

In France, at Saint-Yriex-la-Perche, about 10 leagues from Limoges. The Kaolin occurs there in a bed, or perhaps a vein of beds of granite, or rather of that felspar rock called Pe-tun-tse, which exists here in every stage of decomposition. This Kaolin is generally white, but sometimes a little yellowish, with hardly any mica. It is meagre to the touch, and some beds include large grains of quartz, called pebbly by the China manufacturers. This variety, when ground, affords, without the addition of any fusible ingredient, a very transparent porcelain.

Near Bayonne. A Kaolin possessing the lamellated structure of felspar, in many places. The rock containing it is a graphic granite in every stage of decomposition.

In England, in the county of Cornwall. This Kaolin or China clay is very white, and more unctuous to the touch than those upon the continent of Europe mentioned above. Like them it results from the decomposition of the felspars and granites, occurring in the middle of these rocks. Mr. Wedgewood found it to contain 60 of alumina or pure clay, and 40 of silica, in 100 parts.

Pure clay, the alumina of the chemist, is absolutely infusible; but when subjected to the fire of a porcelain kiln, it contracts into about one-half of its total bulk. It must, however, be heated very cautiously, otherwise it will decrepitate and fly in pieces, owing to the sudden expansion into steam of the water combined with its particles, which is retained with a considerable attractive force. It possesses little plasticity, and consequently affords a very short paste, which is apt to crack when kneaded into a cake.

It is not only infusible by itself, but it will not dissolve in the fusible glasses; making them merely opaque. If either lime or silica be added separately to pure clay, in any proportion, the mixture will not melt in the most violent furnace; but if alumina, lime, and silica be mixed together, the whole melts, and the more readily, the nearer the mixture approaches to the following proportions: — 1 of alumina, 1 of lime, and 3 of sand. If the sand be increased to five parts, the compound becomes infusible. These interesting facts show the reciprocal action of those earths which are mixed most commonly in nature with alumina.

Iron in small quantity, but in a state not precisely determined, though probably of protoxide, does not colour the clays till they are subjected to a powerful heat. There are very white clays, such as those of Montereau, which do not become red till calcined in the porcelain kiln; the oxide of iron contained in them, which colours them in that case, was previously imperceptible. It appears from this circumstance, that the clays fit for making fine white stone ware, as also the Kaolins adapted to the manufacture of porcelain, are very rare.

Iron, in larger proportion, usually colours the clays green or slate-blue, before they have been heated. Such clays, exposed to the action of fire, become yellow or red according to the quantity of iron which they contain. When the iron is very abundant, it renders the clays fusible; but a little lime and silica must also be present for this effect. The earthenware made with these ferruginous clays can bear but a moderate baking heat; it is thick, porous, and possesses the advantage merely of cheapness, and of bearing considerable alternations of temperature without breaking.

Alumina and the very aluminous natural clays which possess most plasticity are apt to crack in drying, or to lose their shape. This very serious defect for the purposes of pottery is rectified, in some measure, by adding to that earth a certain quantity of sand or silica. Thus, a compound is formed which possesses less attraction for water, and dries more equably from the openness of its body. The principal causes of the distortion of earthenware vessels, are the unequal thickness of their parts, and quicker desiccation upon one side than another. Hard burnt stone-ware ground to powder, and incorporated with clay, answers still better than sand for counteracting the great and irregular contraction which natural pottery paste is apt to experience. Such ground biscuit is called *cement;* and its grains interspersed through the ware, may be regarded as so many solutions of continuity, which arrest the fissures.

The preceding observations point out the principles of those arts which employ clay for moulding by the wheel, and baking in a kiln. See PORCELAIN and POTTERY.

The chemical composition of the clays shown at the Great Exhibition was unfortunately not given, as it ought to have been. The injurious effect of this ignorance will, by-and-by, come under consideration, when speaking of the art of the potter; but, for the present, we shall content ourselves with a hasty glance at the various specimens of clay exhibited in Class I.,—adding, as usual, a few practical hints for the analysis of these substances, together with some analytical investigations recently made upon average market samples of clay, for the express purpose of elucidating this obscure subject. In a manufacturing point of view, clays may be conveniently divided into three classes; for although a fourth (that is to say, common marl clay) exists, yet, as its employment is limited to the making of bricks, and other coarse articles in which improvement is nearly hopeless, so far as regards material, we shall confine our observations to the three finer qualities, named, respectively, china clay or kaolin, fire-clay, and potter's clay. In china clay, Jenkins & Courtney, of Truro; Whitley, of Truro; C. Thriscutt, of St. Austell; the West of England China Stone and Clay Company; Truscott, Martyn, Brown, Michell, and Wheeler, Philip & Co., all of St. Austell; and W. Phillips, of the Morley Works, near Plympton, together with Sir G. Hodson, Bart., of Wicklow in Ireland, exhibit some samples of great beauty and apparent purity. In fire-clay, the articles shown by King & Co., Squires & Son, and F. T. Rafford, of Stourbridge, with those from Cowan & Co., Ramsey & Co., and Potter, of Newcastle, are excellent; and a sample from Pease, of Darlington, also deserves notice. In potter's clay, Whiteway, Watts, & Co., of Dorset; Fayle & Co., of Thames Street, London; W. & J. Peike, of the Isle of Purbeck; N. Burnet, of Gateshead; and the North Devon Pottery Company, are the most remarkable, though there are many very respectable looking samples from other quarters.

In the manufacture of earthenware goods, it is indispensably necessary to mix the clay, in the first instance, with some infusible material, which does not contract or diminish under the influence of heat; for all kinds of clay shrink very much by the action of a high and prolonged temperature, and are therefore liable, during such exposure, to warp and twist out of shape, or become cracked in the furnace. Hence a remedy is sought as above indicated, and for this purpose, silica, in a minute state of division, is generally preferred; though felspar, and a kind of decomposing granite, called Cornish stone, are also used. But whatever may be the material, its introduction into the body of the earthenware is conducted on purely empirical principles, for, as the composition of the clay is unknown, no attempt can be or is made to effect a combination in unison with the laws of chemical affinity. The substances employed are recognised only as clay, and perhaps ground flint; nor is any other test used to ascertain the proper proportion of each towards the other, than the uncertain judgment of a workman, or the equally fallacious practice of an established rule. As, however, all clays, in a state of natural purity, consist of silica and alumina, united together in definite atomic proportions, there can be no doubt that perfection in earthenware depends upon this simple law; and

that the only true mode of fabricating a uniform and really valuable kind of pottery-ware, would be to follow out the indications of nature, and constantly preserve an atomic ratio in the admixture of the flint and clay of which that pottery-ware is composed. Of course, under existing circumstances, this is impossible; for, as we have previously remarked, the precise composition of the different clays used in the arts is totally unknown; and, independent of any chemical difficulties that may be presumed to exist in determining this important fact for themselves, our manufacturers may justly plead that no simple and satisfactory mode of analyzing clay has yet been published. Hence the present empirical system is universal; and the accidental admixtures it produces testify to the truth of our remarks, by cracking and flying to pieces under very trivial alterations of temperature, no less to the annoyance than loss of the public at large. Nor can this be wondered at, when it is remembered that, in almost every tea-cup, saucer, or plate upon our tables, the laws of natural combination have been violated by the prevalence of an artificial and incompatible form of arrangement, the work of sheer ignorance and chance. So far as our investigations have yet gone, it appears that kaolin, or china clay, has arisen from the decomposition of felspar under two different conditions; for the resulting compound is not alike in both cases; though to what cause this difference can be ascribed we are unable with certainty to say. Felspar, in its original state, has exactly the same composition as anhydrous alum, with this exception, that in the one case the bases are united to sulphuric, and in the other to silicic acid. Felspar, therefore, consists of one atom of potash and one of silica, united to two atoms of alumina and three of silica; or, in other words, it is formed of the silicate of potash and the silicate of alumina, combined in the ratio of one atom of the former to two of the latter. Now, it is found that, when felspar is long exposed to the action of the weather, it becomes disintegrated and falls into a state of powder, which, ultimately, by absorbing water, assumes a pasty consistence, and thus forms the article called china clay. The nature of this decomposition is not, however, uniform or invariable, for analysis proves that the residuary produce has not always the same composition. When felspar decomposes in an absolutely wet or rainy atmosphere, the silicate of potash would appear to be simply washed away by the excess of water; and, in this case, the resulting clay has a composition of three atoms of silica and two of alumina; but, when merely a moist atmosphere has existed, then the silicate of potash itself seems to become decomposed, probably by carbonic acid, thus leaving the whole of the silica united to the alumina; the potash then escaping as a carbonate. Under such circumstances, we have found china clay to consist of four atoms of silica and two of alumina; or, what is the same thing, of two of acid and one of base. Of course an alternating atmosphere would produce a mixture of these; and such layers may actually be traced in many specimens of clay, as though the summer and winter portions of the year had each furnished a distinctly separate amount of decomposed felspar. But felspar is not the only source from whence our silicate of alumina has been formed; as there are many other minerals which, by the action of the atmosphere, furnish clays of different compositions: thus, the substances known to mineralogists under the names leucite, albite, analcime, nepheline, mesotype, and sodalite, all yield silicate of alumina, which contains, indeed, various proportions of the two ingredients, but is nevertheless, in a commercial sense, clay. In point of fact even granite has contributed its quota to the clay formation, for though slowly and imperfectly, yet in time it crumbles down into supersilicate of alumina: as may be noticed by carefully examining the once smooth surface of the granite on Waterloo and London Bridges, which is gradually assuming a cavernous character. With such evidence before us of the infinite variety existing in clay, it is surely high time that the attention of manufacturers was directed to the necessity of analyzing this substance, and adding to it neither more nor less silica than is sufficient to produce a useful atomic compound. The proper proportion might soon be arrived at by a few carefully conducted experiments, after which the whole of the uncertainty now connected with differences in the material would vanish for ever, and with it no small amount of the loss occasionally caused by earthenware spoilt or broken in the kiln.

To determine the quantity of alumina in clay, a given weight of this substance, say 100 grs., well dried and in fine powder, should be mixed with double its weight of fluor spar, also in fine powder, then the mixture placed in a platinum or leaden vessel, and about 400 grs. of strong sulphuric acid poured over it. Next expose the whole to a heat of from 212° to 250° Fahr. for half an hour; then add three or four ounces of water, and throw the mixture on a filter, adding a little water at the end of the filtration, so as to obtain the whole of the soluble matter. To the filtered fluid add now an excess of a solution of ammonia, by which the alumina will be precipitated; and this, after being well washed on a filter, and dried at a red heat, must have its amount determined by the balance. If, however, the precipitate thrown down by ammonia has a deep yellow or red colour, the presence of iron is indicated; and this must be removed before drying the alumina. For this purpose, a quantity of tartaric acid should be added, so as to redissolve the

mixed precipitate, and the solution slightly superaturated with carbonate of soda; when, on adding hydrosulphate of ammonia, the iron will separate as a black sulphuret, leaving the alumina still in solution; from whence it may be obtained by evaporating the whole to dryness, heating red hot, and then washing away the alkaline salts by hot water; the alumina is then left pure, and, after being dried, may be weighed. As the presence of iron in clay is a serious drawback, the quantity of black sulphuret formed becomes a good indication of the impurity of the sample under examination, and is therefore worthy of notice.

Although the proportion of alumina in clay is the chief commercial feature required by the makers of earthenware, yet it may sometimes be requisite to determine also the amount of silica present; which may be done by fusing together in an iron crucible or pan, at a full red heat, one part of the clay in question with three parts of pure potash,—both being in fine powder, and carefully mixed before fusion. The fused mass must, when cold, be boiled for some time in water, until it is thoroughly disintegrated; when it should be poured into a porcelain vessel, and supersaturated with muriatic acid; after which, by evaporating to dryness, a residue will be obtained, that, after careful washing with boiling water, consists merely of the silica contained in the clay in question. After being heated red hot, it may be weighed as usual. If lime be suspected to exist with the alumina in clay, this may be separated, when in solution, by means of tartaric acid and carbonate of soda, as above indicated; for, in such cases, the lime will fall at once as a carbonate, leaving the alumina behind in the fluid. Independent, however, of the defects in British earthenware due to the non-atomic admixture of its ingredients, there are others arising out of the nature of the ingredients themselves; so that, taken as a whole, we cannot avoid coming to the unpleasant conclusion, that, in the great arena of competition at the Crystal Palace, England is decidedly beaten in the manufacture of fine earthenware, even by countries greatly its inferiors in capital, intelligence, and natural resources. France, Germany, Sweden, Denmark, Spain, Russia, Turkey, and China, all exhibited porcelain of a quality unmatched by anything in the British department, and no more lamentable contrast could possibly be drawn than between the chemical apparatus from Saxony and the clumsy abortions, which, under that name, disfigured some of the compartments claimed by one or two of our Staffordshire manufacturers. In the one case we find a really handsome, light, and elegant article, the glaze of which has evidently penetrated throughout the entire substance of the body, and has converted the whole into a uniform vitrification; in the other, a thick, coarse, opaque, and spongy mass, is merely glazed over on its extreme surface by a fusible compound, having no properties in common with the body of the article, and endowed with very different powers of expansibility by heat; so that, after being used a few times, the glaze becomes cracked and shivered in a thousand directions, as may be seen by examining the earthenware in common use throughout Great Britain. Nor is the unsightly appearance caused by this cracking of the glaze the whole evil; for earthen vessels thus flawed acquire the property of absorbing fluids into their pores, and can never afterwards be thoroughly cleaned. In spite, therefore, of "warranted not to absorb," and other groundless legends of similar import, imprinted upon many British goods, a piece of really non-absorbent earthenware, for common use, is an actual curiosity in this country, and invariably suggests the idea of a foreign origin. Now this defect can be remedied only in two ways; and, as our manufacturers have vainly endeavoured to carry out, practically, one of these ways, we are not without hopes of persuading them to try the other. If a glazing material could be discovered, the expansions and contractions of which, by heat, exactly corresponded with those of the biscuit ware, or silicate of alumina, under the same influence, then the present system of covering a spongy body by a coating of vitrifiable glaze would answer the desired intention well enough; for to the cheapness and durability of earthenware would thus be superadded the cleanliness of glass. But this desideratum has been sought for, over and over again, during the last half century, and nothing but disappointment has resulted. In proof of which we have only to ask — where is that glazed earthen vessel, which, though made expressly for the use of the apothecary, will retain oil, after being two or three times heated and cooled? The answer to this question must be our argument in favour of abandoning such a system of glazing, and adopting the only other mode by which a non-absorbent pottery ware can be fabricated. The body of the ware itself must undergo a semivitrification, as happens with the finest kind of china; so that, even if by long use the glaze come to be fairly worn off, still the non-absorbent principle would remain as perfect as at first. We know that this is impracticable under existing circumstances; and that, so long as the present empirical mode of compounding the materials of which the body of the ware is made continues, no chance of improvement remains. A mixture of silica and alumina, in the proportion of four atoms of the former to one of the latter, would bear or require a certain quantity of fusible material to induce semivitrification throughout the mass; but a compound of three atoms of silica and one of

alumina would probably be melted down into a worthless slag by exactly the same addition. Here then lies the root of that difficulty which has hitherto so injuriously restricted the employment of felspar and other vitrifiable bodies in the fabrication of British earthenware. Those who have attempted to use such substances have occasionally succeeded to admiration; and nothing but the uncertainty of the result, and repeated failures, have induced them to abandon the employment of a class of articles which, if capable of being controlled, every intelligent manufacturer admits would confer perfection on his art. But it is a great mistake to suppose that these inequalities of action arise out of some peculiarity in the vitrifiable materials themselves, or are in any way the work of chance. The materials are, or ought to be, uniform, and certainly can be made so, whilst, for the rest, there is no such thing as chance in nature, — the laws of chemistry are not accidental or variable, they are immutable. We have shown, however, that clays not only differ from each other, but, as it were, from themselves; since, from the same pit, and within a few inches of the same spot, clays of very contrary characters may be procured. Plasticity is no more an indication of the presence or purity of clay, than sweetness is a test of sugar. In a rough way both these qualities have a value; but the arts are now fast approaching an epoch, when all such fallacious aids must give place to the guidance of philosophy; and the sooner our manufacturers become convinced of this grand truth the better for themselves and their country. The propriety of knowing the exact composition of the raw materials employed in any art or manufacture does not, indeed, admit of dispute — it is imperative; and hence we are the more astonished at the scantiness of information respecting the analysis of so important a production as clay. In face of such apathetic ignorance, would any one believe that, independently of an immense home consumption, our exports of earthenware last year amounted to a million sterling? Had the clays of this country been of a tolerably uniform composition, like some of those in China and on the continent, of course mere practice would long ago have enabled our pótters to produce articles of the highest quality. But surely this is a sorry compliment to men surrounded by all the resources of science and capital. Where there is no difficulty there can be but little merit, and still less profit. It is the great glory of British enterprise and industry to despise so low and facile a position. Our manufacturers must meet and overcome the trivial impediments connected with variations in the clay they purchase, and, by properly adjusting the other materials (so as to bring on exactly the due amount of vitrification needed in the body of the ware), produce, from any kind of clay, articles identical with those which other nations fabricate from the very finest clays only. With the prodigious commercial and other advantages possessed by Great Britain, the world at large ought to expect this at our hands, and not the sub-mediocre workmanship displayed in the Great Exhibition.

Before quitting this subject, a few remarks upon the substances used in the formation of glazes may not be inappropriate. The million is still supplied with earthenware, the glaze of which contains lead, and is, consequently, dangerous to health, though, when well burned on, this danger is greatly diminished, from the increased insolubility of the silicate of lead in weak acids. It is, however, an objectionable mode of glazing earthenware, and requires to be watched with caution, more especially where borax is used at the same time, for the borate of lead is more easily acted on than the silicate. It has been lately suggested that oxide of zinc would form a sufficiently fusible compound with silica, and is cheap enough to supplant oxide of lead in the glazing of common earthenware. The latter assertion is undoubtedly true, and, although we entertain some suspicions as to the easy fusibility of silicate of zinc, yet this is precisely one of those problems which, from their important sanitary bearing, deserve immediate investigation. On the continent a very pure kind of felspar, mixed probably with a little carbonate of baryta and oxide of tin, forms the only glaze used upon porcelain and the china vessels intended for chemical purposes. This glaze is practically perfect. It is so hard as to withstand the attack of a file, and it resists the action of the strongest acids and alkalis at all temperatures below 300° Fahr. — the hydrofluoric acid and its salts alone excepted. In the French, Saxon, and Prussian departments of the Crystal Palace, there were several good specimens which illustrated the value of this kind of glaze.

Amongst the English goods — and chiefly those from Staffordshire — were a variety of articles made in what is termed Parian, a compound, the unfitness of which for statuary purposes we now briefly animadvert upon, with reference however only to its employment in the higher branches of Decorative Art. The employment of this material, or indeed any other form of alumina where sharpness and symmetry are wanted, cannot be sufficiently condemned, since it is totally contrary to the natural properties of alumina, and betrays infinite ignorance regarding first principles. The philosophical mind of Wedgewood would have revolted at so palpable an absurdity; for not alone was he well acquainted with the continuous contractility of aluminous compounds, but, taking advantage of that knowledge, he was able to construct an instrument for measuring high degrees of heat, which, although not rigidly perfect, is at this day still

found the only available guide for furnace operations on a large scale. And the value of this instrument or pyrometer, as it is termed, depends upon the fact, that the longer and higher the temperature to which clay is exposed, the smaller it becomes. Now, bearing in mind that earthenware is an extremely bad conductor of heat, let us imagine the Greek Slave, for example, correctly modelled in clay or Parian, and subjected to the heat of a porcelain furnace. The smaller portions of the figure, as the nose, eyelids, fingers, &c., would receive much more of the impress of the fire than the larger ones,—as the head, shoulders, &c.; consequently, however symmetrical the original model might have been, the extra contraction in the smaller parts must destroy every thing like anatomical harmony and beauty. The fingers would become short and dumpy, and the nose flat and snubbed. But this is a small part of the mischief, for since clay, when burnt, is a bad conductor of heat, and the action of the fire is from without to within, the exterior of the figure must contract vastly more than the interior; consequently, the outside becoming too small for the inside, a series of cracks or fissures make their appearance to compensate for the inequality. These, of course, are filled up by a subsequent operation; but, it is needless to add, at the expense of every thing which would have rendered the result valuable as a work of art. The general appearance of the Parian figures shown in the Exhibition bears us out in this censure; for the features are universally flat, soulless, and devoid of expression; nor can we imagine a more hopeless task than attempting to remedy this defect.

CLOTH, MANUFACTURE OF. See Cotton, Flax, Weaving, Wool.

CLOTH-BINDING. Nothing places in so striking a point of view the superior taste, judgment, and resources of London tradesmen over those of the rest of the world, than the extensive substitution which they have recently made of embossed silks and calicoes for leather in the binding of books. In old libraries, cloth-covered boards indeed may occasionally be seen, but they have the meanest aspect, and are no more to be compared with our modern cloth-binding, than the *jupon* of a trull with the ballet dress of Taglioni. The silk or calico may be dyed of any shade which use or fancy may require, impressed with gold or silver foil in every form, and variegated by ornaments in relief, copied from the most beautiful productions in nature. This new style of binding is distinguished not more for its durability, elegance, and variety, than for the economy and dispatch with which it ushers the offspring of intellect into the world. For example, should a house eminent in this line, such as that of Westleys, Friar-street, Doctors'-commons, receive 5000 volumes from Messrs. Longman & Co. upon Monday morning, they can have them all ready for publication within the incredibly short period of two days; being far sooner than they could have rudely boarded them upon the former plan. The reduction of price is not the least advantage incident to the new method, amounting to fully 50 per cent. upon that with leather.

The dyed cloth being cut by a pattern to the size suited to the volume, is passed rapidly through a roller press, between engraved cylinders of hard steel, whereby it receives at once the impress characteristic of the back, and the sides, along with embossed designs over the surface in sharp relief. The cover thus rapidly fashioned, is as rapidly applied by paste to the stitched and pressed volume; no time being lost in mutual adjustments; since the steel rollers turn off the former, of a shape precisely adapted to the latter. Hard glazed and varnished calico is moreover much less an object of depredation to moths and other insects, than ordinary leather has been found to be.

CLOTH-DRESSING, *by Heycock of Leeds*, without stretching the warp-threads or creasing the cloths from list to list. He lays several pieces of cloth in an extended state above one another upon a wooden platform, until a pile of a suitable thickness is formed, a perforated plate is then brought down on the cloth by screws, and steam is admitted into a hollow chamber beneath, from which it penetrates all the folds of the cloth, but is confined at the sides. It seems to be a purpose-like invention.

COAL. Under Pitcoal, the composition of several excellent coals is stated, with their peculiar qualities, as analyzed by me; such as the Llangenneck, Powell's Duffryn steam coal, the Blackley Hurst coal, Lancashire, the Varley Rock vein coal, near Pontypool, &c. The quantity of coals and culm exported in 1850 was 3,351,880 tons, and in 1851, 3,477,060 tons: declared value respectively, 1,284,224*l.* and 1,302,025*l.*

COAL GAS. From what is generally admitted concerning the impurities which exist in crude coal-gas, it must be evident to those conversant with the principles of chemistry that these impurities can never be thoroughly removed by any single reagent, for some of them possess affinities diametrically opposite to the others. Thus, any means employed to absorb carbonic acid and sulphuretted hydrogen gases would leave the ammonia free; whilst an agent capable of combining with the latter, would not at all affect the former impurities. Hence the process of coal gas purification, as now carried on at the best gas works, is divided into two distinct parts. By one of these the whole of the ammonia and a portion of the carbonic acid and sulphuretted hydrogen are taken away, by the other, the remainder of the carbonic acid and sulphuretted hydrogen are totally re-

moved; so that the gas ultimately passes forth to the consumer free from all contamination either by ammonia, carbonic acid, or sulphuretted hydrogen gas. And the absence of these impurities may at any time be demonstrated by applying the following simple tests: — litmus paper, slightly reddened by an acid, will undergo no change when held for a few minutes in a current of the gas; this proves the absence of ammonia, for otherwise the paper would become blue. Paper, dipped into a solution of the acetate of lead, and held in a current of the gas, will remain white, which shows that the gas is destitute of sulphuretted hydrogen, as, under contrary circumstances, it would assume a deep brown or black hue. Lastly, if the gas be allowed to blow for a few minutes through a clear solution of lime in water, the solution will not become milky and turbid, as it would do if carbonic acid were present in the gas. No coal gas which does not vindicate its purity by resisting the analytical powers of the above tests can be regarded as sufficiently good for the purposes of illumination and heating.

To separate the ammonia from coal gas, a variety of modes is at present in use; thus, Mr. Lowe employs cold water minutely divided in an apparatus which he terms a "scrubber," and which is perfectly analogous to the *cascade chimique* of Clement Desormes. With a similar view Mr. Palmer mixes the gas with steam, and then subjects the mixture to a condensing temperature, so as to obtain water, minutely divided in drops, like rain or dew, and therefore presenting a considerable surface for chemical action. Mr. Johnson prepares a compound, consisting of sulphate and biphosphate of lime, by acting on burnt bones with sulphuric acid; and this he disposes in trays, so as to absorb the ammonia and produce a mixture of sulphate of ammonia and phosphate of lime, which, as might be expected, he finds an extremely efficient fertilizing agent. Mr. Laming employs a solution of chloride of calcium or muriate of lime, absorbed into sawdust, which he disposes in the same manner as that followed by Mr. Johnson, and by which the muriate of lime is gradually decomposed with the formation of carbonate of lime and muriate of ammonia, — the resulting compound being either valuable as a manure, or as a source for the manufacture of sal ammoniac. Sulphate of lime, and various other earthy metallic salts, have also been proposed and employed, — such as the sulphates of magnesia, alumina, zinc, iron, and manganese, and the chlorides of the same metals. With the exception of the sulphate of lime, they do not, however, seem to possess any advantage over the modes we have mentioned as now in use for the absorption of ammonia; and hence it may be as well to examine more minutely the actions of those methods, and their effects upon the gas undergoing purification. The process of Lowe is extremely simple in theory, and, where the saving of the ammonia is not an object of importance, has much to recommend it. Here the ammonia is, so to say, washed out by means of water; and the application of the scrubber may either be made before or after the other impurities are taken away, with, however, this difference in the result: — if the gas, after quitting the condenser, is passed at once into the lime purifier, and the scrubber applied afterwards, nothing but ammonia will be removed by the water; but if the scrubber be employed in the *first* instance, then, with every atom of ammonia taken away, one of carbonic acid or sulphuretted hydrogen will follow, and hence a great economy of lime in this way arises; for the ammonia, though itself an impurity, thus becomes a purifying agent, and the liquid from the scrubber consists, not of aqueous ammonia merely, but of a solution of carbonate and hydrosulphate of ammonia. It is, however, very difficult to separate the whole of the ammonia, either free or combined with carbonic acid, by Lowe's scrubber, without the application of a very large body of water; and it has been suggested, that excessive ablution diminishes considerably the illuminating power of coal gas. This circumstance, if true — and it is far from improbable — demonstrates the necessity of limiting the action of water upon gas, and must, in some degree, interfere with the employment of an otherwise invaluable instrument of purification. The plan of Palmer is precisely similar in its effect to the scrubber of Lowe, but more costly, and, except when conducted with great care, less efficacious, as the entire success depends upon the perfection of the condensation; for, unless the condensed water be cooled down to the mean temperature of the atmosphere, little or no ammonia will combine with it; and there is, moreover, a still greater danger of injuring the light-giving power of the gas by condensed steam, than by an equal weight of cold water. This method cannot, therefore, be considered as equal to the former, more especially when coal gas, of low specific gravity, is to be purified. The mere recital of Johnson's process almost details its mode of action; and it would scarcely be necessary to say more concerning it, but for the contrast it presents to that of Laming, and the substances before alluded to. If the phosphate of lime or bone earth, mentioned as part of Johnson's mixture, be regarded as a sponge for holding the sulphuric acid which he employs, then the ammonia is taken up from the gas by simple elective affinity with the production of sulphate of ammonia; and this is, beyond doubt, a true explanation of the *modus operandi* in Johnson's case. Here, however, it will be noticed that nothing but ammonia is removed, for the carbonic acid and sulphu-

retted hydrogen remain unaffected; consequently this system might be employed either before or after lime purification. Now, Laming's plan differs altogether from this, and, as will readily be seen, admits of application only before lime purification. The foul coal gas from the condenser contains carbonate of ammonia in a gaseous condition; and it has just been shown, that the process of Laming depends upon the use of muriate of lime. But at the ordinary temperature of this country these two substances are incompatible with each other; and, consequently, as fast as the carbonate of ammonia is brought by the current of gas into contact with the muriate of lime, mutual decomposition ensues, and both the ammonia and carbonic acid are solidified; the former becoming converted into muriate of ammonia, and the latter into carbonate of lime, by an interchange of elements with the muriate of lime used in the process; therefore the result differs thus far from that of Johnson, — that carbonic acid as well as ammonia is taken from the gas, and consequently a saving of lime, or other purifying material, effected: of course sulphate of lime would act in the same way, though less powerfully; whereas metallic salts, in general, having more affinity, after decomposition, for sulphuretted hydrogen than for carbonic acid, will produce an economy of lime by removing the former and not the latter impurity. Such, then, is a descriptive outline of the methods actually followed at the present day for the purification of coal-gas from the ammonia it contains; and although seemingly abundant enough to have exhausted the subject, yet there is still an extensive field open to improvement even here.

Amongst the large class of ammoniacal compounds known to chemists, it seems strange that no one has yet taken advantage of that interesting series which suffers decomposition by the mere application of a moderate temperature, evolving at the same time pure ammoniacal gas, and yielding, as a residue, the substance originally employed for purification. We shall enumerate but one or two substances of this kind for the purpose of illustrating our argument, leaving the whole question as open as ever to practical investigation. When phosphate of magnesia is exposed to the action of ammoniacal gas, its acid becomes divided in such a way as to produce the triple salt called ammoniaco-phosphate of magnesia; and as this is a much more insoluble substance than the simple phosphate, we have only to pass impure coal gas through a solution or aqueous mixture of the latter, to insure the precipitation of all the ammonia contained in the gas; whilst, at the same time, the compound which it has formed with the phosphate of magnesia is very easily decomposed, so as to admit of a continuous usage of the same material; for at a temperature considerably below a red heat, the triple phosphate of magnesia parts with all its ammonia, and becomes simple phosphate again, with the renewal of its primitive power as an absorber of ammoniacal vapours. But the ammonia which is expelled by heat might very easily be condensed in water, and thus originate a valuable commodity for the market. By this means there can be no doubt phosphate of magnesia might be employed over and over again in the purification of coal gas, whilst the ammonia procured from it would contain neither sulphur nor any other impurity. An iron vessel might be used for the distillation; and if too high a heat was not given to the phosphate of magnesia, its purifying action would remain unaltered; thus presenting altogether a fair opening for the investment of talent and industry. Similarly, boracic acid deserves attention, from the facility with which, even at the temperature of boiling water, it parts with the greater portion of any ammonia previously united to it, at the ordinary heat of the climate in this country. It offers, consequently, a commodious vehicle for collecting and conveying the ammonia of gas works into public use, without the risk of nuisance or loss. Many other substances possessing this double property of absorbing and giving off ammonia by a trifling change of temperature might be pointed out; but this lies beyond our province; it is the principle only which we attempt to elucidate, with a view to its practical application in some specific instance.

Presuming that the impure gas has had all its ammonia separated by proper treatment, we have now to consider in what way the carbonic acid and sulphuretted hydrogen may be most easily got rid of. Lime is the agent commonly selected, and all things duly admitted, there is a great mass of evidence in its favour,—so much so indeed, that, until lately, it has had no competitor. At present, however, the oxide of iron is becoming a formidable rival; and therefore we propose to examine into their respective merits, which, after all, are less alike than might be supposed in two substances selected to perform one and the same operation. When properly prepared and moistened, lime removes from impure coal gas both carbonic acid and sulphuretted hydrogen with extreme energy, and consequently effects thorough purification after the ammonia has been got rid of. Oxide of iron combines only with the sulphuretted hydrogen contained in the gas, and not with the carbonic acid; so that coal gas purified in this way requires subsequent application of lime, or some other material capable of combining with carbonic acid. Thus far, therefore, the advantage is much in favour of lime. But when lime has absorbed all the impurity it can attract from coal gas, or, in technical

phrase become "foul," it is not only altogether useless, but, much worse than this, it is a serious nuisance, in consequence of the evolution of sulphuretted hydrogen the moment it comes in contact with atmospheric air, which arises from the action of the atmospheric carbonic acid upon the hydrosulphate of lime contained in the foul mass. Gas-lime refuse is therefore a grave inconvenience to many gas companies. Now with oxide of iron no such inconvenience is felt; for this substance in uniting with sulphuretted hydrogen produces a compound which yields no noxious or unhealthy emanations by the contact of air, but is, under such influence, simply oxidized, and in a great measure restored to its primitive power, so that it may be used over and over again, ten, twenty, or even thirty times in succession. These peculiarities give the oxide of iron a decided superiority in many situations, though up to the present moment its practical application has been extremely limited. When lime contained in a purifier has ceased to purify gas, the general impression is that it has been wholly resolved into carbonate and hydrosulphate of lime; but this is very far indeed from being the case, for even the foulest lime seldom contains less than one-fifth of all its lime free or uncombined; and gas-lime refuse is occasionally to be had so imperfectly saturated that fully one-half of the lime paid for by the gas company may be said to be thrown away. In the first place, it is not customary to examine the lime itself, so as to determine its chemical value or combining proportion, and still worse, it is not usual, secondarily, to analyze the lime refuse with a view to ascertain how much lime is passing away unacted on. As both of these desiderata may be secured without the application of any great chemical skill, we shall proceed to give a brief description of the means needed to solve the trifling problems, beginning with the lime itself. Having selected from the bulk a fair sample of lime, let this be ground to a fine powder in a clean and dry mortar; then weigh out 100 grs. of the powder, and place it in a tumbler or other suitable vessel, where it is to be repeatedly washed with a warm but not hot solution of sal ammoniac in water,—the temperature being about 80° or 90° Fahr. Great care must be taken that, in washing the lime, no solid particles are allowed to escape with the ammoniacal solution; and, as soon as it is observed that the fluid containing the sal ammoniac ceases to restore the colour of reddened litmus paper, after it has been poured upon the lime, then common water may be used to wash the remaining lime; after which, it must be dried at a red heat, and then weighed;—the loss will indicate the amount of pure lime present in the 100 grs. taken This mode of analysis depends upon the fact that lime, at the temperature indicated, decomposes muriate of ammonia and becomes soluble, but any carbonate of lime, silicate of lime, alumina, or other inactive impurity, remains undissolved, and may therefore have its quantity determined by the balance.

Foul gas-lime, or refuse, is somewhat more complex, but nevertheless far from difficult in its analysis. Having, as before, selected a fair sample, let 200 grs. be weighed out, and placed in a stoppered bottle, with an equal weight of sal ammoniac, and four ounces of water, heated, as before, to about 80° or 90°; shake the whole well together, and keep the mixture warm for 20 minutes; then filter rapidly into a stoppered retort, and wash the filter with two ounces of hot water, which are to be added to the filtered solution. Next distil over one-half of the fluid into a receiver containing 100 grs. of sulphate of copper, dissolved in water, and set the fluid remaining in the retort aside to cool. Collect the black precipitate now contained in the receiver upon a filter, and wash it well with hot water, then dry and weigh it: it is the sulphuret of copper, and contains one-third of its weight of pure sulphur. The fluid in the retort must now be mixed with an excess of carbonate of soda, and the white precipitate which ensues well washed, dried, and then weighed. One hundred grains of this precipitate, which is carbonate of lime, indicate 56 grs. of pure lime; and if from this we deduct the quantity combined with sulphuretted hydrogen, as given by the sulphuret of copper, the remainder will be the total quantity of pure lime in the 200 grs. of gas-lime refuse, which had not been utilized in the purifier. Thus, suppose that 200 grs. of any sample in question have given 24 grs. of sulphuret of copper, and 80 of carbonate of lime, then the total amount of lime will be 44·8 grs., from which 14 grs. must be deducted for that united to sulphuretted hydrogen, since the atom of sulphur is to that of lime as 16 to 28, and 24 grs. of sulphuret of copper contain 8 grs., or one-third of its weight of copper, which is consequently equal to 14 grs. of pure lime. This supposed sample has therefore given 30·8 grs., or 15·4 per cent. of free lime. Thus, in place of the mere rule of thumb system, too commonly pursued in gas works, a good gas engineer will control the entire produce of his manufactory by determining, first, the total amount of sulphur given off in a gaseous form by the coal he uses; next the chemical power of his lime; and lastly, whether or not the action and arrangement of the purifying apparatus is such as to insure the proper saturation of the lime with the impure constituents of the coal gas. Without the occasional employment of analytical processes, similar to those previously given, it is altogether impossible to conduct gas-works with that certainty and confidence essential to perfect economy.

It might be supposed that with the purification of coal gas the chief difficulties of a gas engineer ended, but this is very wide of the truth; for upon no point is there greater diversity of opinion, and more discrepancy in result, than exists regarding the proper mode of burning gas for the purposes of illumination and heating. As regards the former question, it seems hitherto to have been impossible of solution, from the fact that quantity and intensity of light have been confounded together; and persons have been surprised to find that a bright white light, of great intensity to the eye, has, nevertheless, illuminated a given space worse than a large quantity of a dull, yellow, smoky-looking light. Thus, if when an argand oil lamp is burning with great brilliancy the central aperture for the admission of air be closed, the flame will immediately become yellow and smoky, yet, on examining the walls of the apartment, it will be found that they are better illuminated than with the more brilliant light. In the former case, many of the particles of carbon are consumed before they take on the solid condition, whereas in the latter, they are all separated from the hydrogen of the oil, and become red-hot solid bodies ere they enter into combustion. But as the quantity of light is proportioned to the number of solid particles heated, and its intensity to the elevation of the temperature to which they are heated, it follows, that part of the carbon is employed in producing heat, to give intensity of light to the remainder, in the one case, whilst in the other, the whole of the carbon becoming solid reflects a great quantity of light of less intensity. For the ordinary wants of society, the latter is the best light. A knowledge of these matters enables us easily enough to explain the vast difference in illuminating power which one and the same gas displays when consumed in different burners. Thus, a thin gas, of low specific gravity, which affords an excellent light in an argand burner, will scarcely yield any light at all with a fish-tail or bat's-wing; and a rich cannel coal gas, well adapted to either of the latter burners, requires infinite care to prevent it from smoking in an argand. In determining the relative illuminating powers of different gases, it is therefore necessary to select for each gas that form of burner best suited to display its light-giving properties, and not continue the present Procrustean system of cutting down the power of the gas to an arbitrary standard of burner; the only result of which has been a series of assertions and contradictions too disgraceful for further notice. In photometrical experiments, a spermaceti candle, of a determined size, is commonly employed, and, in a rough way, answers remarkably well. But sperm, like wax and tallow, gives quantity of light, but not of an intensity equal to gas, as may be seen in a moment by contrasting the comparatively yellow flame of the one with the brilliant white light of the other. They are therefore like musical instruments tuned to a different pitch, and can never harmonize with each other. The better plan would be to select olefiant gas as a photometrical standard, since this compound is uniform in composition, and can be easily prepared at a few minutes' notice. It possesses, moreover, the advantage of being consumed in similar burners to that employed for the gas to be tested, and is under the influence of the same barometric and thermometric variations. The Bunsen photometer, as modified by Mr. A. King, of Liverpool, is, perhaps, the best instrument to employ in experiments on comparative illumination. Regarding the ultimate analysis of coal gas little need be said, as the results have no specific value or meaning. The only correct mode of analysis is by passing a known volume of the gas over oxide of copper in a tube heated red-hot, and collecting first the moisture by chloride of calcium; secondly, the carbonic acid by hydrate of lime or solution of potash, as followed in ordinary organic analyses; and, lastly, receiving the incombustible residue over water in the pneumatic receiver: from which three products, the quantity of hydrogen, carbon, and nitrogen may be deduced. The ultimate analyses of coal gas, as also the estimation of its value from the condensation of what is termed its olefiant gas, whether by chlorine, sulphuric or nitric acid, are processes of no practical value to the public, and serve only to mislead the ignorant. From the vast reduction which is now taking place in the prices of coal gas, its calorific power has become one of the most interesting questions of the day; and when the waste of fuel consequent upon lighting a common fire, with the quantity consumed after the fire is no longer wanted, are carefully inquired into, it seems very clear, that for at least 4 or 5 months of the year it is cheaper to cook by gas in London than by coal, at the existing prices of these articles. An apposite illustration of the correctness of this assertion is afforded by the warm bath of Mr. Defries, in which 45 gallons of water are heated from the temperatures of 50° to 100° Fahr. by 30 cubic feet of gas, and at a cost of only three pence. Now, to effect this at all by coal would entail an expense of at least fourpence; but to do so in the same period of time (5 minutes), would certainly entail an outlay of not less than a shilling. Of course, where the operation is to be repeated, or go on continuously, a different result would ensue; but for extemporaneous use, coal gas will always be cheaper than coal. But even this surprising economy has been exceeded by a very elegant arrangement, invented by Mr. F. I. Evans, of Westminster, in which a coil of iron tubing is so disposed, as to present an immense surface to the heating influence of the burnt gas, and thus absorb the whole of the heat. In this way, a current of cold

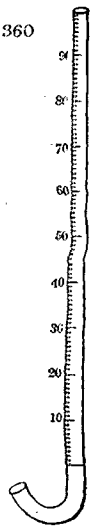
water entering at one end of the tube flows out of the other continuously, and at any required temperature, according to the velocity of the current, and the quantity of gas consumed in a given time. For the requirements of the Humane Society, for the public hospitals and charities, a simple apparatus of this kind must find a ready application, and deserves to be better known. According to direct experiments, made with great care, Mr. Evans has found that common Newcastle coal gas, of sp. gr. ·416, has an evaporative value equal to about 22 times its weight, or, in other words, that 1 lb. of such gas will convert, theoretically, 22 lbs. of water into steam; and this accords very well with the results given by Defries with his bath, in which 30 cubic feet of gas are stated to heat 45 gallons, or 450 lbs. of water at 50°. This is equal to 15 lbs. similarly heated for each cubic foot of gas, weighing, say 206 grains, or 750 lbs. of water heated one degree by the same means. This, estimating the latent heat of steam at 960, gives 25 parts of water boiled off for every one part of gas consumed, which is very nearly three times as great as the heating power of good Newcastle coal. But practical experiments were wanting to show the real amount of water which can be boiled off by gas, as burnt in ordinary burners beneath a boiler. This deficiency has been supplied by Mr. Evans, to whom we are indebted for the following tabular statement: — One cubic foot of gas, weighing about 205 grs., and of sp. gr. ·413, boiled off $\frac{4}{10}$ths of a pound of water, or 13·6 times its weight. One cubic foot, weighing about 290 grs., and of sp. gr. ·564, boiled off $\frac{5}{10}$ths of a pound, or 12 times its weight. One cubic foot, weighing about 360 grs., and of sp. gr. ·700, boiled off $\frac{7}{10}$ths of a pound, or 13·6 times its weight. Thus showing that in the case of gas, one-third at least of all the heat evolved passes off unabsorbed by the boiler. In our comments on coal we had occasion to remark that something like one-half of all the fuel consumed under steam boilers is wasted; and it now appears that fully one-third of all the gas employed in our culinary operations must be thrown away, and will continue to be so until the hand of improvement is applied in the proper quarter. There is, unquestionably, much scope for ingenuity in devising the best forms of apparatus for burning gas, and utilizing its waste heat. A very elegant little machine, which promises to elucidate some obscure points as regards the purity of gas, has lately been added to the ordinary testing chemicals of a gas engineer. This consists of a bent tube, forming, as it were, the horizontal flue of a furnace, in which the products of combustion arising from gas may be condensed, and afterwards examined with reference to their nature. Mr. A. Wright, of Westminster, is the inventor and maker of the apparatus in question, and by its means two curious facts may at almost any time be demonstrated. One of these is, that sulphuric acid is an invariable product of the combustion of coal gas; the other, that very frequently, and more especially with cannel coal gas, a substance possessing all the properties of aldehyde makes its appearance. The latter seems to be a product of imperfect combustion, and gives rise to that peculiarly offensive odour produced wherever large quantities of coal gas are burnt in a close compartment. It is commonly believed by chemists, that coal gas contains ammonia, which in burning is converted into nitrous or nitric acid; but the apparatus of Mr. Wright demonstrates at once the fallacy of this opinion, by proving that whenever gas contaminated with ammonia is consumed, the ammonia either passes off unchanged, or is simply decomposed into its elements; for carbonate of ammonia, and not nitrate, makes its appearance in the condensed products. Before quitting the subject of coal gas, it is necessary to say a few words upon the composition and use of what is called ammoniacal liquor. This fluid condenses in the hydraulic main, and flows out with the tar, from which it afterwards separates by gravitation. Its specific gravity varies, as does also its composition; but the following may be regarded as a fair average: in one gallon, of specific gravity of 1·017, there were found of sesquicarbonate of ammonia 5984 grains, hydrosulphate of ammonia 420 grains, muriate of ammonia 985 grains, with a trace of ferrocyanate and sulphocyanate of ammonia; consequently, if the small quantity of sulphuretted hydrogen existing in ammoniacal liquor be removed, as it may be by the application of the requisite proportion of carbonate of lead, an ammoniacal solution will be produced, extremely well adapted for many useful purposes in the arts, such as scouring woollens, flax, and other goods, as well as for washing in general. In all these cases, ammonia is greatly to be preferred to soda, even at the same price; but as the ammoniacal liquor of many gas works is actually thrown away, and under no circumstance sells for more than a farthing a gallon, it is discreditable to our industrial economy that this very obvious application of ammoniacal liquor should continue to be neglected; more especially as the fluid, even after being used as above indicated, is still an excellent fertilizing agent. In the Great Exhibition, there were but few illustrations of the manufactures peculiar to gas; a circumstance attributable to the risk of permitting the necessary experiments to take place, by which alone the actual value of any improvement in gas apparatus can be correctly determined. Hence, in the Crystal Palace, merely articles of established reputation were shown, which, having been long before

the public eye, by no means represented the existing condition of this branch of manufacture. On this account, although the decision of the executive committee to exclude experimental gas apparatus seems somewhat unfortunate; yet when the great value of the goods shown in the Exhibition is duly considered, there cannot be two opinions concerning the propriety of the step. The various samples exhibited were nevertheless extremely good of their kind, both in the British and Foreign departments. In clay retorts, the best specimen was in Class 27., by Cowan & Co., of Blaydonburn, Newcastle-on-Tyne; and the next in quality stood in the Belgian portion of the Exhibition. M. Pauvels, of Paris, exhibited a very good retort also; and there were several satisfactory-looking samples from other quarters.

Coal Gas, Composition of. From the most recent investigations into the composition of coal gas, it appears extremely doubtful whether any gaseous compound exists in it to which the name olefiant gas can, with propriety, be accorded, and it certainly seems to have been assumed on very hasty and unfounded data, that to the presence of olefiant gas the illuminating force of common coal gas is chiefly due. Without pretending to deny altogether the presence of the olefiant in the gas of our streets, it is nevertheless susceptible of proof that the quantity which, on the most liberal computation, can be allowed, is infinitely small and insignificant, and, in a practical sense, warrants the now prevailing opinion that there is really none. In support of this, it can be shown that if common coal gas be made to traverse very slowly a great length of tube exposed to the refrigerating effect of a bath of ice and salt, the gas will issue from the other end of the tube almost entirely deprived of its illuminating power; and a similar result may be obtained at ordinary temperatures by passing the gas through alcohol and other reagents. In the case of alcohol, the effect is, however, very instructive, for the alcohol gains exactly that which the gas loses in illuminating power, and, after the experiment, it is found to burn with a bright white flame, and to become milky with water. Now, on the supposition that the photogenic power of coal gas was due to olefiant, none of these results should follow, for no such cold would liquefy olefiant gas, nor would alcohol absorb it in any great degree. Moreover, all attempts to obtain, through the agency of fuming sulphuric acid, any compound like sulpho-vinic acid have utterly failed, even when tried upon a rather large scale. Hence, in regarding coal gas, it is theoretically more correct to consider its luminosity, as arising from the presence of various volatile hydrocarbons or naphthas, rather than from any permanently elastic fluid whatever. This view of the case has latterly become very prevalent, and is now leading to the most important improvements in the manufacture of illuminating gas. It has long been known that ordinary bituminous coals will yield a much larger volume of gas than may, with propriety, as regards the photogenic power of that gas, be taken away from the coal. This arises from the circumstance, that the first portions of gas are much richer in hydrocarbons than the remainder of the charge, and a period arrives at which the gas, though still great in quantity and eminently combustible, ceases to possess any value whatever as an illuminating agent. Moreover, it is known that the mixed gas obtained by decomposing water through the agency of carbon at a red heat is also combustible, but devoid of photogenic power; and it is owing to a correct appreciating of the circumstances upon which the value of common coal gas depends, that both these and other forms of combustible gas have lately been rendered as permanently luminous and well-adapted for the production of light as the best kinds of common coal gas. Having once clearly comprehended the cause of luminosity in ordinary gas, but few steps are required to perceive that the latter portion of a charge of coal, when distilling in a retort, needs but a part of the surplus hydrocarbons of the first portion to render it equally valuable, and we are insensibly drawn to the means of effecting the desired end. Thus, if the latter portions of the charge be stored away separately, and passed in regulated quantities over coal which is undergoing the primary action of destructive distillation, it is clear that such gas will become charged with the hydrocarbons of that primary distillation, and thus, in all respects, resemble the first part of the charge, or, in other words, be made equal to the best gas; at the same time the amount of labour and expense incurred in condensing out these surplus hydrocarbons must be much diminished by the presence of an amount of gas capable of retaining them permanently in solution at ordinary temperatures. Not only, therefore, is it possible to procure in this way a much larger quantity of gas of an average illuminating power from a given weight of coal, but the expense of this production is decreased by the diminished condensation needed for the whole, as compared with that required for a part of the gas under the old system. But there is a still greater advantage than these, and one scarcely to have been expected. These poor gases consist chiefly of hydrogen gas, and it has been discovered that this gas possesses the remarkable property of preventing the decomposition of every form of hydrocarbon at a red heat. The consequence therefore of passing such gas over coals, in its primary state of distillation, is to prevent the decomposition of the various naphthas by the heat employed, and which, without the presence of hydrogen, would be resolved into solid carbon and light carburetted hydrogen, the former of which

remaining in the retort impairs the utility of that vessel, whilst the illuminating power of the gas produced is greatly diminished by the loss of solid matter. Now it has been stated that to these naphthas the luminosity of gas is to be attributed, and therefore their preservation in the way described, by the action of hydrogen, would of itself be an immense step in advance of our former practice; but when to this is added the fact that, with a vastly increased preservation of hydrocarbon, there is also a vastly increased production of combustible gas to render that hydrocarbon available for public use, the real merit of the new discoveries in gas-making must strike even the most thoughtless observer. Of course, the same argument which applies to the use of the residuary gas from a charge of coal, is equally fitted to illustrate the beneficial operation of the gases evolved by decomposing water with red hot carbon. In this latter instance, however, an important fact presents itself, for unless the whole of the surplus watery vapour has been removed or condensed from this water gas, the hydrocarbons arising from the incipient distillation of the coal are destroyed, and, therefore, the object sought to be gained is lost. This accounts perfectly for the innumerable failures which have taken place in attempting to employ steam and water gas for the purpose of illumination; nor, until this subject was investigated by Mr. T. G. Barlow, does any one appear to have formed a correct opinion of the cause of such invariable want of success. Mr. Barlow, however, not only discovered the peculiar preservative power of hydrogen, but also the no less remarkably destructive action of steam, and hence, by merely condensing this latter, he has been enabled to employ water gas with a success which bids fair to prove a very profitable manufacturing speculation, and for the details of which he has secured her Majesty's letters patent in conjunction with Mr. Gore. For the application of the residuary gas from common coal to the preservation of the hydrocarbons arising from fixed oils and fats during distillation, and for the production from coals, lignite, tar, &c., of a larger amount of illuminating gas than can be obtained by the ordinary process, the public is indebted to Messrs. G. Lowe and F. I. Evans, both well known as engineers in the service of the Chartered Gas Company. That these improvements will, in some measure, revolutionise the manufacture of gas seems pretty obvious.

To determine with any degree of precision the value of a gas as an illuminating agent is really a very difficult, though seemingly a very simple affair. The most general method is by the instrument called the Bunsen photometer. The indications of this instrument (at best but imperfect) have been so largely improved by the ingenious modifications made in its use by Mr. Alfred King, of Liverpool, that it has come to occupy a position in the public confidence, to which in its original condition it had not the slightest title. The great difficulty to overcome was the securing of one uniform standard of illumination, without which, as a matter of course, the indications of the photometer were utterly valueless. This indispensable condition has been in a great measure arrived at by Mr. King, who employs a spermaceti candle, and ascertains the amount of spermaceti actually consumed during the experiment, and then reduces this to one uniform rate of 120 grains of spermaceti burnt per hour as contrasted with an hour's consumption of the gas to be tried at the rate of five feet per hour, or in a series of ratios, from 2 to 5 feet per hour; there are, however, many disturbing causes in the burning both of the candle and of the gas, and a very serious one results from the fact that the shape of the flame of the gas materially affects its photogenic meter, thus the flat side of a bat's-wing burner will give almost one-third more light than the edge of the same burner, though the rate of consumption be unaltered.

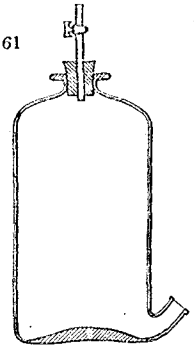


It is necessary, therefore, to adopt some other means of determining the value of a gas than by photometry, and it would appear that this may be effected by the agency of bromine. This substance possesses in a singular degree the power of removing from coal gas the whole of the vapours upon which its luminosity depends, and if these vapours were uniform in composition, all that need be done would be to determine their volume per cent. But this is quite useless, for the vapours differ in themselves to an incredible extent, and therefore it is not only the volume, but the specific gravity of these vapours also, which must be obtained, or in other words, their total weight, for this weight represents the value of the gas. Now if we take a tube bent, closed at one end, and graduated, as shown in the following figure, we possess at once an instrument for determining the value of a gas by volume.

This tube must be filled in the first place with water, and so much of the gas passed up into it as will occupy the graduated portion, when the residuary water will act as a valve. Having placed the whole for a few minutes in a cylindrical vessel containing water, so as to secure a uniform

temperature, the tube must be raised to the water level, and the exact quantity of gas recorded. When this has been done, a few drops of bromine, in all about the size of a pea, are to be dropped through the water in the tube, and a stopper or cork applied; the whole must then be well agitated, until the gas becomes tinged with the red hue of the bromine, after which the stopper must be removed under water, and a few drops of a strong solution of potash being added the stopper is to be replaced, and the whole again agitated until the bromine tint of the gas has disappeared, when the stopper must be again withdrawn under water, and the tube placed as at first in a vessel of water to regain its original temperature, when the water-level must be once more made, and the amount of absorption read off and recorded. This operation does not last more than 10 or 15 minutes, the barometer need not therefore be consulted. Precisely similar to this, but on a larger scale, is the first part of the operation for determining the weight of the condensed portion. In this case a vessel shaped as below is necessary.

361



This, as is evident, differs very slightly from the tube, the bottom being provided with the same water-joint contrivance for the introduction of the bromine, whilst the stopper is pierced by a hole, in which a stop-cock is very carefully fixed, so that after the action of the bromine and caustic potash, the gas may be removed by an exhausted flask so that its specific gravity can be readily determined. Before doing this, it is however advisable to wash the gas two or three times with cold water, which is easily done if we introduce the bottle into a vessel of warm water so as to expand the gas, and thus expel the fluid through the water-joint tube, which being effected, we have only to close this opening and immerse the bottle in cold water, when, by withdrawing the stopper-joint, cold water will rush in, and this may be repeated at pleasure, the object being to wash the residuary or incondensable gas thoroughly; this operation requires but a short time, and if we have taken beforehand the specific gravity of the original gas, the amount of its condensation, and now know the specific gravity of the incondensable portion, it is clear that we possess the means of knowing the exact weight of that which has been condensed. Thus, a cannel coal gas at Westminster was analyzed in this way, its illuminating power by the photometer being 20 candles per 5 feet. This gas had a specific gravity of ·48500, and a condensation of 9 per cent., whilst the specific gravity of the uncondensed portion was ·336. But if 100 weigh ·33600, then 91, the amount of uncondensed, must weigh ·30576, and this deducted from ·48500, leaves ·19924 for the condensed gas, which, as we have seen, is equal to 9·5 per cent., and bringing this to the uniform standard of 100 measures, we have 2·09 for the specific gravity of this condensed vapour; and if this specific gravity be multiplied by the amount of condensation, we shall have the true value of the gas in numbers, which, by a singular coincidence, run very close with the indications of the photometer as chosen by Mr. King, that is to say, the number of spermaceti candles burning 120 grains per hour, which the gas is equal to when consumed at the rate of 5 feet per hour. In this instance that number, it will be remembered, was 20, and 2·09, the specific gravity of the condensed gas, multiplied by 9·5, its per centage absorption by bromine, gives 20·855, a very close approximation. A vast number of experiments have been made, all of which are equally conclusive as to the value of these indicators.

Coals (*heating powers of*). An accurate, systematic, and intelligible report upon the calorific properties of coal has long been needed by the manufacturing and mercantile interests of this country. In addition to the vast importance of such an inquiry, it would be perhaps impossible to point out a subject on which less difference of opinion exists as to the extent and nature of the information wanted than the one before us. Science, properly speaking, has little or nothing to do with the question; the object in view is purely and exclusively practical, and is meant for the guidance of practical men and for practical purposes. Theory, above all things, should be carefully avoided in such investigations; and supremely indifferent about the assistance of any eminent chemist on such an occasion, we should, nevertheless, insist strongly upon the necessity of providing a good stoker. Mr. Hume, M. P., however, thought otherwise; and to him the country is indebted for the first report upon the coals destined for the steam navy. Of this report we will venture to say at once that a more garbled, more inaccurate, and less impartial job was never exhibited — nay, not even in the House of Commons. To begin at the beginning of this disgraceful affair, we will merely remark that Mr. Hume (whose honesty and integrity are beyond suspicion) directed the attention of the Lords of the Admiralty to a subject which, if these lords attended to anything but their salaries, must have occupied their attention years ago. Mr. Hume, after referring their

lordships to an American report, with experiments, on the evaporative value of coals, says: —

"They have decided by direct and practical tests the comparative usefulness of American and English coals, as well as the relative value of the former in their numerous varieties; and I submit to your lordships that a similar inquiry should be instituted into the comparative usefulness of English, Scotch, and Irish coals, with the view of ascertaining the best for the naval steamers of this country. I may be allowed to point out to your lordships that there is a public establishment in Craig's-court perfectly qualified to apply the requisite direct and positive tests to the coals without delay; and to that establishment may be added one chemist of eminence to assist in what is an object of great national importance."

Upon this the Admiralty applied to Sir H. de la Beche, who, after the usual preliminary remarks, observes: —

"As the funds of the Museum of Economic Geology are, unaided, inadequate to an investigation of this order, I would suggest that the Admiralty be requested to furnish aid to the amount of 600*l.* for the remainder of the year ending the 31st of March, 1846. With this aid I have little doubt that we should be enabled to accomplish much this year which may be of value, and have organized a system of inquiry alike effective, and, viewing its national importance, which can be carried out at comparatively small cost to the public."

We must content ourselves by guessing at the meaning of the last paragraph, and, as far as this can be done with safety, we may conclude that, in the opinion of Sir H. de la Beche, the funds of the Economic, plus 600*l.*, would answer the object in view, to wit, the obtaining a practical report upon the evaporative power of English, Scotch, and Irish coals. If anything else is meant, why is 600*l.* named? The question is very fairly put by Lord Lincoln, who, in reference to the establishment in Craig's-court, asks, in plain English, "What is the course you would recommend for making it effective for the purposes to which such an inquiry would be obviously directed?" Sir H. de la Beche in answer mentions 600*l.* in addition to the funds of the Museum of Economic Geology; yet something more appears to have been given by the following "memorandum": —

"The Admiralty having acceded to the recommendation made in the foregoing letter, and subsequently also supplied additional funds for the investigation, the latter was commenced as soon as the needful apparatus was erected and proper assistance procured, which could not be accomplished until March, 1846."

Now, what is the meaning of the additional funds supplied for the investigation? Were the funds of the Economic, plus 600*l.*, spent on apparatus alone? And was it to the mere erection of this apparatus that Sir H. de la Beche alluded when, in 1845, he wrote, "With this aid I have little doubt that we should be enabled to accomplish *much* this year," &c.?

There is a mystery about the very commencement of that business. Seldom do we find Government officials ready to comply with the prayer of a petition which has merely public utility to recommend it; but Mr. Hume has nothing to complain of on that score in the present instance, for in addition to the Craig's-court establishment he solicited but one chemist, when lo! the investigation falls into the hands of Dr. Lyon Playfair, Mr. Wilson, Mr. J. Arthur Phillips, Mr. Kingsbury, Mr. Wrightson, Mr. Galloway, Mr. Hoy, and William Hutchinson, all and each endowed with qualifications of a peculiar and important character bearing upon the investigation in hand, and tending of course to render the report superlatively correct, useful, impartial, &c. &c. There is an old axiom regarding broth made by a multiplicity of cooks, but perhaps it does not apply to parliamentary reports and chemists.

The mystery does not, however, end here. Mr. Hume had requested that the inquiry should be made upon English, Scotch, and Irish coals. Now, the following is the list of coals operated on: —

NAMES OF COALS EMPLOYED IN THE EXPERIMENTS.

WELSH —

Graigola,
Anthracite, Jones and Co.,
Old Castle Fiery Vein,
Ward's Fiery Vein,
Binea,
Llangenneck,
Pontrepoth,
Pontrefellin,
Duffryn,
Mynydd Newydd,
Three Quarter Rock Vein,
Cwm Frood Rock Vein,
Cwm Nanty Gros,
Resolven,
Pontypool,
Bedwas,
Ebbw Vale,
Porth Mawr,
Coleshill.

Scotch —

Dalkeith Jewel Seam,
Dalkeith Coronation Seam,
Wallsend Elgin,
Fordel Splint,
Grangemouth.

English —

Broomhill,
Lydney (Forest of Dean).

Irish —

Slievardagh Irish Anthracite.

From which it appears that the inquiry has been made almost exclusively upon Welsh coals, for, out of twenty-seven samples of coal examined,

19 were Welsh,
5 „ Scotch,
2 „ English,
1 was Irish.

One of two things is very plainly exhibited by this table: either Wales is, above all other places in the world, blessed with coals "suited to the steam navy," or a most unjust and uncalled-for selection has been made for private purposes. It is vain to talk of a next report; it will require years to complete another report, even if such another disgraceful exhibition of partiality was attempted; and meanwhile our steam navy must be supplied with the euphonious productions of Wales, to the exclusion of the vast coalfields of Newcastle. Of the two samples of English coal examined I am practically acquainted with but one, for of the Lydney coal I know nothing; as regards the Broomhill coal, however, I can safely assert that its only recommendation consists in its belonging to Earl Grey, for at Newcastle it is regarded as an unimportant second-rate coal, the very name of which has not yet found its way into the London market. It is far inferior for steam purposes to the whole of the undermentioned coals, many of which are, in fact, the best steam coals for sea-going vessels in the kingdom; —

Carr's Hartley,
Hasting's Hartley,
Hedley's Hartley,
Newcastle Hartley,
Percy North Hartley,
Richardson's Hartley,
West Hartley,
Bate's West Hartley,
Buddle's West Hartley,
Davidson's West Hartley,
Nelson's West Hartley.

Why these and many others have been passed over so unceremoniously to make room for the wholesale introduction of the Welsh coal remains to be explained; we will now, however, examine the report itself.

The first circumstance which attracts attention in this report is the appearance of certain very simple equations, which, although well enough adapted for a boy just commencing algebra, are singularly out of place here, since those who understand such things generally prefer to make their own equations; and those who do not are but little likely to benefit by such a display of learning.

A curious attempt is made at page 18. to prove that the evaporative value of a bituminous coal is expressed by the evaporative value of its coke: —

"It is easy," says the report, "from analysis to examine whether the duty performed by the coal is to be attributed to its fixed ingredients or coke, by estimating the work which the latter is capable of performing. This may be done by subtracting the ashes in the coal from its amount of coke, and estimating the remainder as carbon; this carbon multiplied by its heating power, 13268, and divided by 965·7, or the latent heat of steam, indicates the number of pounds of water which the coke by itself could evaporate without the aid of the combustible ingredients of the coal. These results are placed, in column 3. of Table 6. (see next page), in juxtaposition with the actual work done by the coal, and it will be seen that, notwithstanding several striking exceptions, which might have been expected, they on the whole show that the work capable of being performed by the coke alone is actually greater than that obtained by experiments with the original coal."

Now, if this table proves anything, it proves the very reverse of the position attempted to be established, unless theory is presumed to be equal to practice, which it certainly is not, or why the necessity of spending upwards of 600*l.* in practical experiments? But theory may justly be compared with theory, and then the table, so far from proving "that the evaporative value of a bituminous coal is expressed by the comparative value of its coke," clearly proves that the evaporative power of a bituminous coal is an immense deal greater than that of its coke; indeed almost double; and that the volatile ingredients of coal evolve in burning relatively a much greater proportion of heat than

the fixed constituents; this is, indeed, precisely what might have been expected from the well-known calorific power of hydrogen, which is three times greater than that

EXTRACT FROM TABLE 6., SHOWING THE ACTUAL DUTY AND THAT WHICH IS THEORETICALLY POSSIBLE OF THE COALS EXAMINED.

Name or Locality of Coal.	Actual Number of lbs. of Water converted into Steam by 1lb. of Coal. Practical.	Number of lbs. of Water converted into Steam by the Coke left by the Coal. Theoretical.	Total Number of lbs. of Water convertible into Steam by 1lb. of the Coal. Theoretical.	Amount of Ammonia corresponding to the Nitrogen contained in the Coal.	Amount of Sulphate of Ammonia corresponding to the Nitrogen contained in the Coal.
Graigola	9·35	11·301	13·563	0·497	1·932
Anthracite, Jones and Co.	9·46	12·554	14·593	0·225	0·990
Old Castle Fiery Vein	8·94	10·601	14·936	1·590	6·175
Ward's Fiery Vein	9·40	—	14·614	1·238	4·808
Binea	9·94	11·560	15·093	1·586	6·741

of carbon. There is, however, clearly a design throughout this report to extol the anthracitic coals at the expense of the bituminous; and, if Messrs. de la Beche and Co. could succeed in establishing the fact that the heating power of coal is due solely or even principally to its relative amount of carbon, it follows that Welsh coal must rise in the market, for the greater part of the coal from that district is of the anthracite kind, none of which is worked in the north of England. To prove the absurdity, however, of the above attempt, I will quote two or three cases from Table No. 6.:—

Name of the Coal.	Theoretical Weight of Water evaporated by Coke.	by Coal.	Excess due to Volatile Ingredients.

After theoretically demonstrating that "the evaporative value of a bituminous coal is expressed by the evaporative value of its coke, the heat of combustion of its volatile products proving in practice little more than that necessary to volatilize them," we are suddenly greeted with the following paragraph:—

"The whole system of manufacturing coke is at present very imperfect. Besides losing the volatile combustible substances, which, under new adjustments, might be made of much value, an immense quantity of ammonia is lost by being thrown into the atmosphere. Ammonia and its salts are daily becoming more valuable to agriculture, and it is their comparative high price alone which prevents their universal use to all kinds of cereal cultivations. By a construction of the most simple kind the coke-ovens now in use might be made to economize much of the nitrogen, which invariably escapes in the form of ammonia. As an inducement to this economy, we have ap-

pended to Table 6. two columns showing the quantity of ammonia and its corresponding quantity of commercial sulphate which each 100 lbs. of the respective coals may be made to produce. When it is remembered that the price of sulphate of ammonia is about 13*l.* per ton, or that 100 tons (of coal, we suppose) in coking is (are?) capable of producing on an average about six tons of this salt, its neglect is highly reprehensible."

Nothing has tended half so much to retard the cultivation of chemistry by our practical manufacturers as the kind of statements of which the above is a sample. Written by individuals wholly ignorant of the subject of which they treat, these assertions serve only to amuse practical men, and to demonstrate the stupendous folly and assurance of their authors. Imperfection is an attribute of humanity, but that the present system of making coke is very imperfect remains to be proved.

The volatile combustible matter of the coal is not lost; on the contrary, it is employed as a means of converting the cinder of the coal into coke, and that, too, by the heat which it evolves in burning; and, if that heat was so inconsiderable as the report would lead us to suppose, mere cinder alone would remain in the coke-oven, even after the heat had been kept up for ninety-six hours. Perhaps the framers of the report may want to know the distinction between cinders and coke. Coke, if good, sinks in water; bad coke or cinder swims. The reason of this is very simple. The longer and higher the heat to which carbon from wood or coal is exposed the more it contracts, and consequently the denser it becomes. The volatile combustible matter of the coal is employed, then, in producing the requisite temperature for coking, and the oven is so contrived as to retain the heat a sufficient time to produce the necessary aggregation of the particles of carbon, or, in plain words, the condensation of the coke: to assert that this volatile combustible matter is lost is perfectly ridiculous. We are next informed that "an immense quantity of ammonia is lost by being thrown into the atmosphere," and that by "a construction of the most simple kind this loss might be avoided." Lord Dundonald, about fifty years ago, had the same idea, and tried it on a large scale; it is unnecessary to say that it proved to be a complete failure, although sulphate of ammonia was then worth four or five times its present price. But the most absurd part of this scientific soap-bubble is contained in the last sentence:—"100 tons in coking is capable of producing on an average about six tons of this salt" (sulphate of ammonia). Now, let us for a few minutes imagine my Lord Grey desirous (as we have no doubt he is) of making the most of his Broomhill coal. Passing his eye down column 1. of Table 6., he sees at a glance that 100 tons of coal will produce 8·674 tons of sulphate of ammonia, worth 13*l.* per ton. Making a little allowance for loss, he says to himself, "Well, call it 8½ tons; and now how much sulphuric acid is required?" We will suppose him practically acquainted with Dr. Wollaston's scale, and that, valuing common "chamber acid" at three farthings per cent., he has arrived at the following conclusion:—

	£	s.	d.
100 tons of coal, at 3*s.* 4*d.* per ton =	16	13	4
6½ tons of sulphuric acid, as above =	45	10	0
	62	3	4

will produce

	£	s.	d.
8½ tons of sulphate of ammonia, worth	110	10	0
and 70 tons of coke, at 8*s.* 6*d.* per ton	29	15	0
	140	5	0

A promising speculation truly, if his lordship could only economize "the nitrogen which *invariably* escapes in the form of ammonia." But, most unfortunately, the nitrogen does not "invariably escape in the form of ammonia," for in practice nine-tenths of it invariably escape in the form of nitrogen, as any experienced gas manufacturer can testify, and as the experiments quoted in the report abundantly prove, for according to Mr. F. C. Wrightson (a pupil of Liebig), who (*vide* Report, page 6.) had fitted "himself by special study for an undertaking requiring so much delicacy of manipulation,"—according, then, to Mr. Wrightson (page 58.), the Binea coal and the Langenneck coal gave by actual experiment in 100 parts 0·08 of ammonia, or ·310 of sulphate of ammonia. Now, if we compare this with Table 6. we shall find—

Binea coal } Langenneck }	might, could, would, or should produce	6·741 5·044	really did produce	0·310 0·310

or about $\frac{1}{20}$th of the quantity theoretically obtained by Sir H. De la Beche and Dr. Lyon

Playfair; yet these are the individuals who find fault with our manufacturers, and pretend to improve our processes. With quite as much practical utility might these gentlemen have detailed to us the quantity of pure diamond which the coals in question would produce, if we knew how; as the amount of ammonia which they might give off if they would. Of the analytical part of the report we will say little more than that it is in perfect keeping with the rest. In the first place, chloride of calcium is employed to remove water and ammonia from the gas, although a very little practical knowledge of gas purification would have taught the operator that, when water and ammonia are absorbed by chloride of calcium, carbonic acid is also taken up, so as to produce carbonate of lime and muriate of ammonia; and as this carbonic acid must have been regarded either as ammonia or water, it follows that the experimental results are valueless. The substance which ought to have been employed to absorb water and ammonia under the circumstances is the fused or glacial phosphoric acid; but what real value can we attach to experiments made upon less than half a grain of coal, in which the errors, and errors there are, have been multiplied at least 300,000 times? For example, at page 58., we find "Anthracite, from T. Aubrey and Co." The quantity of this coal taken for analysis was 0·2763 of a grain, or rather more than ¼ of a grain. Now, supposing it had even equalled ½ of a grain, then to bring this to a pound it must be multiplied 21,000 times, and to raise this last to the weight of water which 1 lb. of such coal could theoretically evaporate, as represented at column 4. of Table 6., this 21,000 must be multiplied by 14·593; therefore, if any error occurred in the analysis of this anthracite coal, it has been multiplied upwards of 306,453 times; in regard to the quantity of water which 1 lb. of such coal can evaporate, as exhibited in column 4. of Table 6. The idea, however, of weighing the $\frac{1}{10000}$th of a grain is perfectly new to us, who have always regarded even the $\frac{1}{1000}$th as something too nearly approaching the imponderable. These remarks apply equally to the experiments with litharge; no allowance is made, or notice taken of the error arising from the presence of iron pyrites in the coal, although this substance would reduce more than 9 times its weight of litharge, and the error thus produced has been multiplied upwards of 90,000 times in column 6. of Table 4.; and in the case of the anthracite coal above mentioned this error has been increased 104,507 times. Nor is the quantity of iron pyrites inconsiderable in many of these coals, for, according to Table 3., the following contain a portion of sulphur equivalent to bisulphuret of iron, as under: —

Slievardagh	12·67 per cwt.	of iron pyrites for which no allowance has been made in the litharge experiments.

Bedwas	6·56 „	
Cwm Nanty Gros	5·64 „	

To pretend to attach any value to such experiments, or to the conclusions drawn from them, is a mere fallacy, and, as the whole of the theoretical part is based upon these analyses, with them it must fall to the ground as erroneous and illusory. Under these circumstances it becomes necessary to inquire most carefully into the large and practical essays made for the purpose of determining the quantity of water evaporated during many successive hours by considerable quantities of each particular coal. With a few exceptions, each coal was burnt for eight hours, and the experiment repeated three times, the quantity of coal consumed and of water evaporated being noted in each instance, and an average drawn from the three results obtained by each coal. If carefully conducted, this method ought to have furnished some valuable information, but the discrepancies in respect to the three results obtained from some of the coals are so enormous and unaccountable as to render the whole table suspicious, doubtful, and therefore valueless; indeed, the differences observable between many of the different samples of coal are much less than the experimental differences given by one and the same coal, and which occasionally amount to little short of twenty per cent., as the following table will show [see p. 446.].

The idea of forming a table from experiments producing such discordant results is altogether preposterous, yet, turn in what direction we may, the same evidence of blundering and incapacity presents itself. In the first place, the selection of the coals was bad and unfair in the extreme, and no way calculated to answer the practical end in view; secondly, the proximate analyses are worthless, from the employment of chloride of calcium to a purpose for which it was not adapted; thirdly, the ultimate analyses are made in quantities too small to entitle them to any confidence when their results are raised to practical purposes; fourthly, the litharge experiments are erroneous; and fifthly, the practical essays by means of the Admiralty boiler are so completely at variance amongst themselves as to defy all arrangement or computation.

The entire report is, in fact, a disgrace to the age and country we live in, and carries with it all the internal evidence of a job.

As it is possible, however, that the Admiralty may really be serious in its desire to ascertain the true value of steam-coal, we will venture to throw out a few hints, in order

that that august body of well-paid functionaries may look before they leap into a subject so intimately connected with our national interests.

In working a seam of coal, experience has shown that the quality of the coal is not uniform, and that a coal may be improving or deteriorating as the workings are carried on, in one or another direction. From this it follows that any particular coal examined, say in 1846, is by no means to be regarded as possessing the same value in 1848, since this may have changed considerably, if the working of the coal has been carried on to any great extent; and it is the determination of this very fact which constitutes the real source of utility to be derived from a Government investigation. The proximate value of a coal is soon determined by actual experiment, from the amount of work done, and a market value is given in accordance with these rough results; but, when once that value has become fixed, there it remains for many years, whether the coal continues uniform or not, and it is only slowly and by degrees that the change becomes apparent. An establishment for determining matters of this kind is, therefore, much needed, but, to be useful, it must obviously be permanent. Again, as the transmission of heat from one body to another is proportional to the difference of temperature between the bodies themselves, it is clear that the water operated on should have one uniform temperature in all the experiments, and there are many reasons why this should be the boiling point. The quantity of water evaporated should not be inferred from the quantity which has escaped from a boiler during an experiment; independent of the possibility of leakage, much water is occasionally carried off mechanically by the steam, hence the origin of "priming." The most unobjectionable method would be to distil the water and afterwards measure it, the still-head being provided with a return-pipe, as is usual, for the fluid mechanically projected. The ordinary modes of favouring the transmission of heat from the furnace to the boiler, and of preventing its escape in any other direction than into the refrigeratory, should be had recourse to. A chemist is of no use for such investigations; if any chemical question should arise out of the experiments, it would be better to consult some one of established reputation. The stoker should be intelligent, and practically acquainted with the different modes of firing necessary for anthracitic, open-burning, and bituminous or caking coal; for whilst the first of these will take, nay requires, eighteen or twenty inches of fuel on the bars, the last will not bear more than four or six, without an enormous loss of heating-power. To this cause must be ascribed much of the discrepancy apparent in the experimental results obtained by the Admiralty boiler.—*Mr. Lewis Thompson, in "The Chemical Times" for December*, 1848.

COBALT. This metal being difficult to reduce from its ores, is therefore very little known, and has not hitherto been employed in its simple state in any of the arts; but its oxide has been extensively used on account of the rich blue colour which it imparts to glass, and the glazes of porcelain and stone-ware. The principal ores of cobalt are

those designated by mineralogists under the names of *arsenical cobalt* and *gray cobalt*. The first contains, in addition to cobalt, some arsenic, iron, nickel, and occasionally silver, &c. The other is a compound of cobalt with iron, arsenic, sulphur, and nickel. Among the gray cobalts, the ore most esteemed for its purity is that of Tunaberg in Sweden. It is often in regular crystals which possess the lustre and colour of polished steel. The specific gravity of cobalt pyrites is 6·36 to 4·66. The Tunaberg variety afforded to Klaproth, cobalt, 44; arsenic, 55·5; sulphur, 0·5; so that it is an arseniuret. Others, however, contain much sulphur as well as iron. It imparts at the blowpipe a blue colour to borax and other fluxes, and gives out arsenical fumes.

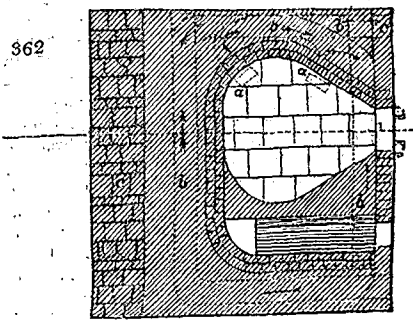
The ore being picked to separate its concomitant stony matters, is pounded fine and passed through a sieve; and is also occasionally washed. The powder is then spread on the sole of a reverberatory furnace, the flue of which leads into a long horizontal chimney. Here it is exposed to calcination for several hours, to expel the sulphur and arsenic that may be present; the former burning away in sulphurous acid gas, the latter being condensed into the white oxide or arsenious acid, whence chiefly the market is supplied with this article. This calcining process can never disengage the whole of these volatile ingredients, and there is therefore a point beyond which it is useless to push it; but the small quantities that remain are not injurious to the subsequent operations. The roasted ore is sifted anew; reduced to a very fine powder, and then mixed with 2 or 3 parts of very pure siliceous sand, to be converted into what is called *zaffre*. With this product glasses are generally coloured blue, as well as enamels and pottery glaze. In the works where cobalt ores are treated, a blue glass is prepared with the zaffre, which is well known under the name of smalt or azure blue. This azure is made by adding to the zaffre 2 or 3 parts of potash, according to its richness in cobalt, and melting the mixture in earthen crucibles. The fused mass is thrown out while hot into water; and is afterwards triturated and levigated in mills mounted for the purpose. There remains at the bottom of the earthen pot a metallic lump, which contains a little cobalt, much nickel, arsenic, iron, &c. This is called *speiss*.

As it is the *oxide* of cobalt which has the colouring quality, the calcination serves the purpose of oxidizement, as well as of expelling the foreign matters.

A finer cobalt-oxide is procured for painting upon hard porcelain, by boiling the cobalt ore in nitric acid, which converts the arsenic into an acid, and combines it with the different metals present in the mineral. These arseniates being unequally soluble in nitric acid, may be separated in succession by a cautious addition of carbonate of soda or potash; and the arseniate of cobalt, as the most soluble, remains unaffected. It has a rose colour; and is easily distinguishable, whence the precipitation may be stopped at the proper point. The above solution should be much diluted, and the alkali should be cautiously added with frequent agitation.

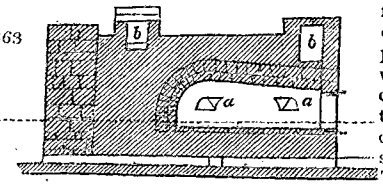
The cobalt ores, rich in nickel, are exposed to slow oxidizement in the air, whereby the iron, cobalt, arsenic, and sulphur get oxygenated by the atmospheric moisture, but the nickel continues in the metallic state. This action of the weather must not be extended beyond a year, otherwise the nickel becomes affected, and injures the cobalt blue. The ore hereby increases in weight, from 8 to 10 per cent. *Fig.* 362. is a longitudinal section of the furnace: *fig.* 363., a horizontal section upon a level with the sole of the hearth. It is constructed for wood fuel, and the hearth is composed of fire-bricks or tiles. The vapours and gases disengaged in the roasting, pass off through the flues *a a*, into the channels *b b*, and thence by *c* into the common vent, or poison chamber. See the representation of the poison tower of Altenberg, under the article Arsenic. The flues are cleared out by means of openings left at suitable situations in the brick-work of the chimneys.

362

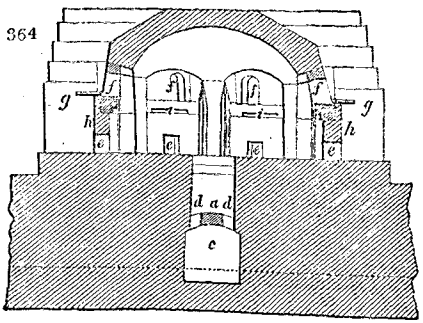


The azure manufacture is carried on chiefly in winter, in order that the external cold may favour the more complete condensation of the acids of arsenic. From 3 to 5 cwt. of Schlich (pasty ore) are roasted at one operation, and its bed is laid from 5 to 6 inches thick. After two hours, it must be turned over; and the stirring must be repeated every half hour, till no more arsenic is observed to exhale. The process being then finished, the ore must be raked out of the furnace, and another charge introduced.

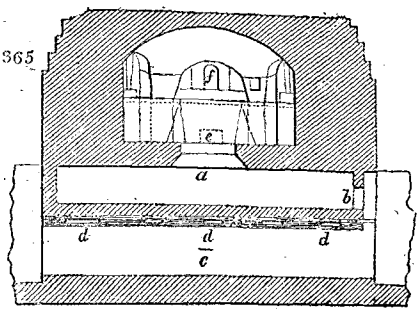
363



364



365



The duration of the roasting is regulated partly by the proportion of sulphur and arsenic present, and partly by the amount of nickel; which must not be suffered to become oxidized, lest it should spoil the colour of the smalt. The nickel ores should be but slighly roasted, so as to convert the nickel into *speiss*. The roasted ore must be sifted in a safety apparatus. The loss of weight in the roasting amounts, upon the average, to 36 per cent. The roasted ore has a brownish gray hue, and is called *safflor* in German, and is distributed into different sorts. F F S is the finest *safre*; F S, fine; O S, ordinary; and M S, middling. These varieties proceed from various mixtures of the calcined ores. The roasted ore is ground up along with sand, elutriated, and, when dry, is called *zaffre*. It is then mixed with a sufficient quantity of potash for converting the mixture into a glass.

Figs. 364. and 365. represent a round smalt furnace, in two vertical sections, at right angles to each other. The fire-place is vaulted or arched; the flame orifice *a*, is in the middle of the furnace; *b* is the feed hole; *c*, a tunnel which serves as an ash-pit, and to supply air; *d*, openings through which the air arrives at the fuel, the wood being placed upon the vault; *e*, knee holes for taking out the scoriæ from the pot bottoms; *f*, working orifices, with cast-iron plates *g*, in front of them. Under these are the additional outlets *h*. The smoke and flame pass off through the orifices *i*, which terminate in expanded flues, where the sand may be calcined or the wood may be baked. Eight hours are sufficient for one vitrifying operation, during which the glass is stirred about several times in the earthen melting pots.

The preparation of the different shades of blue glass are considered as secrets in the smelting works; and marked with the following letters: — F F F C, the finest; F C, fine; M C, middling; O C, ordinary. A melting furnace, containing 8 pots of glass, produces in 24 hours, from 24 cwts. of the mixture, 19 cwts. of blue glass; and from ½ to ¾ cwt. of scoriæ or speiss (*speise*). The composition *speise*, according to Berthier, is, — nickel, 49·0; arsenic, 37·8; sulphur, 7·8; copper, 1·6; cobalt, 3·2 in 100. Nickel, arsenic, and sulphur are its essential constituents; the rest are accidental, and often absent. The freer the cobalt ore is from foreign metals, the finer is the colour, and the deeper is the shade; paler tints are easily obtained by dilution with more glass. The presence of nickel gives a violet tone.

The production of smalt in the Prussian states amounted, in 1830, to 7452½ cwts.; and, in Saxony, to 9697 cwts.; in 1825, to 12,310 cwts.

One process for making fine smalt has been given under the title AZURE; I shall introduce another somewhat different here.

The ore of cobalt is to be reduced to very fine powder, and then roasted with much care. One part, by weight, is next to be introduced, in successive small portions, into an iron vessel, in which three parts of acid sulphate of potassa has been previously fused, at a moderate temperature. The mixture, at first fluid, soon becomes thick and firm, when the fire is to be increased, until the mass is in perfect fusion, and all white vapours have ceased. It is then to be taken out of the crucible with an iron

ladle, the crucible is to be recharged with acid sulphate of potash, and the operation continued as before, until the vessel is useless. The fused mass contains sulphate of cobalt, neutral sulphate of potassa, and arseniate of iron, with a little cobalt. It is to be pulverized, and boiled in an iron vessel, with water, as long as the powder continues rough to the touch. The white or yellowish white residue, may be allowed to separate from the solution, either by deposition or filtration. Carbonate of potassa, free from silica, is then to be added to the solution, and the carbonate of cobalt thrown down is to be separated and well washed, if possible, with warm water; the same water may be used to wash other portions of the fused mass. The filtered liquid which first passes is a saturated solution of sulphate of potassa: being evaporated to dryness in an iron vessel, it may be reconverted into acid sulphate by fusing it with one-half its weight of sulphuric acid: this salt is then as useful as at first.

The oxide of cobalt thus obtained contains no nickel; so little oxide of iron is present, that infusion of galls does not show its presence; it may contain a little copper, if that metal exists in the ore, but it is easily separated by the known methods. Sometimes sulphuretted hydrogen will produce a yellow brown precipitate in the solution of the fused mass; this, however, contains no arsenic, but is either sulphuret of antimony or bismuth, or a mixture of both.

It has been found advantageous to add to the fused mass, sulphate of iron, calcined to redness, and one-tenth of nitre when the residue is arseniate of iron, and contains no arseniate of cobalt. There is then no occasion to act upon the residue a second time for the cobalt in it.

This process is founded on the circumstances that the sulphate of cobalt is not decomposed by a red heat, and that the arseniates of iron and cobalt are insoluble in all neutral liquids. It is quite evident that to obtain a perfect result, the excess of acid in the bisulphate of potassa must be completely driven off by the red heat applied.

202,580 lbs. of smalts were imported into the United Kingdom in 1844, and 125,658 were retained for home consumption.

In 1844, 474,656 lbs. of zaffres were imported, and 481,936 are stated to have been retained for home consumption.

COCCULUS INDICUS, or Indian berry, is the fruit of the *Menispermum Cocculus*, a large tree, which grows upon the coasts of Malabar, Ceylon, &c. The fruit is blackish, and of the size of a large pea. It owes its narcotic and poisonous qualities to the vegeto-alkaline chemical principle called *picrotoxia*, of which it contains about one-fiftieth part of its weight. It is sometimes thrown into waters to intoxicate or kill fishes; and it is said to have been employed to increase the inebriating qualities of ale or beer. Its use for this purpose is prohibited by act of parliament, under a penalty of 200*l.* upon the brewer, and 500*l.* upon the seller of the drug.

COCHINEAL was taken in Europe at first for a seed, but was proved by the observations of Leeuwenhoeck to be an insect, being the female of that species of shield-louse, or *coccus*, discovered in Mexico so long ago as 1518. It is brought to us from Mexico, where the animal lives upon the *cactus opuntia* or *nopal*. Two sorts of cochineal are gathered—the wild, from the woods, called by the Spanish name *grana silvestra*; and the cultivated, or the *grana fina*, termed also *mesteque*, from the name of a Mexican province. The first is smaller, and covered with a cottony down, which increases its bulk with a matter useless in dyeing; it yields, therefore, in equal weight, much less colour, and is of inferior price to that of the fine cochineal. But these disadvantages are compensated in some measure to the growers by its being reared more easily and less expensively; partly by the effect of its down, which enables it better to resist rains and storms.

The wild cochineal, when it is bred upon the field nopal, loses in part the tenacity and quantity of its cotton, and acquires a size double of what it has on the wild opuntias. It may therefore be hoped, that it will be improved by persevering care in the rearing of it, when it will approach more and more to fine cochineal.

The fine cochineal, when well dried and well preserved, should have a gray colour, bordering on purple. The gray is owing to the powder, which naturally covers it, and of which a little adheres; so also to a waxy fat. The purple shade arises from the colour extracted by the water in which they were killed. It is wrinkled with parallel furrows across its back, which are intersected in the middle by a longitudinal one; hence, when viewed by a magnifier, or even a sharp naked eye, especially after being swollen by soaking for a little in water, it is easily distinguished from the factitious, smooth, glistening, black grains, of no value, called East India cochineal, with which it is often shamefully adulterated by certain London merchants. The genuine cochineal has the shape of an egg, bisected through its long axis, or of a tortoise, being rounded like a shield upon the back, flat upon the belly, and without wings.

These female insects are gathered off the leaves of the nopal plant, after it has ripened

its fruit, a few only being left for brood, and are killed, either by a momentary immersion in boiling water, by drying upon heated plates, or in ovens: the last become of an ash-gray colour, constituting the *silver* cochineal, or *jaspeada;* the second are blackish, called *negra*, and are most esteemed, being probably driest; the first are reddish brown, and reckoned inferior to the other two. The dry cochineal being sifted, the dust, with the imperfect insects and fragments which pass through, are sold under the name of *granillo.* Cochineal keeps for a long time in a dry place. Hellot says that he has tried some 130 years old, which produced the same effect as new cochineal.

We are indebted to MM. Pelletier and Caventou for a chemical investigation of cochineal, in which its colouring matter was skilfully eliminated.

Purified sulphuric ether acquired by digestion with it a golden-yellow colour, amounting according to Dr. John to one-tenth of the weight of the insect. This infusion left, on evaporation, a fatty wax of the same colour.

Cochineal, exhausted by ether, was treated with alcohol at 40° B. After 30 infusions in the digester of M. Chevreul, the cochineal continued to retain colour, although the alcohol had ceased to have any effect on it. The first alcoholic liquors were of a red verging on yellow. On cooling, they let fall a granular matter. By spontaneous evaporation, this matter, of a fine red colour, separated, assuming more of the crystalline appearance. These species of crystals dissolved entirely in water, which they tinged of a yellowish-red.

This matter has a very brillant purple-red colour; it adheres strongly to the sides of the vessels; it has a granular and somewhat crystalline aspect, very different, however, from those compound crystals alluded to above; it is not altered by the air, nor does it sensibly attract moisture. Exposed to the action of heat, it melts at about the fiftieth degree Centigrade (122° Fahr.). At a higher temperature it swells up, and is decomposed with the production of carburetted hydrogen, much oil, and a small quantity of water, very slightly acidulous. No trace of ammonia was found in these products.

The colouring principle of cochineal is very soluble in water. By evaporation, the liquid assumes the appearance of syrup, but never yields crystals. It requires of this matter a portion almost imponderable to give a perceptible tinge of bright purplish red to a large body of water. Alcohol dissolves this colouring substance, but, as we have already stated, the more highly it is rectified the less of it does it dissolve. Sulphuric ether does not dissolve the colouring principle of cochineal; but weak acids do, possibly owing to their water of dilution. No acid precipitates it in its pure state. This colouring principle, however, appears to be precipitable by all the acids, when it is accompanied by the animal matter of the cochineal.

The affinity of alumina for the colouring matter is very remarkable. When that earth, newly precipitated, is put into a watery solution of the colouring principle, this is immediately seized by the alumina. The water becomes colourless, and a fine red lake is obtained, if we operate at the temperature of the atmosphere; but if the liquor has been hot, the colour passes to crimson, and the shade becomes more and more violet, according to the elevation of the temperature, and the continuance of the ebullition.

The salts of tin exercise upon the colouring matter of cochineal a remarkable action. The muriatic protoxide of tin forms a very abundant violet precipitate in the liquid. This precipitate verges on crimson, if the salt contains an excess of acid. The muriatic deutoxide of tin produces no precipitate, but changes the colour to scarlet-red. If gelatinous alumina be now added, we obtain a fine red precipitate, which does not pass to crimson by boiling.

To this colouring principle the name *carminium* has been given, because it forms the basis of the pigment called carmine.

The process followed in Germany for making carmine, which consists in pouring a certain quantity of solution of alum into a decoction of cochineal, is the most simple of all, and affords an explanation of the formation of carmine, which is merely the carminium and the animal matter precipitated by the excess of acid in the salt, which has taken down with it a small quantity of alumina; though it appears that alumina ought not to be regarded as essential to the formation of carmine. In fact, by another process called by the name of Madame Cenette of Amsterdam, the carmine is thrown down, by pouring into the decoction of cochineal a certain quantity of the binoxalate of potash. When carbonate of soda is added, then carminated lake also falls down. That carmine is a triple compound of animal matter, carminium, and an acid appears from the circumstance, that liquors which have afforded their carmine, when a somewhat strong acid is poured into them, yield a new formation of carmine by the precipitation of the last portions of the animal matter. But whenever the whole animal matter is thrown down, the decoctions, although still much charged with the colouring principle, can afford no more carmine. Such decoctions may be usefully employed to make carminated lakes, saturating the acid with a slight excess of alkali and adding gelatinous alumina. The precipitates obtained, on adding acid to the alkaline decoctions of

cochineal, are therefore true carmines, since they do not contain alumina; but the small quantity of alumina which is thrown down by alum in the manufacture of carmine, augments its bulk and weight. It gives, besides, a greater lustre to the colour, even though diluting and weakening it a little.

The carmines found in the shops of Paris were analyzed, and yielded the same products. They are decomposed by the action of heat, with the diffusion at first of a very strong smell of burning animal matter, and then of sulphur. A white powder remained, amounting to about one-tenth of the matter employed, and which was found to be alumina. Other quantities of carmine were treated with a solution of caustic potash, which completely dissolved them, with the exception of a beautiful red powder, not acted on by potash and concentrated acid, and which was recognized to be red sulphuret of mercury or vermilion. This matter, evidently foreign to the carmine, appears to have been added, in order to increase its weight.

The preceding observations and experiments seem calculated to throw some light on the art of dyeing scarlet and crimson. The former is effected by employing a cochineal bath, to which there have been added, in determinate proportions, acidulous tartrate of potash, and nitro-muriatic deutoxide of tin. The effect of these two salts is now well known. The former, in consequence of its excess of acid, tends to redden the colour, and to precipitate it along with the animal matter; the latter acts in the same manner, at first by its excess of acid, then by the oxide of tin which falls down also with the carmine and animal matter, and is fixed on the wool, with which it has of itself a strong tendency to combine. *MM.* Pelletier and Caventou remark, that "to obtain a beautiful shade, the muriate of tin ought to be entirely at the maximum of oxidizement; and it is in reality in this state that it must exist in the solution of tin prepared according to the proportions prescribed in M. Berthollet's treatise on dyeing."

We hence see why, in dyeing scarlet, the employment of alum is carefully avoided, as this salt tends to convert the shade to a crimson. The presence of an alkali would seem less to be feared. The alkali would occasion, no doubt, a crimson-coloured bath; but it would be easy in this case to restore the colour, by using a large quantity of tartar. We should, therefore, procure the advantage of having a bath better charged with colouring matter and animal substance. It is for experience on the large scale to determine this point. As to the earthy salts, they must be carefully avoided; and if the waters be selenitish, it would be a reason for adding a little alkali.

To obtain crimson, it is sufficient, as we know, to add alum to the cochineal bath, or to boil the scarlet cloth in alum water. It is also proper to diminish the dose of the salt of tin, since it is found to counteract the action of the alum.

The alkalis ought to be rejected as a means of changing scarlet to crimson. In fact, crimsons by this process cannot be permanent colours, as they pass into red by the action of acids.

According to M. Von Grotthuss, carmine may be deprived of its golden shade by ammonia, and subsequent treatment with acetic acid and alcohol. Since this fact was made known, M. Herschel, colour maker at Halle, has prepared a most beautiful carmine.

The officers of Her Majesty's Customs detected some time since a system of adulterating cochineal, which had been practised for many years upon a prodigious scale by a mercantile house in London. I have analyzed about 100 samples of such cochineal, from which it appears that the genuine article is moistened with gum-water, agitated in a box or leather bag, first, with sulphate of baryta in fine powder, afterwards with bone or ivory black, to give it the appearance of *negra* cochineal, and then dried. By this means about 12 per cent. of worthless heavy spar is sold at the price of cochineal, to the enrichment of the sophisticators, and the disgrace and injury of British trade and manufactures.

The specific gravity of genuine cochineal is 1·25; that of the cochineal loaded with the barytic sulphate, 1·35. This was taken in oil of turpentine and reduced to water as unity, because the waxy fat of the insects prevents the intimate contact of the latter liquid with them, and the ready expulsion of air from their wrinkled surface. They are not at all acted upon by the oil, but are rapidly altered by water, especially when they have been gummed and barytified.

Humboldt states that so long ago as the year 1736, there was imported into Europe from South America cochineal to the value of 15 millions of francs. Its high price had for a long time induced dyers to look out for cheaper substitutes in dyeing red, and since science has introduced so many improvements in tinctorial processes, both madder and lac have been made to supersede cochineal to a very great extent. Its price has, in

consequence of this substitution, as well as from more successful modes of cultivation, fallen very greatly of late years. In January, 1852, the prices of Honduras cochineal ranged from 2*s.* 9*d.* to 5*s.* per lb., and Mexican from 2*s.* 7*d.* to 3*s.* 4*d.* per lb.

COCOA, STEARINE, AND ELAINE. Mr. Soames obtained a patent in September 1829, for making these useful articles, by the following process:

He takes the substance called cocoa-nut oil, in the state of lard, in which it is imported into this country, and submits it to a strong hydraulic pressure, having made it up in small packages, 3 or 4 inches wide, 2 feet long, and 1 or 1½ inches thick. These packages are formed by first wrapping up the said substance in a strong linen cloth, of close texture, and then in an outward wrapper of strong sail cloth. The packages are to be placed side by side, in single rows, between the plates of the press, allowing a small space between the packages for the escape of the *elaine*.

The temperature at which the pressure is begun, should be from about 50 to 55 degrees, or in summer as nearly at this pitch as can be obtained, and the packages of the said substance intended for pressure should be exposed for several hours previously to about the same temperature. When the packages will no longer yield their oil or elaine freely at this temperature, it is to be gradually raised; but it must at no time exceed 65 degrees, and the lower the temperature at which the separation can be effected, the better will be the quality of the oil expressed.

When the packages are sufficiently pressed, that is, when they will give out no more oil, or yield it only in drops at long intervals, the residuum in them is to be taken out and cleansed and purified, which is done by melting it in a well-tinned copper vessel, which is fixed in an outer vessel, having a vacant space between, closed at the top, into which steam is admitted, and the heat is kept up moderately for a sufficient time to allow the impurities to subside; but if a still higher degree of purity is required, it is necessary to pass it through filters of thick flannel lined with blotting paper.

Having been thus cleansed or purified, it is fit for the manufacture of candles, which are made by the ordinary process used in making mould tallow candles. Having thus disposed of the stearine, or what is called the first product, he proceeds with the elaine or oil expressed from it, and which he calls the second product, as follows: that is to say, he purifies it by an admixture, according to the degree of its apparent foulness, of from 1 to 2 per cent. by weight of the sulphuric acid of commerce, of about 1·80 specific gravity, diluted with six times its weight of water. The whole is then to be violently agitated by mechanical means, and he prefers for this purpose the use of a vessel constructed on the principle of a common barrel churn. When sufficiently agitated, it will have a dirty whitish appearance, and is then to be drawn off into another vessel, in which it is to be allowed to settle, and any scum that rises is to be carefully taken off. In a day or two the impurities will be deposited at the bottom of the oil, which will then become clear, or nearly so, and it is to be filtered through a thick woollen cloth, after which it will be fit for burning in ordinary lamps and for other uses.

The process of separating the elaine from the stearine, by pressure, in manner aforesaid, had never before been applied to the substance called cocoa-nut oil, and consequently no product had heretofore been obtained thereby from that substance fit for being manufactured into candles in the ordinary way, or for being refined by any of the usual modes, so as to burn in ordinary lamps, both which objects are attained by this method of preparing or manufacturing the said substance.

Candles well made from the above material are a very superior article. The light produced is more brilliant than from the same sized candle made of tallow; the flame is perfectly colourless, and the wick remains free from cinder, or any degree of foulness during combustion. COCOA BEANS; see CHOCOLATE.

COFFEE. The coffee is the seed of a tree of the family *rubiaceæ*, and belongs to the Pentandria monogynia of Linnæus. There are several species of the genus, but the only one cultivated is the *Coffæa Arabica*, a native of Upper Ethiopia and Arabia Felix. It rises to the height of 15 or 20 feet; its trunk sends forth opposite branches in pairs above and at right angles to each other; the leaves resemble those of the common laurel, although not so dry and thick. From the angle of the leaf-stalks small groups of white flowers issue, which are like those of the Spanish jasmine. These flowers fade very soon, and are replaced by a kind of fruit not unlike a cherry, which contains a yellow glairy fluid, enveloping two small seeds or berries convex upon one side, flat and furrowed upon the other in the direction of the long axis. These seeds are of a horny or cartilaginous nature; they are glued together, each being surrounded with a peculiar coriaceous membrane. They constitute the coffee of commerce.

It was not till towards the end of the 15th century that the coffee tree began to be cultivated in Arabia. Historians usually ascribe the discovery of the use of coffee as a beverage to the superior of a monastery there, who, desirous of preventing the monks from sleeping at their nocturnal services, made them drink the infusion of coffee upon the report of shepherds, who pretended that their flocks were more lively after browsing on the fruit of that plant. The use of coffee was soon rapidly spread, but it encountered much

opposition on the part of the Turkish government, and became the occasion of public assemblies. Under the reign of Amurath III. the mufti procured a law to shut all the coffee-houses, and this act of suppression was renewed under the minority of Mahomet IV. It was not till 1554, under Solyman the Great, that the drinking of coffee was accredited in Constantinople; and a century elapsed before it was known in London and Paris. Solyman Aga introduced its use into the latter city in 1669, and in 1672 an Armenian established the first *café* at the fair of Saint Germain.

When coffee became somewhat of a necessary of life from the influence of habit among the people, all the European powers who had colonies between the tropics, projected to form plantations of coffee trees in them. The Dutch were the first who transported the coffee plant from Moka to Batavia, and from Batavia to Amsterdam. In 1714 the magistrates of that city sent a root to Louis XIV. which he caused to be planted in the Jardin du Roi. This became the parent stock of all the French coffee plantations in Martinique.

The most extensive culture of coffee is still in Arabia Felix, and principally in the kingdom of Yemen, towards the cantons of Aden and Moka. Although these countries are very hot in the plains, they possess mountains where the air is mild. The coffee is generally grown half-way up on their slopes. When cultivated on the lower grounds it is always surrounded by large trees which shelter it from the torrid sun, and prevent its fruit from withering before their maturity. The harvest is gathered at three periods: the most considerable occurs in May, when the reapers begin by spreading cloths under the trees, then shaking the branches strongly, so as to make the fruit drop, which they collect, and expose upon mats to dry. They then pass over the dried berries a very heavy roller, to break the envelopes, which are afterwards winnowed away with a fan. The interior bean is again dried before being laid up in store.

In Demerara, Berbice, and some of our West India islands, where much good coffee is now raised, a different mode of treating the pulpy fruit and curing the beans is adopted. When the cherry-looking berry has assumed a deep-red colour it is gathered, and immediately subjected to the operations of a mill composed of two wooden rollers, furnished with iron plates, which revolve near a third fixed roller called the *chops*. The berries are fed into a hopper above the rollers, and falling down between them and the chops, they are stripped of their outer skins and pulp, while the twin beans are separated from each other. These beans then fall upon a sieve, which allows the skin and the pulp to pass through, while the hard beans accumulate and are progressively slid over the edge into baskets. They are next steeped for a night in water, thoroughly washed in the morning, and afterwards dried in the sun. They are now ready for the peeling mill, a wooden edge wheel turned vertically by a horse yoked to the extremity of its horizontal axis. In travelling over the coffee, it bursts and detaches the coriaceous or parchment-like skin which surrounds each hemispherical bean. It is then freed from the membranes by a winnowing machine, in which four pieces of tin made fast to an axle are caused to revolve with great velocity. Corn fanners would answer better than this rude instrument of negro invention. The coffee is finally spread upon mats or tables, picked clean, and packed up for shipment.

The most highly esteemed coffee is that of Moka. It has a smaller and a rounder bean; a more agreeable taste and smell than any other. Its colour is yellow. Next to it in European reputation is the Martinique and Bourbon coffees; the former is larger than the Arabian and more oblong; it is rounded at the ends; its colour is greenish, and it preserves almost always a silver gray pellicle, which comes off in the roasting.

The Bourbon coffee approaches nearest to the Moka, from which it originally sprung. The Saint Domingo coffee has its two extremities pointed, and is much less esteemed than the preceding.

The coffee tree flourishes in hilly districts where its root can be kept dry, while its leaves are refreshed with frequent showers. Rocky ground, with rich decomposed mould in the fissures, agrees best with it. Though it would grow, as we have said, to the height of 15 or 20 feet, yet it is usually kept down by pruning to that of 5 feet for increasing the production of the fruit, as well as for the convenience of cropping. It begins to yield fruit the third year, but is not in full bearing till the fifth, does not thrive beyond the twenty-fifth, and is useless in general at the thirtieth. In the coffee husbandry, the plants should be placed 8 feet apart, as the trees throw out extensive horizontal branches, and in holes 10 or 12 feet deep to secure a constant supply of moisture.

Coffee has been analyzed by a great many chemists, with considerable diversity of results. The best analysis perhaps is that of Schrader. He found that the raw beans distilled with water in a retort communicated to it their flavour and rendered it turbid, whence they seem to contain some volatile oil. On reboiling the beans, filtering, and evaporating the liquor to a syrup, adding a little alcohol till no more matter was precipitated, and then evaporating to dryness, he obtained 17·58 per cent. of a yellowish-

brown transparent extract, which constitutes the characteristic part of coffee, though it is not in that state the pure proximate principle, called *caffeine*. Its most remarkable reaction is its producing, with both the protoxide and the peroxide salts of iron, a fine grass green colour, while a dark green precipitate falls, which re-dissolves when an acid is poured into the liquor. It produces on the solution of the salts of copper scarcely any effect, till an alkali be added, when a very beautiful green colour is produced which may be employed in painting. Coffee beans contain also a resin, and a fatty substance somewhat like suet. According to Robiquet, ether extracts from coffee beans nearly 10 per cent. of resin and fat, but he probably exaggerates the amount. The peculiar substance caffeine contained in the above extract is crystallizable. It is remarkable in regard to composition, that after urea and the uric acid, it is among organic products the richest in azote. It was dissolved and described in 1820 by Runge. It does not possess alkaline properties. Pfaff obtained only 90 grains of caffeine from six pounds of coffee beans. There is also an acid in raw coffee to which the name of *caffeic acid* has been given. When distilled to dryness and decomposed, it has the smell of roasted coffee.

Coffee undergoes important changes in the process of roasting. When it is roasted to a yellowish-brown it loses, according to Cadet, 12½ per cent. of its weight, and is in this state difficult to grind. When roasted to a chestnut brown it loses 18 per cent., and when it becomes entirely black, though not at all carbonized, it has lost 23 per cent. Schrader has analyzed roasted coffee comparatively with raw coffee, and he found in the first 12½ per cent. of an extract of coffee, soluble in water and alcohol, which possesses nearly the properties of the extract of the raw coffee, although it has a deeper brown colour, and softens more readily in the air. He found also 10·4 of a blackish brown gum; 5·7 of an oxygenated extract or rather *apothème* soluble in alcohol, insoluble in water; 2 of a fatty substance and resin; 69 of burnt vegetable fibre, insoluble. On distilling roasted coffee with water, Schrader obtained a product which contained the aromatic principle of coffee; it reddened litmus paper, and exhaled a strong and agreeable odour of roasted coffee. If we roast coffee in a retort, the first portions of the aromatic principle of coffee condense into a yellow liquid in the receiver; and these may be added to the coffee roasted in the common way, from which this matter has been expelled and dissipated in the air.

Chenevix affirmed that by the roasting of coffee a certain quantity of tannin possessing the property of precipitating gelatine is generated. Cadet made the same observation, and found, moreover, that the tannin was most abundant in the lightly roasted coffee, and that there was nearly none of it in coffee highly roasted. Payssé and Schrader, on the contrary, state that solution of gelatine does not precipitate either the decoction of roasted coffee or the alcoholic extract of this coffee. Runge likewise asserts that he could obtain no precipitate with gelatine; but he says that albumen precipitates from the decoction of roasted coffee the same kind of tannin as is precipitated from raw coffee by the acetate of lead, and set free from the lead by sulphuretted hydrogen. With these results my own experiments agree. Gelatine certainly does not disturb clear infusion of roasted coffee, but the salts of iron blacken it.

Schrader endeavoured to roast separately the different principles of coffee, but none of them exhaled the aromatic odour of roasted coffee except the horny fibrous matter. He therefore concludes that this substance contributes mainly to the characteristic taste of roasted coffee, which cannot be imitated by any other vegetable matter, and which, as we have seen, should be ascribed chiefly to the altered caffeic acid. According to Garot, we may extract the caffeine without alteration from roasted coffee by precipitating its decoction by subacetate of lead, treating the washed precipitate with sulphuretted hydrogen, and evaporating the liquid product to dryness.

Of late years, much ingenuity has been expended in contriving various forms of apparatus for making infusions of coffee for the table. I have tried most of them, and find, after all, none so good as a *cafetière à la Belloy*, the coffee *biggin*, with the perforated tin plate strainer, especially when the filtered liquor is kept simmering in a close vessel, set over a lamp or steam pan. The useful and agreeable matter in coffee is very soluble: it comes off with the first waters of infusion, and needs *no boiling*.

To roast coffee rightly we should keep in view the proper objects of this process, which are to develop its aroma, and destroy its toughness, so that it may be readily ground to powder. Too much heat destroys those principles which we should wish to preserve, and substitutes new ones which have nothing in common with the first, but add a disagreeable empyreumatic taste and smell. If, on the other hand, the rawness or greenness is not removed by an adequate heat, it masks the flavour of the bean, and injures the beverage made with it. When well roasted in the sheet iron cylinder set to revolve over a fire, it should have a uniform chocolate colour, a point readily hit by experienced roasters, who now manage the business very well for the principal coffee dealers both of London and Paris, so far as my judgment can determine. The de-

velopment of the proper aroma is a criterion by which coffee roasters frequently regulate their operations. When it loses more than 20 per cent. of its weight, coffee is sure to be injured. It should never be ground till immediately before infusion.

Liebig's views of the process of nutrition have given fresh interest to every analysis of articles of food. A watery infusion of coffee is used in almost every country as a beverage, and yet it is uncertain whether it is an article of nutrition or merely a condiment. A minute examination of the raw seed, or coffee bean as it is called, must precede the determination of that disputed point. Caffeine is the principle best known, being most easily separated from the other substances, resisting most powerfully chemical reagents, and by assuming a crystalline state is discoverable in very small quantities.

The constituents of coffee are: 1. *Vegetable fibrine*, which is the largest constituent, being an elastic horny substance, in which the other substances are incorporated. If we dry the beans at the heat of boiling water for several weeks we can easily reduce them to a fine powder, and by washing with ether, and then boiling in alcohol and water, we extract the soluble matter from the fibrine, which may then be boiled with weak solution of potash, and afterwards weak muriatic acid, as long as any matter is taken up. The purification being completed by boiling in water the fibrine remains; and when rubbed in a mortar resembles starch; when roasted it gives out the odour nearly of wood.

2. *Fatty matter:* the beans digested in ether give out a yellow-coloured matter, which on evaporation becomes buttery with an odour of raw coffee, and amounts to 10% of the beans.

3. *Caffeine:* the ethereal solution contains caffeine, which may be removed by shaking with a solution of water.

4. *Legumine:* in addition to an *acid* which agrees in its properties with the acid found in oak and cinchona, we find in the coffee beans legumine similar to that of beans. This legumine contains sulphur, which is the cause of their blackening a silver vessel in which the beans may be boiled with an alkali. Legumine and caffeine are the only nitrogenous constituents of coffee beans, consequently the only substances which could be nutritious, but they are not soluble in hot water as they exist in roasted coffee, and therefore it may be reckoned merely an exhilarating beverage.

Roasted coffee affords a much richer infusion to hot water containing a minute quantity of carbonate of soda, and improves the quality of the coffee on the stomach, by neutralizing the caffeic acids.

Coffee as sold in the shops in its roasted and ground state is often adulterated with a variety of substances, but chiefly with chicory. This is the dried, roasted, and ground root of a plant called *Cichorium Intybus*, better known under the name of wild succory. The chicory imported from Belgium and Prussia is better than the British, which is usually coloured with Venetian red, and is sold at a cheaper rate; chicory itself is frequently very impure, containing roasted peas and coffee flights, which are the membranous coat of the bean separated in the act of roasting. If a little genuine ground coffee be thrown in a wine glassfull of water, it mostly floats, and slowly moistens, communicating scarcely any colour to the liquid. Powdered chicory treated in the same way very speedily absorbs moisture, communicates a deep reddish brown tint to the water, and in a few minutes falls to the bottom. Hambro' powder contains roasted starch, and acquires a deep purplish colour when moistened with a solution of iodine. The microscope shows in the chicory powder fragments of dotted ducts which do not exist in coffee. There is another substance which is mixed with coffee, called refining powder; it is merely caramel or burnt sugar. It is used for enabling drained coffee to afford a dark coloured infusion.

If tannin exists in roasted coffee, as maintained long ago by Chenevix, and generally admitted since, it must be very different from the tannin present in tea, catechu, kino, oak-bark, willow-bark, and other astringent vegetables; for I find that it is not, like them, precipitated by either gelatine, albumen, or sulphate of quinine. With regard to the action upon the animal economy of coffee, tea, and cocoa, which contain one common chemical principle called caffeine or theine, Liebig has lately advanced some ingenious views, and has, in particular, endeavoured to show that, to persons of sedentary habits in the present refined state of society, they afford eminently useful beverages, which contribute to the formation of the characteristic principle of *bile*. This important secreted fluid, deemed by Liebig to be subservient to the function of respiration, requires for its formation much azotised matter, and *that* in a state of combination analogous to what exists in caffeine. The quantity of this principle in tea and coffee being only from 2 to 5 per cent., might lead one to suppose that it could have little effect upon the system even of regular drinkers of their infusions; but if the bile contains only one-tenth of solid matter, called choleic acid, which contains less than 4 per cent. of azote, then it may be shown that 3 grains of caffeine would impart to 500 grains of

bile the azote which occurs in that crystalline precipitate of bile called *taurine*, which is thrown down from it by mineral acids.

One atom of caffeine, 9 atoms of oxygen, and 9 of water, being added together, produce the composition of 2 atoms of taurine. Now this is a very simple combination for the living organism to effect; one already paralleled in the generation of hippuric acid in urine, by the introduction of benzoic acid into the stomach; a physiological discovery made by my son, which is likely to lead to a more successful treatment of some of the most formidable diseases of man, particularly gout and gravel.

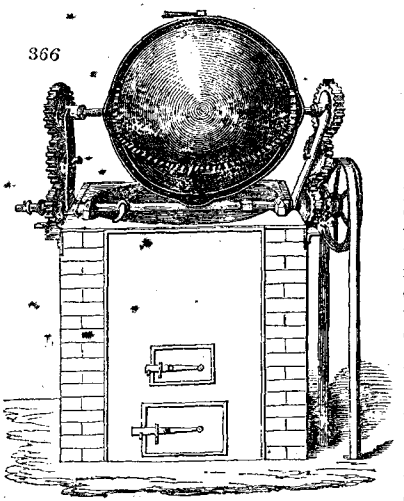
If the preceding views be established, they will justify the instinctive love of mankind for tea, coffee, and cocoa, in spite of the denunciations and vetos of *neuropathic, homœopathic* and *hydropathic* doctors; sorry pathologists—*hoc genus omne*. See TEA.

In the years ending 5th January 1851 and 1852 the imports of coffee were as follows:—

	Importations.		Entries for Home Consumption.		Gross Amount of Duty.	
	1851.	1852.	1851.	1852.	1851.	1852.
Entered before 15th April 1851:	*lbs.*	*lbs.*	*lbs.*	*lbs.*	*lbs.*	*lbs.*
Of British Possessions	36,814,036	1,818,514	28,891,294	6,510,346	505,515	113,931
Foreign	13,989,116	5,018,806	2,335,546	443,418	61,305	11,637
Entered from 15th April 1851:						
From British Possessions out of Europe	- -	34,077,563	- -	21,486,170	- -	268,599
From other Parts	- -	12,035,269	- -	4,124,230	- -	51,572
Total	50,803,152	52,950,152	31,226,840	32,564,164	566,820	445,739

The duty is 3*d.* per lb. The exports in the above years were respectively 12,169,752 lbs. and 22,712,859 lbs., of which 3,399,333 lbs. and 12,606,333 lbs. were the produce of British Possessions, and 8,770,419 lbs. and 10,106,526 lbs. were Foreign.

COFFEE ROASTING AND GRINDING. The gratefulness of the beverage afforded by this seed depends upon many circumstances, which are seldom all combined. The nature of the soil, the climate, seed, mode of culture, and cure, influence greatly the quality of the fruit. But when all these particulars concur, and the berry is of the finest sort, and most highly appreciated by the importer, it may be ruined in the roasting; for if some berries be under and some over done, the whole when ground will yield an unpalatable infusion. The due point to which the torrefaction should be carried, may be determined partly by the colour and partly by the loss of weight, which points, however, are different for each sort of coffee. But perfect equality of ustulation is difficult of attainment with the ordinary cylindrical machines. Messrs. Law, of London and Edinburgh, coffee merchants to the Queen, had long been dissatisfied with the partial manner in which the cylinder performed its duty, as it generally left some part of its contents black, some dark brown, and others paler; results which greatly injure the flavour of the beverage made with the coffee. Mr. William Law has conquered all these difficulties by his happy invention of the globular roaster, actuated by a compound motion like that of our earth. This roaster, with its double rotary motion, is heated not over an open fire but in an atmosphere of hot air, through a cast metal casing. The globe is so mounted as to revolve horizontally, and also from time to time vertically, whereby the included beans are tossed about and intermingled in all directions. Inequality of torrefaction becomes impossible. The consequence is the production of an article which on being ground evolves the most fragrant aroma, and when infused the most grateful and exhilarating beverage. The position of the globe in *fig.* 366. shows



366

it as turned up by a powerful leverage out of the cast iron heater, preparatory to its being emptied and re-charged.

The coffee thus equally roasted is finely ground in a mill between horizontal stones, like that of a corn-mill, and is thereby capable of giving out all its virtues to either boiling or cold water.

COKE is carbonized pitcoal. See CHARCOAL; and PITCOAL at the end.

In manufacturing coke on the large scale, Mr. Wilkinson of Jarrow, near Gateshead, has contrived a system of machinery for saving manual labour in discharging the coke from the ovens, while he has so arranged the ovens themselves as to equalize the distribution of air among the coals and to improve the produce and increase its quantity. The preferable size of oven in his opinion is 14 feet long, 8 feet wide, with the floor raised one foot above the level of the ground, and having an inclination to the front of 6 inches in the length of the bottom; the perpendicular height of the walls up to the springer, being 3 feet, while the radius of the arch is 4 feet. He connects crystallizing and evaporating pans for chemical purposes with a range of 12 coke ovens. The patentee claims as inventions his forming in the walls of coke ovens, flues with lateral openings for supplying air to the interior of the oven, as also his peculiar mechanical apparatus for discharging the coke, and his plan of economizing heat by evaporation.

COLCOTHAR OF VITRIOL (*Rouge d' Angleterre*, Fr.; *Rothes Eisenoxyd*, Germ.) is the brown-red peroxide of iron, produced by calcining sulphate of iron with a strong heat, levigating the resulting mass, and elutriating it into an impalpable powder. A better way of making it so as to complete the separation of the acid, is to mix 100 parts of the green sulphate of iron with 42 of common salt, to calcine the mixture, wash away the resulting sulphate of soda, and levigate the residuum. The sulphuric acid in this case expels the chlorine of the salt in the form of muriatic acid gas, and saturates its alkaline base produced by the chemical reaction; whence an oxide will be obtained free from acid, much superior to what is commonly found in the shops. The best sort of polishing powder, called *jeweller's red rouge* or plate powder, is the precipitated oxide of iron prepared by adding solution of soda to solution of copperas, washing, drying, and calcining the powder in shallow vessels with a gentle heat, till it assumes a deep brown-red colour. See IRON.

COLLODION. M. Malgaigne has recently communicated to the French Medical Journals some remarks on the preparation of gun cotton for surgical purposes. Several French chemists, at the suggestion of M. Malgaigne, attempted to make an ethereal solution of this compound by pursuing the process recommended by Mr. Maynard in the American Journal of Medical Sciences, but they failed in procuring the cotton in a state in which it could be dissolved in ether. It appears that these experimentalists had employed a mixture of nitric and sulphuric acids; but M. Miallie ascertained, after many trials, that the collodion, in a state fitted for solution, was much more easily procured by using a mixture of nitrate of potash and sulphuric acid.

For the information of our readers who may be disposed to try this new adhesive material, we here give a description of M. Miallie's process for its preparation. It appears from the results obtained from this chemist, that cotton in its most explosive form is not the best fitted for making the ethereal solution—

	Parts by weight.
Finely powdered nitrate of potash	40
Concentrated sulphuric acid	60
Carded cotton	2

Mix the nitrate with the sulphuric acid in a porcelain vessel, then add the cotton, and agitate the mass for three minutes by the aid of two glass rods. Wash the cotton, without first pressing it, in a large quantity of water, and when all acidity is removed (indicated by litmus paper) press it firmly in a cloth. Pull it out into a loose mass, and dry it in a stove at a moderate heat.

The compound thus obtained is not pure fulminating cotton; it always retains a small quantity of sulphuric acid, is less inflammable than gun cotton, and it leaves a carbonaceous residue after explosion. It has, however, in a remarkable degree the property of solubility in ether, especially when mixed with a little alcohol, and it forms therewith a very adhesive solution to which the name of collodion has been applied.

Preparation of Collodion.

	Parts by weight.
Prepared cotton	8
Rectified sulphuric ether	125
Rectified alcohol	8

Put the cotton with the ether into a well-stopped bottle, and shake the mixture for some minutes. Then add the alcohol by degrees, and continue to shake until the whole

COLOURS USED IN PAINTING, WITH NOTICES OF THEIR CHEMICAL AND ARTISTICAL PROPERTIES.—*By William Linton.*

MINERAL.

SAFELY USED AS PERMANENT ONES.

	Colours.	Chemical Designation.	Preparation.	Chemical Characteristics.	Artistical Properties.	Additional Colours,—with Remarks.
WHITES.	FLAKE WHITE	Carbonate of Lead, with an excess of Oxide.	Plates of lead exposed to the action of vinegar-steam in beds of fermenting tan.	Blackened by Sulphuretted Hydrogen, Hydro-Sulphuret of Ammonia, and other foul gases, common to most domestic atmospheres; for which reason a rapidly drying and protective vehicle is essential to seal it up against such evil influences. It has no injurious action upon Vegetable and other colours, as some have conjectured. It is perfectly soluble in diluted Nitric or Acetic Acid when free from Pipe-clay or Sulphate of Barytes.	The best White extant for Oil or Resin vehicles when pure, which is generally ascertained by its exceeding whiteness and opacity. Its usual adulterations are Sulphate of Barytes, Chalk, Pipe-clay, &c., all of which are partially transparent, and consequently appear darker in unctuous or resinous vehicles.	There are other Whites of Lead, varying in body and brilliancy, and equally obnoxious to the action of mephitic vapours; as *Krems, Roman*, and *Venetian Whites*, and *Sulphate of Lead*. The Whites of *Bismuth, Pearl*, and *Antimony* are injured by light as well as by mephitic vapours. Those of *Zinc, Tin, Barytes*, and *Strontian*, although they are comparatively secure against the foul gases, are too feeble in body to be satisfactory in unctuous or resinous vehicles.
YELLOWS.	CADMIUM YELLOW	Sulphuret of Cadmium.	A combination of Cadmium and Sulphur.	Resists the action of the foul gases, light, &c. It is a most durable and brilliant colour.	A beautiful Orange tinted Yellow, of an excellent body; and an admirable substitute for Naples Yellow, the Chromes, and other Mineral Yellows, which are liable to injury from noxious vapours, light, &c.	There are other Mineral Yellows, but they are all more or less objectionable. The *Chromates of Lead*, like all preparations of that metal, are blackened by the foul gases. The *Chromate of Barytes* is strongly acted upon by light. The united oxides of Lead and Antimony furnish *Naples Yellow*, a colour readily affected by Sulphuretted Hydrogen and other foul gases, as well as by light, and by a moist steel spatula. *Turpith Mineral* or Subsulphate of Mercury is rapidly blackened by light, and by the foul airs. *Orpiment*, or *King's Yellow* (Arsenic and Sulphur) is equally destructible; also *Patent Yellow* (Lead and Salt heated violently). The Vegetable Yellows are not to be depended upon. They soon disappear when applied in delicate tints or thin glazings, especially if subjected to the action of the solar rays (a summary mode of ascertaining the probable results of lengthened periods in subdued lights). *Gamboge* dissolved by Æther or Alcohol, is equally fugitive.
	STRONTIAN YELLOW	Chromate of Strontian.	A Solution of Strontian added to one of Chromate of Potash.	Resists the action of the foul gases and light, and is perfectly durable.	A pale Canary Yellow;—another safe substitute for the faulty Yellows mentioned above.	
	YELLOW OCHRE OXFORD OCHRE ROMAN OCHRE STONE OCHRE BROWN OCHRE TERRA DI SIENNA UMBER	Oxides of Iron.	Native Earths, consisting of Silica and Alumina coloured by Oxide of Iron.	All Permanent Colours, whether Native or Calcined.	The Oxides of Iron are among the most staple colours of the palette. When properly washed and prepared for oil painting, they are incapable of injuring other colours, and may be said to constitute the soundest materials with which the chemistry of nature has furnished the painter for the imitation of her works.	
	JAUNE DE MARS		A Chemical Preparation.			
REDS.	LIGHT RED		Yellow Ochre, Calcined.			There are other Mineral Reds which are durable; but they are of inferior quality and are not needed. *Native Cinnabar* is inferior in every respect to Vermillion. *Venetian Red* is an inferior representative of Indian Red, and *Colcothar* a still coarser one. *Red Lead* blackens in oil; and *Iodide of Mercury* has no claim to durability. Among Vegetable Reds, the *Madders* have the best reputation for standing. All vegetable colours however should be looked upon with suspicion.
	INDIAN RED		A Native Earth.			
	VERMILLION	Bisulphuret of Mercury.	Mercury and Sulphur sublimed together.	A perfectly permanent colour, not affected by acids or caustic alkalies.—Vaporized by a red heat if pure.	A beautiful colour, and of an excellent body.	

MINERAL ALL THESE COLOURS MAY BE	Carb.	Blu.	Anl.	Veg.		Consists of	Prepared from a mineral called Lapis Lazuli.	Acids, which will not affect other Mineral Blues, will destroy the colour in Ultramarine.—This is one of its best chemical tests. None of the mephitic gases, or light, or other pigments do it any injury. It is perfectly durable.	A most invaluable pigment: too well known and appreciated to require any comment.	There are other Mineral Blues, but they are either violated when used in Oil, or are valuable. The Ores of Cobalt and Alumina form *Cobalt Blue*; and the Oxide of Cobalt and Glass form *Smalt*; they are both blackened by foul airs. *Prussian* and *Antwerp Blues* are in much use from the want of a permanent deep blue: they are injured by light and alkalies. *Indigo* is inferior in colour and very fugitive.
BLUES.					NATIVE ULTRAMARINE	Consists of Silica, Alumina, Lime, Soda, and Potash, Oxide of Iron, Magnesia, Sulphuric Acid, Sulphur and Chlorine, (according to Gmelin, Varrentrapp and others) in its native state.				
					ARTIFICIAL ULTRAMARINE	It is regarded as a compound of Silicate of Alumina, Silicate of Soda, with Sulphuret of Sodium; the colour is owing to the reaction of the latter on the two former constituents.	Prepared by several difficult processes, some of which are kept secret by the makers.	Responds to the same tests as the native mineral.	A cheap and really valuable substitute for the native product. The best is that which is the least purple in its tint.	
GREENS.					CHROME GREEN	Sesquioxide of Chromium.	When Chromate of Mercury (the Orange precipitate one meets with in Nitrate of Mercury and Chromate of Potash) is strongly ignited, Oxide of Chromium remains in a powder.	A permanent colour in all respects. (The colouring matter of emeralds.)	An opaque light Green, of a full body.	There are other Mineral Greens. Those of Copper, the *Emerald Green*, and *Mineral Green*, are very insecure in oil vehicles.
					TERRA VERTE	Oxide of Copper.	Native Minerals.	Both quite permanent—native or calcined. Like the Ultramarines, acids destroy their colours.	Beautiful delicate Greens; deservedly favourite pigments with most painters.	
					MALACHITE	Carbonate of Copper, united with Silicate.				
BROWNS.					VANDYKE BROWN COLOGN EARTH	Decomposed Vegetable Matter.	Decayed Wood, Peat, or Bog Earth.	These Browns are reputed permanent in themselves; the opacity with which time generally invests them in pictures, being attributable probably to a loss of translucency in the vehicle, rather than to any change in the pigments: dark colours making the defect more evident than light ones.	Dark transparent Browns.	The dark Browns, though chiefly of vegetable *origin*, seem to be the only deep transparent colours which have proved permanent. The deep Reds, Yellows, Greens, and Blues, are all more or less of a fugitive nature.
					MUMMY	Vegetable and Animal Matter combined.	White Pitch and Myrrh, with Animal Matter.			
					ASPHALTUM	Bitumen.	A Mineral Pitch or Resin, found floating on the Dead Sea, also of the distillation of natural naphtha.			
BLACKS.					IVORY BLACK	Animal Matter.	Calcined Ivory.	A perfectly durable pigment.	Of a Brownish-black tint.	
					BLUE BLACK	Vegetable Matter.	Calcined Vine Stalks, Cocoa Nut Shells, &c.	Quite durable when the blue tints natural.	Of a Bluish-black tint.	

In recording the defects and liabilities of colours, it should not be forgotten that the painter's vehicle or diluent must have considerable effect in preventing chemical action among such as are inimical to each other, by isolating and sustaining their component particles from mutual contact. And if the vehicle be of a sound and firmly drying quality, even the external attacks from damp and foul airs, to which many of the oily etonable colours are liable, may often be successfully resisted. But should the vehicle be of a flimsy and impure character, instead of being a protector, it may become in itself an originator of mischief among the colours.

of the liquid acquires a syrupy consistency. It may be then passed through a cloth, the residue strongly pressed, and the liquid kept in a well-secured bottle.

Collodion thus prepared possesses remarkably adhesive properties. A piece of linen or cotton cloth covered with it and made to adhere by evaporation to the palm of the hand, will support a weight of twenty or thirty pounds. Its adhesive power is so great that the cloth will commonly be torn before it gives way. The collodion cannot be regarded as a perfect solution of the cotton. It contains suspended and floating in it a quantity of vegetable fibre, which has escaped the solvent action of the ether. The liquid portion may be separated from these fibres by a filter, but it is doubtful whether this is an advantage. In the evaporation of the liquid these undissolved fibres by felting with each other appear to give a greater degree of tenacity and resistance to the dried mass.

In the preparation of collodion it is indispensable to avoid the presence of water, as this renders it less adhesive, hence the ether as well as the alcohol should be purely rectified. The parts to which the collodion is applied should be first thoroughly dried, and no water allowed to come in contact with them until all the ether is evaporated to dryness by a steam heat, which must be continued for some time so as entirely to expel the alcohol or ether. The residuary matter should have the transparency and general characters of common resin.

COLOPHANY, black resin, the solid residuum of the distillation of turpentine, when all the oil has been worked off.

COLOURING MATTER. (*Matière colorante*, Fr.; *Farbstoff*, Germ.) See DYEING, the several dye-stuffs and pigments.

COLUMBIUM, a peculiar metal extracted from a rare mineral brought from Haddam in Connecticut. It is also called Tantalium from the mineral *tantalite* and *yttrotantalite*, found in Sweden. It has hitherto no application to the arts. It combines with two successive doses of oxygen; by the second it becomes an acid.

COLZA, is a variety of cabbage, the *brassica oleracea*, whose seeds afford by pressure an oil much employed in France and Belgium for burning in lamps, and for many other purposes. This plant requires a rich but light soil; it does not succeed upon either sandy or clayey lands. The ground for it must be deeply ploughed and well dunged. It should be sown in July, and be afterwards replanted in a richly manured field. In October it is to be planted out in beds, 15 or 18 inches apart. Colza may also be sowed in furrows 8 or 10 inches asunder.

Land which has been just cropped for wheat is that usually destined to colza; it may be fresh dunged with advantage. The harvest takes place in July, with the sickle, a little before the seeds are completely ripe, lest they should drop off. As the seed is productive of oil, however, only in proportion to its ripeness, the cut plants are allowed to complete their maturation, by laying them in heaps under airy sheds, or placing them in a stack, and thatching it with straw.

The cabbage stalks are thrashed with flails, the seeds are winnowed, sifted, and spread out in the air to dry; then packed away in sacks, in order to be subjected to the oil mill at the beginning of winter. The oil-cake is a very agreeable food to cattle, and serves to fatten them. It is reckoned to defray the cost of the mill.

Colza impoverishes the soil very much, as do, indeed, all the plants cultivated for the sake of their oleaginous seeds. It must not, therefore, be come back upon again for six years, if fine crops be desired. The double ploughing which it requires effectually cleans the ground. See OILS, UNCTUOUS.

COMB, the name of an instrument made of a thin plate either plane or curved of wood, horn, tortoise-shell, ivory, bone, or metal, cut out upon one or both of its sides or edges, into a series of somewhat long teeth, not far apart; which is employed for disentangling, laying parallel and smooth the hairs of man, horses, or other animals.

A thin steel saw bow, mounted in an iron or wooden handle, is the implement used by the comb-maker to cut the bone, ivory, and wood into slices of from a twelfth to a quarter of an inch thick, and of a size suitable to that of the comb. The pieces of tortoise-shell as found in commerce are never flat, or, indeed, of any regular curvature, such as the comb must have. They are therefore steeped in boiling water sufficiently long to soften them, and set to cool in a press between iron or brass moulds, which impart to them the desired form, which they preserve after cooling. After receiving their outline shape and curvature by proper flat files or fine rasps, the place of the teeth is marked with a triangular file, and then the teeth themselves are cut out with a double saw, composed of two thin slips of tempered steel, such as the main-spring of a watch, notched with very fine sharp teeth. These slips are mounted in a wooden or iron stock or handle, in which they may be placed at different distances to suit the width of the comb teeth. A comb-maker, however, well provided in tools, has an assortment of double saws set at every ordinary width. The two slips of this saw have their teeth in different planes, so that when it begins to cut, the most prominent slip alone acts, and

when the teeth of this one have fairly entered into the comb, the other parallel blade begins to saw. The workman, meanwhile, has fixed the plate of tortoise-shell or ivory between the flat jaws of two pieces of wood, like a vice, made fast to a bench, so that the comb intended to be cut is placed at an angle of 45° with the horizon. He now saws perpendicularly, forming two teeth at a time, proceeding truly in the direction of the first tracing.

A much better mode of making combs is to fix upon a shaft or arbour in a lathe a series of circular saws, with intervening brass washers or discs to keep them at suitable distances; to set in a frame like a vice, in front of these saws, the piece of ivory or horn to be cut; and to press it forward upon the saws at an angle of 45° by means of a regulated screw motion. After the teeth are thus cut, they are smoothed and polished with files, and by rubbing with pumice stone and tripoli.

Mr. Bundy, of Camden Town, obtained a patent so long ago as 1796, for an apparatus of that kind, which had an additional arbour fitted with a series of circular saws or rather files, for sharpening the points of the comb teeth.

More recently, Mr. Lyne has invented a machine in which, by means of pressure, two combs are cut out at once with chisels from any tough material, such as horn or tortoise-shell, somewhat softened at the moment by the application of a heated iron to it. The piece of horn is made fast to a carriage, which is moved forwards by means of a screw until it comes under the action of a ratchet-wheel, toothed upon a part of its circumference. The teeth of this wheel bring a lever into action, furnished with a chisel or knife, which cuts out a double comb from the flat piece, the teeth of which combs are opposite to each other. By this means no part of the substance is lost, as in sawing out combs. The same carriage may be used, also, to bear a piece of ivory in the hard state towards a circular saw, on the principles above explained, with such precision, that from 80 to 100 teeth can be formed in the space of one inch by a proper disposition of the tool.

Bullocks' horns, after the tips are sawed off, are roasted in the flame of a wood fire, till they are sufficiently softened; when they are slit up, pressed in a machine between two iron plates, and then plunged into a trough of cold water, whereby they are hardened. A paste of quicklime, litharge, and water is used to stain the horn to resemble tortoise-shell. See HORN.

COMBINATION (*Combinaison*, Fr.; *Verbindung*, Germ.); a chemical term which denotes the intimate union of dissimilar particles of matter into a homogeneous looking compound, possessed of properties generally different from those of the separate constituents.

COMBUSTIBLE (Eng. and Fr.; *Brennstoff*, Germ.); any substance which exposed in the air to a certain temperature, consumes spontaneously with the emission of heat and light. All such combustibles as are cheap enough for common use go under the name of Fuel; which see. Every combustible requires a peculiar pitch of temperature to be kindled, called its *accendible* point. Thus phosphorus, sulphur, hydrogen, carburetted hydrogen, carbon, each takes fire at successively higher heats.

COMBUSTIBLE SUGAR. When sugar is acted on by a mixture of nitric and sulphuric acids, a peculiar substance is produced, having a close resemblance to common resin, not only in its appearance and physical characters, but also in regard to its solubility in alcohol, ether, volatile oils, &c., and insolubility in water. This substance is, however, extremely inflammable and explosive, and possesses many of the properties ascribed to the celebrated Greek fire. Its affinity for alcohol and ether is so great that water will not remove these fluids from it. "Not having yet succeeded in producing with it any definite basic compound which would enable me to control my results, I have not attempted its analysis. The only purposes to which I have applied it are to the formation of fusees for shells, and to the preservation of gunpowder and pyrotechnical articles from damp and moisture. As a fusee, it is easily lighted, burns with great regularity, and appears absolutely incapable of being extinguished, circumstances which would render it of great use in ricochet practice. As a means of preventing the mischievous effect of damp and moisture on gunpowder it is of great value. The best mode of application is to plunge the gunpowder for a few seconds into an alcoholic or ethereal solution of the sugar compound, then withdraw it and allow it to dry at a gentle heat, say 120° Fahr., though there is no danger of an explosion at 212°. In this way the gunpowder is covered by a coat of varnish easy of ignition and insoluble in water, which cannot therefore penetrate to the gunpowder, the explosive nature of which is rather augmented than diminished by this treatment. An ethereal solution of gun-cotton does not answer so well for this purpose, nor is it so manageable. I have not ascertained how far this new substance is useful in retaining the edges of wounds in approximation, but its alcoholic solution merits a trial. The following is the method which I have found most successful in the manufacture of this compound.

"Mix together sixteen parts of concentrated sulphuric acid and eight parts of nitric

acid, specific gravity 1·50; place the mixture in cold water, and when the temperature has fallen to 60° or less, stir in one part of finely-powdered sugar, which will become pasty in a few seconds, and is then to be removed and plunged in cold water, when more sugar may then be added to the acid mixture, and removed as before. The compound is to be washed in water and dissolved in alcohol, to which a solution of carbonate of potash must be added in excess, so as to precipitate the substance, and neutralize its uncombined acid. After careful washing with water it is again to be dissolved in alcohol or ether and cautiously evaporated to dryness by a steam heat, which must be continued for some time, so as entirely to expel the alcohol or ether. The residuary matter should have the transparency and general character of common rosin." — *Mrs L. Thompson.*

COMBUSTION (Eng. and Fr.; *Verbrennung*, Germ.) results in common cases from the mutual chemical reaction of the combustible, and the oxygen of the atmosphere, whereby a new compound is formed; the heat and light evolved being most probably produced by the rapid motions of the particles during the progress of this combination.

COMPOUND COLOURS. If the effects of the colouring particles did not vary according to the combinations which they form, and the actions exercised upon them by the different substances present in a dyeing bath, we might determine with precision the shade which ought to result from the mixture of any two colours, or of the ingredients affording these colours separately. Though the chemical action of the mordants and of the liquor in the dye-bath often changes the results, yet theory may always predict them within a certain degree. It is not the colour appropriate to the dye-stuffs which is to be considered as the constituent part of compound colours, but that which they must assume with a certain mordant and dye-bath. Our attention ought therefore to be directed principally to the operation of the chemical agents employed.

1. The mixture of blue and yellow dyes produces green. D'Ambourney, indeed, says that he has extracted a fast green from the fermented juice of the berries of the buckthorn (*rhamnus fragula*), but no dyer would trust to such a colour.

2. The mixture of red and blue produces violet, purple, *columbine* (dove-colour), pansy, amaranth, lilac, mallow, and a great many other shades, determined by the nature and tone of the red and blue dye-stuffs, as well as their relative proportions in the bath.

3. The mixture of red and yellow produces orange, *mordoré*, cinnamon, *coquelicot*, brick, capuchin; with the addition of blue, olives of various shades; and with duns instead of yellows, chestnut, snuff, musk, and other tints.

4. Blacks of the lighter kinds constitute grays; and, mixed with other colours, produce *marrone* (marroons), coffees, damascenes. For further details upon this subject, see CALICO PRINTING, DYEING, as also the individual colours in their alphabetical places.

CONCRETE. The name given by architects to a compact mass of pebbles, sand and lime cemented together, in order to form the foundations of buildings. Semple says that the best proportion are 80 parts of pebbles, each about 7 or 8 ounces in weight, 40 parts sharp river sand, and 10 of good lime; the last is to be mixed with water to a thinnish consistence, and grouted in. It has been found that Thames ballast as taken from the bed of the river, consists nearly of 2 parts of pebbles to 1 of sand, and therefore answers exceedingly well for making concrete, with from one-seventh to one-eighth part of lime. The best mode of making concrete, according to Mr. Godwin, is to mix lime, previously ground, with the ballast in a dry state; sufficient water is now thrown over it to effect a perfect mixture, after which it should be turned over at least twice with shovels, or oftener; then put into barrows, and wheeled away for use instantly. It is generally found advisable to employ two sets of men to perform this operation, with three in each set; one man to fetch the water, &c., while the other two turn over the mixture to the second set, and they, repeating the process, turn over the concrete to the barrow-men. After being put into the barrows, it should at once be wheeled up planks, so raised as to give it a fall of some yards, and thrown into the foundation, by which means the particles are driven closer together, and greater solidity is given to the whole mass. Soon after being thrown in, the mixture is observed usually to be in commotion, and much heat is evolved with a copious emission of vapour. The barrow-load of concrete in the fall spreading over the ground, will form generally a stratum of from 7 to 9 inches thick, which should be allowed to set before throwing in a second.

Another method of making concrete, is first to cover the foundation with a certain quantity of water, and then to throw in the dry mixture of ballast and lime. It is next turned and levelled with shovels; after which more water is pumped in, and the operation is repeated. The former method is undoubtedly preferable.

In some cases it has been found necessary to mix the ingredients in a pug-mill, as in mixing clay, &c., for bricks. For the preparation of a concrete foundation, as the hardening should be rapid, no more water should be used than is absolutely necessary to

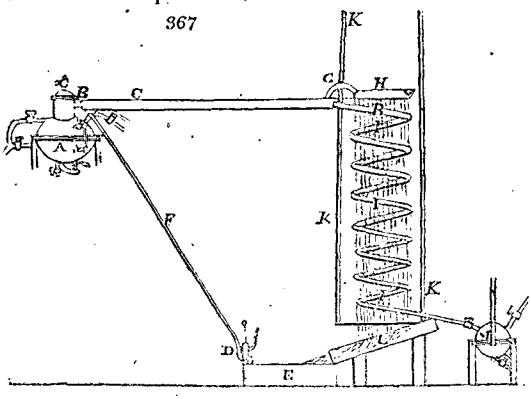
effect a perfect mixture of the ingredients. Hot water accelerates the induration. There is about one-fifth of contraction in volume in the concrete, in reference to the bulk of its ingredients. To form a cubical yard of concrete, about 30 feet cube of ballast and 3½ feet cube of ground lime must be employed, with a sufficient quantity of water.

CONGELATION (Eng. and Fr.; *Gefrierung*, Germ.); the act of freezing liquids. Many means are supplied by chemistry for effecting or promoting this process, but they do not constitute any peculiar art or manufacture. See ICE-HOUSE.

COOLING OF FLUIDS. In Mr. Derosnes's method, the cooling agents employed are a current of atmospheric air, and warm water of the same or nearly the same temperature as that of the vapours which are to be operated upon.

Fig. 367. represents merely a diagram of the general features of an apparatus constructed upon the principles proposed to be employed, which will serve to explain the nature of this improvement.

367



Let A be the source of the vapours, or the vessel, boiler, alembic, or closed pan that contains the liquid or syrup to be evaporated or concentrated. The pipe B, through which the vapour passes as it rises in the boiler, is surrounded by another tube C, of large diameter, closed at both ends. A pump D, draws from the reservoir E, warm water, which water has been heated by its previous and continual passage through the apparatus in contact with the surface of the vapour pipes. This pump forces the water by the pipe F, into the annular space or chamber between the pipes B and C, in which chamber, by its immediate contact with the pipe B, it acquires the temperature of the vapours intended to be refrigerated. The pipe G conveys the water from the pipe C, into the annular colander or sieve H, which has a multitude of small holes pierced through its under part, and from whence the warm water descends in the form of a continued shower of rain. To the end of the pipe B, a distiller's worm I I is connected, which is placed beneath the colander H. The entire length of the worm-pipe should be bound round with linen or cotton cloth, as a conductor of heat, which cloth will be continually moistened by the rain in its descent from the colander. As this water has been heated in passing along the tube C, the shower of rain descending from the colander will be at a higher temperature than that of the atmosphere, and, consequently, by heating the surrounding air as it descends, a considerable upward draft will be produced through the coils of the worm-pipe.

If the colander and the worm-pipe are enclosed within a chimney or upright tube, as K K, open at top and bottom, a current of ascending air will be produced within it by the descending shower of hot water, similar in effect to that which would be produced in a chimney communicating with a furnace, or to that of the burner of an argand lamp. Consequently, it will be perceived that in opposition to the descending rain, a strong upward current of air will blow through that part of the cylinder K K, which is beneath the colander. When the air first enters the lower aperture of the chimney or tube K, it is of the same temperature and moisture as the external atmosphere; but in its passage up the tube it meets with a warmer and damper atmosphere, caused by the heat given out from the hot fluid continually passing through the pipes, and by the hot shower of rain, and also by the steam evolved from the surfaces of the coils of the worm, which are continually wetted by the descending rain, the evaporation being considerably augmented by the cloth bound round the worm-pipe retaining the water as it descends in drops from coil to coil.

The atmosphere within the tube being of a higher temperature than without, a current of air consequently ascends and escapes at the upper aperture K, and its place is supplied by fresh air from the surrounding atmosphere, entering the tube below. The fresh air thus admitted at the bottom of the tube being cold and dry, will be suited to take up the heat and moisture within, because the water within the tube being in a state of dispersion as rain, presents to the air many points, or a very extended surface, and also because it is of a higher temperature than the air; and, besides, cold dry air is continually renewed, and a source of warmth furnished by the latent caloric to the

steam, as fast as it is evolved. Thus a portion of the descending rain, or water, is evaporated, and the effect of this evaporation is to abstract caloric not only from the water held in contact with the coils of the worm-pipe by the cloth enveloping it, but also from the hot vapours which pass through the worm. This process of evaporation has, therefore, a cooling power, which is but slight in the lower part of the chimney or tube K, because the temperature of the water, or rain, and of the worm, at this part, are of a lower temperature; but its refrigerating power increases as it rises towards the colander, and there it acquires its maximum of intensity, so that at any point between the lower aperture of the cylinder and the colander the current of air is always a little cooler than the atmosphere of the region through which it passes (that is, as its maximum); and in passing this region of higher temperature, it is not only put in equilibrium of temperature, but also made to take up an additional quantity of aqueous vapours, which equalizes the new temperature it acquires with its capacity of saturation. The cooling caused by the evaporation acts in an incessant and progressive manner from the lower aperture of the cylinder to the under side of the colander; and this cooling not only acts as an agent of the evaporation which the current of air cools, but it refrigerates also, because it becomes warmed in abstracting caloric from the vapours or liquids passing through the worm; and this refrigeration acts also incessantly and progressively from the lower part of the tube or chimney to the colander.

The patentee states, in conclusion, that "the velocity or force of the current of air that passes through the chimney or tube K can be accelerated by artificial means, either by conducting the air and vapour passing from the upper aperture of the cylinder into the chimney or flues of a furnace, or by means of a revolving, forcing, or exhausting fan, or ventilator, or any other contrivance which will produce an increased current of air, but which it is not necessary to be particularly described, as I only wish to explain the principles of a simple apparatus, constructed in any convenient form; and I would remark, that the area of the lower aperture through which the air is introduced into the chimney or tube K, and also the area of the upper aperture, or that through which it passes to the atmosphere, should be in accordance with the effect intended to be obtained.

"It is further to be remarked, that in order to obtain from this apparatus the best effect, the velocity of the current of air must be itself a maximum; and as the speed or velocity of the current of air is owing to and determined by the excess of the temperature of the descending water, or rain, and of the coils of the worm to that of the exterior atmosphere, it ensues that the temperature of the water, or rain, must be a maximum. But this excess of temperature is a maximum only when the source of the rain is at the same temperature as the vapours to be condensed: if less warm, it would attract less air; or, if warmer, it would augment the temperature of the vapours intended to be condensed. Consequently, the shower of water employed in the tube K, as the agent for cooling, bestows its maximum of effect when it is as warm as the vapours to be condensed; therefore, I may express this proposition, viz., 'That in refrigerating with water, less of it may be expended when it is warm than when it is cold, and that the least quantity of water will be evaporated when it is as warm as the aqueous or spirituous vapours upon which it is to operate.'

"This proposition may appear strange, nevertheless it is conformable to the laws of nature; and appears only strange, because until now warm water has not been employed with currents of air for refrigerating.

"Hence it is necessary to raise the temperature of the water in the colander to the temperature of the vapours to be condensed; therefore, I cause the lukewarm water, pumped from the reservoir E, to circulate in the chamber C. In this circulation it also begins to act as a refrigerating medium, taking up a portion of heat from the vapours that pass through the pipe B, and afterwards it acts as a further condenser in the cylinder, in the way described. Finally, the portion of this water that is still in the fluid state, after having fallen down from coil to coil, arrives lukewarm to the inclined surface I, which conducts it into the reservoir E, from whence it is pumped up into the chamber C, as before described.

"The tube or chimney K may have more or less altitude; the higher it is the greater is the current produced. The force or velocity of the current of air can be governed by the areas of the introduction and exit apertures. If the cylinder rises only to the height of the sieve, the effect is much less than when it is prolonged beyond this height. I would further remark, that if the cylinder was removed, a slight effect might be produced, provided that a current of air be preserved in the cylindrical space limited by the coils of the worm, and also if the current was produced between the coils; or a central passage might be formed in an apparatus of another shape than that above described.

"I have only shown the application of the worm, because intending only to explain the principles of this method of condensing and refrigerating.

"The small quantity of water wasted in this manner of condensation, (that is, that portion passed off to the atmosphere in the form of vapours, at the upper aperture of the

cylinder K,) may be replaced by a small stream of cold water, which may be brought to the apparatus, and perhaps most conveniently introduced into the reservoir E, or into the chamber between the pipes B and C. When operating upon aqueous vapours, the waste of water is always less in weight than that of the vapours liquefied. When this apparatus is applied to the purposes of distillation, the end of the worm should terminate in a vessel M, which is to receive the produce of the condensation. It will be seen that this improved process is applicable to various purposes, where condensation or refrigeration is required; for instance, in the boiling or concentration of sugar; to condensing and refrigerating distilled vapours, or steam, or saline liquids, either in vacuum or not; to cooling brewers' worts; and to the refrigeration of other liquors, or any other processes, when it may be required."

I have inserted the specification of this patent *verbatim*. M. Derosne has busied himself during a long life with a prodigious number of ingenious little contrivances for clarifying and boiling syrups, distillation, &c., but he has in this invention taken a bolder flight, having secured the exclusive privilege of condensing vapours, and cooling liquors, with hot water, in preference to cold. No man at all versant in the scientific doctrines, or the practical applications of caloric, will ever seek to meddle with his monopoly of such a scheme. He may find, perhaps, some needy coppersmith ready to espouse that or any other equally foolish project, provided a productive job can be made of it, against credulous customers.

For some rational methods of cooling liquors and condensing vapours, see REFRIGERATION, STILL, and SUGAR.

COPAL, a resin which exudes spontaneously from two trees, the *Rhus copallinum*, and the *Elæocarpus copalifer*, the first of which grows in America, and the second in the East Indies. A third species of copal tree grows on the coasts of Guinea, especially on the banks of some rivers, among whose sands the resin is found. It occurs in lumps of various sizes and of various shades of colour, from the palest greenish yellow to darkish brown. I found its specific gravity to vary in different specimens from 1·059 to 1·071, being intermediate in density between its two kindred resins, animé and amber. Some rate its specific gravity so high as 1·139, which I should think one of the errors with which chemical compilations teem. Copal is too hard to be scratched by the nail, whence the excellence of its varnish. It has a conchoidal fracture, and is without smell or taste. When exposed to heat in a glass retort over a spirit lamp it readily melts into a liquid, which being further heated boils with explosive jets. A viscid oily-looking matter then distils over. After continuing the process for some time, no succinic acid is found in the receiver, but the copal blackens in the retort. Anhydrous alcohol boiled upon it, causes it to swell, and transforms it by degrees into an elastic viscid substance. It is not soluble in alcohol of 0·825 at the boiling point, as I have ascertained. Copal dissolves in ether, and this ethereous solution may be mixed with alcohol without decomposition. Caoutchoucine acts very slightly upon it by my experiments, even at the boiling temperature of this very volatile fluid; but a mixture of it with alcohol of 0·825, in equal parts, dissolves it very rapidly in the cold into a perfectly liquid varnish. Alcohol holding camphor in solution also dissolves it, but not nearly so well as the last solvent. According to Unverdorben, copal may be completely dissolved by digesting one part of it for 24 hours with one part and a half of alcohol (probably anhydrous), because that portion of copal which is insoluble in alcohol dissolves in a very concentrated solution of the soluble portion. Oil of petroleum and turpentine dissolve only 1 or 2 per cent. of raw copal. By particular management, indeed, oil of turpentine may be combined with copal, as we shall describe under the article VARNISH.

Fused copal possesses different properties from the substance in its solid state; for it then may be made to combine both with alcohol and oil of turpentine.

Unverdorben has extracted from the copal of Africa, five different kinds of resin, none of which has however been applied to any use in the arts.

The ultimate constituents of copal by my analysis are, carbon 79·87, hydrogen 9·00, oxygen 11·1; being of hydrogen 7·6 in excess above the quantity necessary to form water with the oxygen.

Much information has been received from various sources concerning this somewhat ill-understood product of late years. It is now known that there are three different kinds of copal in commerce, but nothing is known of their distinguishing characteristics. We have East Indian and West Indian copal, and, under the latter name, two very different substances. The East Indian, called also African, is more colourless, soft, and transparent than the others; it forms a fine surface, and when heated emits an agreeable odour. It furnishes the finest varnish. Fresh essence of turpentine dissolves it completely, but not old. Essence digested upon sulphur will dissolve double its own weight, without letting any fall. Fresh rectified oil of rosemary will dissolve it in any proportion, but if the oil is thickened by age it serves only to swell this copal.

When cautiously melted, it may be then dissolved in good essence of turpentine in any proportion, producing a fine varnish, of little colour.

A good varnish may be made by dissolving 1 part of copal, 1 of essence of rosemary, with from 2 to 3 of pure alcohol. This varnish should be applied hot, and when cold, becomes very hard and durable.

The West India species, or American, comes to us not in lumps of a globular form, but in small flat fragments, which are hard, rough, and without taste or smell. It is usually yellow, and never colourless like the other. Insects are very rarely found in it. It comes from the Antilles, Mexico, and North America. It will not dissolve in essence of rosemary.

The third kind of copal, known also as West Indian, was formerly sold as a product of the East Indies. It is found in fragments of a concavo-convex form, the outer covering of which appears to have been removed. It contains many insects. When rubbed it emits an aromatic odour. It gives out much ethereous and empyreumatic oil when melted. It forms a soft varnish, which dries slowly.

Fusel oil, or amyle spirit, has been lately used as a solvent of the hard copal; but it does not dry into a very solid varnish.

Annexed is an account of the import of animé and copal, in the undermentioned years.

COPPER is one of the metals most anciently known. It was named from the island of Cyprus, where it was extensively mined and smelted by the Greeks. It has a reddish brown colour inclining to yellow; a faint but nauseous and rather disagreeable taste; and when rubbed between the fingers it imparts a smell somewhat analogous to its taste. Its specific gravity is from 8·8 to 8·9. It is much more malleable than it is ductile; so that far finer leaves may be obtained from it than wire. It melts at the 27th degree of Wedgewood's pyrometer, and at a higher temperature it evaporates in fumes which tinge the flame of a bluish green. By exposure to heat with access of air, it is rapidly converted into black scales of peroxide. In tenacity it yields to iron; but surpasses gold, silver, and platinum, considerably in this respect.

In mineralogy, the genus copper includes about 13 different species, and each of these contains a great many varieties. These ores do not possess any one general exterior character by which they can be recognised; but they are readily distinguished by chemical re-agents. Water of ammonia digested upon any of the cupreous ore in a pulverized state, after they have been calcined either alone or with nitre, assumes an intense blue colour, indicative of copper. The richest of the ordinary ores appear under two aspects; the first class has a metallic lustre, a copper red, brass yellow, iron gray, or blackish gray colour, sometimes inclining to blue; the second is without metallic appearance, has a red colour, verging upon purple, blue, or green, the last tint being the most usual. Few copper ores are to be met with, indeed, which do not betray the presence of this metal by more or less of a greenish film.

Dr. Scherer, of Freyberg, has arranged the ores of copper as follows:—

Symbol.	Copper in 100.
1. Copperglanz (*Kupferglaserz*) Cu_2S	79·7
2. Kupferkies, Copper pyrites, Cu_2S, Fe_2S_3	34·8
3. Buntkupfererz 3 Cu_2S, Fe_2S_3	55·7
4. Fahlerz 4 (Cu_2S, FeS, ZnS, AgS (Sb S_3 As S_3)	14—41
5. Rothkupfererz Cu_2O	88·5
6. Malachit 2 CuO, CO_2 + HO	57·4
7. Kupferlasur (2 (CuO, CO_2) + CuO . HO	55·3

Both Fahlerz and Buntkupfererz vary greatly in their proportion of copper. Fahlerz is very difficult to convert into pure copper by smelting, on account of the presence of antimony and arsenic in it. Kupferglanz is a disulphuret of copper. Buntkupfererz is purple or variegated copper ore. Rothkupfererz is the orange or red oxide of copper. Kuferlasur is blue carbonate of copper.

Pure copper may be obtained in the solid state either by the reduction of the powder of the pure oxide by a stream of hydrogen gas passed over it in an ignited tube, or by the galvanoplastic process. See ELECTRO-METALLURGY, or ELECTROTYPIE.

1. *Native Copper* occurs in crystals, branches and filaments, its most common locality being in primitive rocks. It is found abundantly in Siberia, at the mines of Tourinski, in those of Hungary, of Fundo-Moldavi in Gallicia, of Fahlun in Sweden,

of Cornwall, &c. The gangues of native copper are granite, gneiss, mica-slate, clay-slate, quartz, carbonate or fluate of lime, sulphate of barytes, &c. The most remarkable masses of native copper hitherto observed were; first, one in Brazil, 14 leagues from Basa, which weighed 2616 pounds; and secondly, another which Dr. Francis-le-Baron discovered in America to the south of Lake Superior. It was nearly 15 feet in circumference.

2. *Sulphuret of Copper, the vitreous ore of Brochant.* The texture of this ore is compact: its fracture, conchoidal, surface sometimes dull; colour, iron black or lead gray, often bluish, iridescent, or reddish from a mixture of protoxide. It is easily melted even by the heat of a candle; but more difficult of reduction than protoxide. This ore yields to the knife, assuming a metallic lustre when cut. Its density varies from 4·8 to 5·34. Its composition according to Klaproth is 78·5 copper, 18·5 sulphur, with a little iron and silica. Its equivalent constitution by theory is 80 copper + 20 sulphur = 100; whence 78·5 of metal should be associated with 19·6 of sulphur. This ore is therefore one of the richest ores, and forms very powerful veins, which likewise contain some orange protoxide. It is to be found in all considerable copper districts; in Siberia, Saxony, Sweden, and especially Cornwall, where the finest crystals occur.

3. *Copper Pyrites*, resembles in its metallic yellow hue, sulphuret of iron; but the latter is less pale, harder, and strikes fire more easily with steel. It presents the most lively rainbow colours. Its specific gravity is 4·3. It contains generally a good deal of iron; as the following analysis will show; copper 30, sulphur 37, iron 33, in 100 parts. According to Hisinger, the Swedish pyrites contains 63 of copper, 12 of iron, and 25 of sulphur. These ores occur in primitive and transition districts in vast masses and powerful veins; and are commonly accompanied with gray copper, sulphuret of iron, sparry iron, sulphurets of lead, and zinc.

4. *Gray Copper*, has a steel gray colour, more or less deep, either shining or dull; fracture uneven; a distinct metallic lustre; difficult of fusion at the blowpipe; it communicates to glass of borax a yellowish-red colour. Its density in crystals is 4·86. Its composition is very variable; consisting essentially of copper, iron, antimony, and sulphur. The exploration of this ore is profitable, in consequence of the silver which it frequently contains. It occurs in primitive mountains; and is often accompanied with red silver ore, copper pyrites, and crystallized quartz.

5. *Protoxide of Copper*, or *red oxide of Copper*: its colour is a deep red, sometimes very lively, especially when bruised. It is friable, difficult of fusion at the blowpipe, reducible on burning charcoal, soluble with effervescence in nitric acid, forming a green liquid. Its constitution when pure, is 88·9 copper + 11·1 oxygen = 100.

6. *Black oxide of Copper*, is of a velvet black, inclining sometimes to brown or blue; and it acquires the metallic lustre on being rubbed. It is infusible at the blowpipe. Its composition is, copper 80 + oxygen 20; being a true peroxide.

7. *Hydrosilicate of Copper*, consists essentially of oxide of copper, silica, and water. Its colour is green; and its fracture is conchoidal with a resinous lustre, like most minerals which contain water. Its specific gravity is 2·73. It is infusible at the blowpipe alone, but it melts easily with borax.

8. *Dioptase Copper*, or *Emerald Malachite*; a beautiful but rare cupreous mineral, consisting of oxide of copper, carbonate of lime, silica, and water in varying proportions.

9. *Carbonate of Copper, Malachite*; is of a blue or green colour. It occurs often in beautiful crystals.

10. *Sulphate of Copper, Blue Vitriol*, similar to the artificial salt of the laboratory. The blue water which flows from certain copper mines, is a solution of this salt. The copper is easily procured in the metallic state by plunging pieces of iron into it.

11. *Phosphate of Copper*, is of an emerald green, or verdigris-colour with somes pots of black. It presents fibrous or tuberculous masses with a silky lustre in the fracture. It dissolves in nitric acid without effervescence, forming a blue liquid; melts at the blowpipe, and is reducible upon charcoal, with the aid of a little grease, into a metallic globule. Its powder does not colour flame green, like the powder of muriate of copper.

12. *Muriate of Copper*, is green of various shades; its powder imparts to flame a remarkable blue and green colour. It dissolves in nitric acid without effervescence; and is easily reduced before the blowpipe. Its density is 3·5. By Klaproth's analysis it consists of oxide of copper 73, muriatic acid 10, water 17.

13. *Arseniate of Copper.* It occurs in beautiful blue crystals. Before the blowpipe it melts exhaling fumes of a garlic odour, and it affords metallic globules when in contact with charcoal. See more upon the ores at the end of this article.

In the article METALLURGY, I have described the mode of working certain copper mines; and shall content myself here with giving a brief account of two cupreous formations, interesting in a geological point of view; that of the copper slate of Mansfeldt, and of the copper veins of Cornwall.

The curious strata of bituminous schist in the first of these localities, are among the

most ancient of any which contain the exuviæ of organised bodies not testaceous. From among their tabular slabs the vast multitudes of fossil fish were extracted, which have rendered the cantons of Mansfeldt, Eisleben, Ilmenau, and other places in Thuringia and Voigtland so celebrated. Many of the fish are transformed into copper pyrites. Here, also, have been found the fossil remains of the lizard family, called *Monitors*.

Such is the influence of a wise administration upon the prosperity of mines, that the thin layer of slate in this formation, of which 100 pounds commonly contain but one pound and a half of copper, occasionally argentiferous, has been for several centuries the object of smelting works of the greatest importance to the territory of Mansfeldt and the adjoining country.

The frequent derangements which this metallic deposit experiences, led skilful directors of the under-ground operations at an early period to study the order of superposition of the accompanying rocks. From their observations, there resulted a system of facts which have served to guide miners, not only in the country of Mansfeldt, but over a great portion of Germany, and in several other countries where the same series of rocks, forming the immediate envelope of the cupreous schists, were found to occur in the same order of superposition.

Of the English copper works. — The deposits of copper in Cornwall occur always as veins in granite, or in the schistose rocks which surround and cover it; and hence, the Cornish miners work mostly in the granite or greenish clay slate; the former of which they call *growan*, the latter *killas*. But tin is sometimes desseminated in small veins in porphyry or *elvan*, which itself forms great veins in the above rocks. No stratification has been observed in Cornwall.

The copper veins are abundant in the killas and rare in the granite; but most numerous near the line of junction of the two rocks. The different kinds of mineral veins in Cornwall may be classed as follows: —

1. Veins of elvan; elvan courses, or elvan channels.
2. Tin veins, or tin *lodes*; the latter word being used by the Cornish miners to signify a vein rich in ore, and the word *course*, to signify a barren vein.
3. Copper veins running east and west; east and west copper lodes.
4. Second system of copper veins, or *contra* copper lodes.
5. Crossing veins; cross courses.
6. Modern copper veins; more recent copper lodes.
7. Clay veins; of which there are two sets, the more ancient, called. *Cross-Fluckans*; and the more modern, called *Slides*.

There are therefore three systems of copper veins in Cornwall; of which the first is considered to be the most ancient, because it is always traversed by the two others, and because, on the contrary, it never cuts them off. The width of these veins does not exceed 6 feet, though occasional enlargements to the extent of 12 feet sometimes take place. Their length is unknown, but the one explored in the *United Mines* has been traced over an extent of seven miles. The gangue of these veins is generally quartz, either pure, or mixed with green particles analogous to chlorite. They contain iron pyrites, blende, sulphuret, and several other compounds of copper, such as the carbonate, phosphate, arseniate, muriate, &c. The most part of the copper veins are accompanied with small argillaceous veins, called by the miners *fluckan of the lode*. These are often found upon both sides of the vein, so as to form cheeks or *salebandes*.

When two veins intersect each other, the direction of the one thrown out becomes an object of interest to the miner and geologist. In Saxony it is regarded as a general fact that the rejected portion is always to the side of the *obtuse angle*; this also holds generally in Cornwall, and the more obtuse the angle of incidence, the more considerable the out-throw.

The great copper vein of *Carharack*, in the parish of Gwenap, is a most instructive example of intersection. The power of this vein is 8 feet; it runs nearly from east to west, and dips towards the north at an inclination of 2 feet in a fathom. Its upper part is in the killas, its lower part in the granite. The vein has suffered two intersections; the first results from encountering the vein called *Steven's fluckan*, which runs from north-east to south-west, throwing it out several fathoms. The second has been caused by another vein, almost at right angles to the first, and which has driven it 20 fathoms out to the right side. The fall of the vein occurs, therefore, in one case to the right, and in the other to the left; but in both instances, it is to the side of the obtuse angle. This disposition is very singular; for one portion of the vein appears to have ascended, while another has sunk.

The mining works in the copper veins are carried on by reverse steps; see MINES. The grand shafts for drainage and extraction are vertical, and open upon the roof side of the vein, traversing it to a certain depth. These pits are sunk to the lowest point of the exploration; and, in proportion as the workings descend, by means of excavations in the vein, the pits are deepened and put into communication towards their bottom with

each new gallery of elongation, by means of transverse galleries. At present, the main shafts are fully 160 fathoms deep. Their horizontal section is oblong, and is divided into two compartments; the one destined for extraction, the other for the pumps. Their timbering has nothing remarkable, but is executed with every attention to economy, the whole wood employed in these mines being brought from Norway.

The descent of the workmen is effected by inclined shafts scooped out of the vein; the ladders are slightly inclined; they are interrupted every 10 fathoms by floors; the steps are made of iron, and, to prevent them from turning under the foot, the form of a miner's punch or jumper has been given them, the one end being round, and the other being wedge-shaped.

The ore is raised either by means of horse-gins, or by steam-engine power most frequently of high pressure. I shall take the *Consolidated Mines* as an example.

The draining, which is one of the most considerable sources of expense, both from the quantity of water, and from the depth of the mine, is executed by means of sucking and forcing pumps, the whole piston-rods of which, 120 feet long, are attached to a main-rod suspended at the extremity of the working beam of a steam-engine.

On this mine three steam-engines are erected of very great power, for the purpose of drainage; the one called the *Maria* engine is of the first-rate force, and most improved construction. The cylinder is 90 inches in internal diameter, and the length of the stroke is 9 feet 11 inches. It works single stroke, and is encased in a coating of bricks to prevent dissipation of the heat. The vapour is admitted at the upper end of the cylinder during the commencement of the fall of the piston, at a pressure capable of forming an equilibrium with a column of 60 inches of mercury. The introduction of the steam ceases whenever the piston has descended through a certain space, which may be increased or diminished at pleasure. During the remainder of the descent the piston is pressed merely by this vapour in its progressive expansion, while the under side of the piston communicates with the condenser. It ascends by the counterweight at the pump end of the working beam. Hence, it is only during the descent of the piston, that the effective stroke is exerted. Frequently the steam is admitted only during the sixth part of the course of the piston, or 18 inches. In this way the power of the engine is proportioned to the work to be done; that is, to the body of water to be raised. The *maximum* force of the above engine is about 310 horses; though it is often made to act with only one third of this power.

The copper mines of the isle of Anglesey, those of North Wales, of Westmoreland, the adjacent parts of Lancashire and Cumberland, of the south west of Scotland, of the Isle of Man, and of the south east of Ireland, occur also in primitive or transition rocks. The ores lie sometimes in masses, but more frequently in veins. The mine of Ecton in Staffordshire, and that of Cross-gill-burn, near Alston-moor in Cumberland, occur in transition or metalliferous limestone.

The copper ores extracted both from the granitic and schistose localities, as well as from the calcareous, are uniformly copper pyrites more or less mixed with iron pyrites; the red oxide, carbonate, arseniate, phosphate, and muriate of copper, are very rare in these districts.

The working of copper in the isle of Anglesey may be traced to a very remote era. It appears that the Romans were acquainted with the Hamlet mine near Holyhead; but it was worked with little activity till about 70 years ago. This metalliferous deposit lies in a greenish clay slate, passing into talc slate; a rock associated with serpentine and euphotide (*gabbro* of Von Buch). The veins of copper are from one to two yards thick; and they converge towards a point where their union forms a considerable mass of ore. On this mass the mine was first pierced by an open excavation, which is now upwards of 300 feet deep, and appears from above like a vast funnel. Galleries are formed at different levels upon the flank of the excavation to follow the several small veins, which run in all directions, and diverge from a common centre like so many radii. The ore receives in these galleries a kind of sorting, and is raised by means of hand windlasses, to the summit of a hill, where it is cleaned by breaking and riddling.

The water is so scanty in this mine that it is pumped up by a six-horse steam-engine. A great proportion of it is charged with sulphate of copper. It is conveyed into reservoirs containing pieces of old iron; the sulphate is thus decomposed into copper of cementation. The Anglesea ore is poor, yielding only from 2 to 3 *per cent.* of copper: a portion of its sulphur is collected in roasting the ore.

Mechanical preparation of the copper ores in Cornwall. — The ore receives a first sorting, either within the mine itself, or at its mouth, the object of which is to separate all the pieces larger than a walnut. These are then reduced by the hammer to a smaller size; after which the whole are sorted into four lots, according to their relative richness. The fragments of poor ore are pounded in the stamps so that the metallic portion may be separated by washing.

The rich ore is broken into small bits, of the size of a nut, with a flat beater, formed

of a piece of iron 6 inches square and 1 inch thick, adapted to a wooden handle. The ore to be broken is placed upon plates of cast-iron; each about 16 inches square and 1¼ inch thick. These iron plates are set towards the edge of a small mound about a yard high, constructed with dry stones rammed with earth. The upper surface of this mound is a little inclined from behind forwards. The work is performed by women, each furnished with a beater; the ore is placed in front of them beyond the plates; they break it, and strew it at their feet, whence it is lifted and disposed of to the smelting-houses.

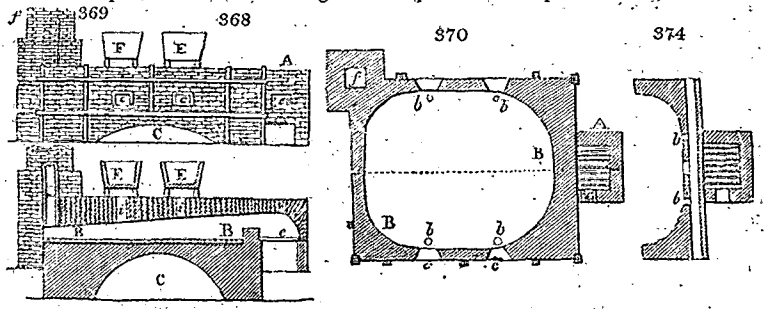
Inferior ores, containing a notable proportion of stony matters, are also broken with the beater, and the rich parts are separated by riddling and washing from the useless matters.

The smaller ore is washed on a sieve by shaking it in a stream of water, which carries away the lighter stony pieces, and leaves the denser metalliferous. They are then sorted by hand. Thus by beating, stamping, and riddling in water, the stony substances are in a great measure separated. The finer ground matter is washed on a plane table, over which a current of water is made to flow. Finally, the ore nearly fine is put into a large tub with water, and briskly stirred about with a shovel, after which it settles in the order of richness, the pure metallic ore being nearest the bottom. The stamps used for copper ore in Cornwall are the same as those used for tin ores, of which we shall speak in treating of the latter metal, as well as of the boxes for washing the fine powder or *slime*. These in fact do not differ essentially from the stamping mills and washing apparatus described in the article METALLURGY. Crushing rolls are of late years much employed. See LEAD and TIN.

Cornwall being destitute of coal, the whole copper ore which this county produces is sent for smelting to South Wales. Here are 15 copper works upon the Swansea and Neath, which pursue a nearly uniform and much improved process, consisting in a series of calcinations, fusions, and roastings, executed upon the ores and the matters resulting from them.

The furnaces are of the reverberatory construction; they vary in their dimensions and in the number of their openings, according to the operations for which they were intended. There are 5 of them: — 1. The calcining furnace or calciner; 2. The melting furnace; 3. The roasting furnace or roaster; 4. The refining furnace; 5. The heating or igniting furnace.

1. The calcining furnace rests upon a vault, c, into which the ore is raked down after being calcined; it is built of bricks, and bound with iron bars, as shown in the elevation, *fig.* 368. The hearth, B B, figs. 368. and 370. is placed upon a level with the lower horizontal binding bar, and has nearly the form of an ellipse, truncated at the two extremities of its great axis. It is horizontal, bedded with fire-bricks set on edge, so that it may be removed and repaired without disturbing the arch upon which it reposes. Holes, not visible



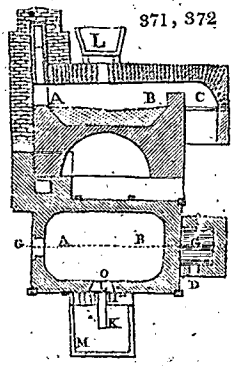
in the figure, are left in the shelves before each door, c c, through which the roasted ore is let fall into the subjacent vault. The dimensions of the hearth B B are immense, being from 17 to 19 feet in length, and from 14 to 16 in breadth. The fire-place, A, *fig.* 370., is from 4½ to 5 feet long, and 3 feet wide. The bridge or low wall, *b*, *fig.* 374., which separates the fire-place from the hearth, is 2 feet thick; and in Mr. Vivian's smelting-works is hollow, as shown in the figure, and communicates at its two ends with the atmosphere, in order to conduct a supply of fresh air to the hearth of the furnace. This judicious contrivance will be described in explaining the *roasting* operation. The arched roof of the furnace slopes down from the bridge to the beginning of the chimney, *f*, *fig.* 369., 370., its height above the hearth being at the first point about 26 inches, and from 8 to 12 at the second.

Such great calcining furnaces have 4 or 5 doors, c c c c, *fig.* 370., one for the fire-place, as shown at the right hand in *fig.* 369., and 3 or 4 others for working the ore upon the

reverberatory hearth. If there be 3, 2 of them are placed between the vertical binding bars upon one side, and a third upon the opposite side of the furnace; if there be 4, 2 are placed upon each side, facing one another. These openings are 12 inches square, and are bound with iron frames. The chimney is about 22 feet high, and is placed at one angle of the hearth, as at *f*, *fig.* 370., being joined by an inclined flue to the furnace.

For charging it with ore there is usually placed above the upper part of the vault 2 hoppers, E E, in a line with the doors; they are formed of 4 plates of iron, supported in an iron frame. Beneath each of them there is an orifice for letting the ore down into the hearth.

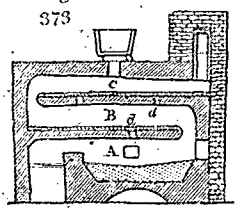
These furnaces serve for calcining the ore, and the *matts* or *crude coppers*: for the latter purpose, indeed, furnaces of two stories are sometimes employed, as represented in *fig.* 373. The dimensions of each floor in this case are a little less than the preceding. Two doors, *c c*, correspond to each hearth, and the workmen, while employed at the upper story, stand upon a raised movable platform.



371, 372

2. *Melting furnace, figs.* 371 and 372.—The form of the hearth is also elliptical, but the dimensions are smaller than in the calcining furnace. The length does not exceed 11 or 11½ feet, and the breadth varies from 7 to 8. The fire-place is however larger in proportion, its length being from 3½ feet to 4, and its breadth from 3 to 3½; this size being requisite to produce the higher temperature of this furnace. It has fewer openings, there being commonly three; one to the fire-place at D, a second one, O, in the side, kept generally shut, and used only when incrustations need to be scraped off the hearth, or when the furnace is to be entered for repairs; and the third or working-door, G, placed on the front of the furnace beneath the chimney. Through it the scoriæ are raked out, and the melted matters are stirred and puddled, &c.

The hearth is bedded with infusible sand, and slopes slightly towards the side door, to facilitate the discharge of the metal. Above this door there is a hole in the wall of the chimney (*fig.* 372.) for letting the metal escape. An iron gutter, O, leads it into a pit, K, bottomed with an iron receiving-pot, which may be lifted out by a crane. The pit M is filled with water, and the metal becomes granulated as it falls into the receiver. The melting furnaces are surmounted by a hopper, L, as shown in *fig.* 371.



373

Melting furnaces are sometimes used also for calcination. There are some such near Swansea, which serve this double purpose; they are composed of 3 floors (*fig.* 373.) The floor A is destined for melting the calcined ore; the other two, B C, serve for calcination. The heat being less powerful, upon the upper sole *e*, the ore gets dried upon it, and begins to be calcined—a process completed on the next floor. Square holes, *d*, left in the hearths B and C, put them in communication with each other, and with the lower one A; these perforations are shut during the operation by a sheet of iron, removable at pleasure.

The hearths *b* and *c* are made of bricks; they are horizontal at the top slightly vaulted beneath; they are 2 bricks thick, and their dimensions are larger than those of the inferior hearths, as they extend above the fire-place. On the floors destined for calcination the furnace has two doors on one of its sides; on the lower story there are also two; but they are differently collocated. The first, being in the front of the furnace, serves for drawing off the scoriæ, for working the metal, &c.; and the second, upon the side, admits workmen to make necessary repairs. Below this door the discharge or tap-hole A is placed, which communicates by a cast-iron gutter with a pit filled with water. The dimensions of this furnace in length and breadth are nearly the same as those of the melting furnace above described; the total height is nearly 12 feet. It is charged by means of one or two hoppers.

3. *Roasting furnace.*—The furnaces employed for this purpose are in general analogous to the calcining ones; but in the smelting works of Hafod, the property of Messrs. Vivian, these furnaces, alluded to above, present a peculiar construction, for the purpose of introducing a continuous current of air upon the metal, in order to facilitate its oxidizement. This process was originally invented by Mr. Sheffield, who disposed of his patent right to Messrs. Vivian.

The air is admitted by a channel, *e e*, through the middle of the fire-bridge, *fig.* 374, and extending all its length; it communicates with the atmosphere at its two ends *c c*; square holes, *b b*, left at right angles to this channel, conduct the air into the fur-

nace. This very simple construction produces a powerful effect in the roasting operation. It not only promotes the oxidizement of the metals, but burns the smoke, and assists in the vaporisation of the sulphur; while by keeping the bridge cool it preserves it from wasting, and secures uniformity of temperature to the hearth.

4. *Refining furnace.* — In this, as in the melting furnace, the sole slopes towards the door in front, instead of towards the side doors, because in the refining furnace the copper collects into a cavity formed in the hearth towards the front door, from which it is lifted out by ladles; whereas, in the melting furnaces, the metal is run out by a taphole in the side. The hearth sole is laid with sand; but the roof is higher than in the melting furnace, being from 32 to 36 inches. If the top arch were too much depressed, there might be produced upon the surface of the metal a layer of oxide very prejudicial to the quality of the copper. When the metal in that case is run out, its surface solidifies and cracks, while the melted copper beneath breaks through and spreads irregularly over the cake. This accident, called the *rising of the copper*, hinders it from being laminated, and requires it to be exposed to a fresh refining process, when lead must be added to dissolve the oxide of copper. This is the only occasion upon which the addition of lead is proper in refining copper When the metal to be refined is mixed with others, particularly with tin, as in extracting copper from old bells, then very wide furnaces must be employed, to expose the metallic bath upon a great surface, and in a thin stratum, to the oxidizing action of the air.

The door G, fig. 372., upon the side of the refining furnace, is very large, and is shut with a framed brick door, balanced by a counter-weight. This door being open during the refining process, the heat is stronger at B than at A (*figs.* 371, 372.)

5. *Heating furnaces*, being destined to heat the pigs or bars of copper to be laminated, as well as the copper sheets themselves, are made much longer in proportion to their breadth. Their hearth is horizontal, the vault not much depressed; they have only one door, placed upon the side, but which extends nearly the whole length of the furnace: this door may be raised by means of a counter-weight, in the same way as in the furnaces for the fabrication of sheet-iron and brass.

Series of operations to which the ore is subjected. — The ores which are smelted in the Swansea works are cupreous pyrites, more or less mingled with *gangue* (vein-stone). The pyrites is composed of nearly equal proportions of sulphuret of copper and sulphuret of iron.

The earthy matters which accompany the pyrites are usually siliceous, though in some mines the metalliferous deposit is mixed with clay or fluate of lime. Along with these substances, pretty uniformly distributed, tin and arsenical pyrites occur occasionally with the copper; and though these two metals are not chemically combined, yet they cannot be separated entirely in the mechanical preparations. The constituent parts of the ore prepared for smelting are, therefore, copper, iron, sulphur, with tin, arsenic, and earthy matters in some cases. The different ores are mixed in such proportions that the average metallic contents may amount to 8½ per cent. The smelting process consists in alternate roastings and fusions. The following description of it is chiefly taken from an excellent paper, published by John Vivian, esq., in the Annals of Philosophy for 1823.

In the roasting operation the volatile substances are disengaged mostly in the gaseous state, while the metals that possess a strong affinity for oxygen become oxidized. In the fusion the earthy substances combine with these oxides, and form glassy scoriæ or slags, which float upon the surface of the melted metal.

These calcinations and fusions take place in the following order:—

1. Calcination of the ore. 2. Melting of the calcined ore. 3. Calcination of the coarse metal. 4. Melting of the calcined coarse metal. 5. Calcination of the fine metal (second matt). 6. Melting of the calcined fine metal. 7. Roasting of the coarse copper. In some smelting works, this roasting is repeated four times; in which case a calcination and a melting are omitted. In the Havod works, however, the same saving is made without increasing the number of roastings. 8. Refining or toughening the copper.

Besides these operations, which constitute the treatment of copper properly speaking, two others are sometimes performed, in which only the scoriæ are melted. These may be designated by the letters *a* and *b*. *a* is the re-melting of the portion of the scoriæ of the second process, which contain some metallic granulations. *b* is a particular melting of the scoriæ of the fourth operation. This fusion is intended to concentrate the particles of copper in the scoriæ, and is not practised in all smelting works.

First operation. Calcination of the ore.—The different ores, on arriving from Cornwall and other districts where they are mined, are discharged in continuous cargoes at the smelting works, in such a way, that by taking out a portion from several heaps at a time, a tolerably uniform mixture of ores is obtained; which is very essential in foundry, because, the ores being different in qualities and contents, they act as

fluxes upon each other. The ore thus mixed is transported to the works in wooden measures that hold a hundred-weight. The workmen entrusted with the calcination convey the ore into the hoppers of the calcining furnace, whence it falls into the hearth; other workmen spread it uniformly on the surface by iron rakes. The charge of a furnace is from three tons to three tons and a half. Fire is applied and gradually increased, till, towards the end of the operation, the temperature be as high as the ore can support without melting or agglutinating. To prevent this running together, and to aid the extrication of the sulphur, the surfaces are renewed, by stirring up the ore at the end of every hour. The calcination is usually completed at the end of 12 hours, when the ore is tumbled into the arch under the sole of the furnace. Whenever the ore is cold enough to be moved, it is taken out of the arch, and conveyed to the calcined heap.

The ore in this process hardly changes weight, having gained in oxidizement nearly as much as it has lost in sulphur and arsenic; and if the roasting has been rightly managed, the ore is in a black powder, owing to the oxide of iron present.

Second operation. Fusion of the calcined ore.—The calcined ore is likewise given to the melters in measures containing a hundred-weight. They toss it into hoppers, and after it has fallen on the hearth, they spread it uniformly. They then let down the door, and lute it tightly. In this fusion there are added about 2 cwt. of scoriæ proceeding from the melting of the calcined matt, to be afterwards described. The object of this addition is not only to extract the copper that these scoriæ may contain, but especially to increase the fusibility of the mixture. Sometimes also, when the composition of the ore requires it, lime, sand, or fluor spar is added; and particularly the last fluxing article.

The furnace being charged, fire is applied, and the sole care of the founder is to keep up the heat so as to have a perfect fusion; the workman then opens the door, and stirs about the liquid mass to complete the separation of the metal (or rather of the matt) from the scoriæ, as well as to hinder the melted matter from sticking to the sole. The furnace being ready, that is, the fusion being perfect, the founder takes out the scoriæ by the front door, by means of a rake. When the matt is thus freed from the scoriæ, a second charge of calcined ore is then introduced to increase the metallic bath; which second fusion is executed like the first. In this way, new charges of roasted ore are put in till the matt collected on the hearth rises to a level with the door-way, which happens commonly after the third charge. The tap hole is now opened; the matt flows out into the pit filled with water, where it is granulated during its immersion; and it collects in the pan placed at the bottom. The granulated matt is next conveyed into the matt warehouse. The oxidation with which the grains get covered by the action of the water, does not allow the proper colour of the matt or coarse metal to be distinguished; but in the bits which stick in the gutter, it is seen to be of a steel gray. Its fracture is compact, and its lustre metallic. The scoriæ often contain metallic grains; they are broken and picked with care. All the portions which include some metallic particles are re-melted in an accessory process. The rejected scoriæ have been found to be composed of siliceous matter 59, oxide of copper 1, oxide of tin 0·7.

In this operation, the copper is concentrated by the separation of a great part of the matters with which it was mixed or combined. The granulated matt produced, contains in general 33 per cent. of copper; it is therefore four times richer than the ore; and its mass is consequently diminished in that proportion. The constituent parts are principally copper, iron, and sulphur.

The most important point to hit in the fusion just described, is to make a fusible mixture of the earths and the oxides, so that the matt of copper may, in virtue of its greater specific gravity, fall to the under-part, and separate exactly from the slag. This point is attained by means of the metallic oxides contained in the scoriæ of the fourth operation, of which 2 cwt. were added to the charge. These consist almost entirely of black oxide of iron. When the ores are very difficult to melt, a measure of about half a hundred-weight of fluor spar is added; but this must be done with precaution, for fear of increasing the scoriæ too much.

The business goes on day and night. Five charges are commonly put through hands in the course of 24 hours; but when all circumstances are favourable, that is to say, when the ore is fusible, when the fuel is of the first quality, and when the furnace is in good condition, even six charges a day have been despatched.

The charge is a ton and a half of calcined ore, so that a melting furnace corresponds nearly to a calcining furnace; the latter turning out nearly 7 tons of calcined ore in 24 hours.

The workmen are paid by the ton.

Third operation. Calcination of the coarse metal, or the matt.—The object of this operation is principally to oxidize the iron, an oxidation easier to execute than in the first

calcining, because the metal is now disengaged from the earthy substances, which screened it from the action of the air.

This calcination is executed in the furnace already represented, *fig.* 368, 369, 370. page 470. exactly in the same way as the ore was calcined. The metal must be perpetually stirred about, to expose all its surfaces to the action of the hot air, and to hinder the clotting together. The operation lasts 24 hours; during the first six, the fire should be very moderate, and thereafter gradually increased to the end of the calcination. The charge is, like that of the first, 3 tons and a half.

Fourth operation. Melting of the calcined coarse metal, or calcined matt. — In the fusion of this first calcined matt, some scoriæ of the latter operations must be added, which are very rich in oxide of copper, and some crusts from the hearth, which are likewise impregnated with it. The proportion of these substances varies according to the quality of the calcined matt.

In this second fusion, the oxide of copper contained in the scoriæ, is reduced by the affinity of the sulphur, one portion of which passes to the state of acid, while the other forms a subsulphuret with the copper become free. The matt commonly contains a sufficient quantity of sulphur to reduce the oxide of copper completely; but if not, which may happen if the calcination of the matt has been pushed too far, a small quantity of uncalcined matt must be introduced, which, by furnishing sulphur, diminishes the richness of the scoriæ, and facilitates the fusion.

The scoriæ are taken out by the front door, by drawing them forward with a rake. They have a great specific gravity; are brilliant with metallic lustre, very crystalline, and present, in the cavities, crystals like those of pyroxene; they break easily into very sharp-edged fragments. They contain no granulated metal in the interior; but it sometimes occurs, on account of the small thicknesses of the stratum of scoriæ, that these carry off with them, when they are withdrawn, some metallic particles.

These scoriæ, as we have already stated, under the fusion of the roasted ore, are in general melted with it. In some cases, however, a special melting is assigned to them.

The matt obtained in this second fusion is either run out into water like the first, or moulded into pigs (ingots), according to the mode of treatment which it is to undergo. This matt, called by the smelters *fine metal* when it is granulated, and *blue metal* when it is in pigs, is of a light grey colour, compact, and bluish at the surface. It is collected in the first form when it is to be calcined anew; and in the second, when it must immediately undergo the operation of *roasting*. Its contents in copper are 60 *per cent.* This operation, which is but sometimes had recourse to, lasts 5 or 6 hours. The charge is 1 ton.

(*b*) *Particular fusion of the scoriæ of the fourth operation.* — In re-melting these scoriæ, the object is to procure the copper which they contain. To effect this fusion, the scoriæ are mixed with pulverized coal, or other carbonaceous matters. The copper and several other metals are deoxidized, and furnish a white and brittle alloy. The scoriæ resulting from this melting are in part employed in the first melting, and in part thrown away. They are crystalline, and present crystals often in the cavities, which appear to belong to bisilicate of iron. They have a metallic lustre, and break into very sharp-edged fragments. The white metal is melted again, and then united to the product of the second fusion.

Fifth operation. Calcination of the second matt, or fine metal of the smelter. — This is executed in precisely the same way as that of the first matt. It lasts 24 hours; and the charge is usually 3 tons.

Sixth operation. Melting of the calcined fine metal. — This fusion is conducted like that of the first matt. The black copper, or coarse copper, which it produces, contains from 70 to 80 per cent. of pure metal; it is run into ingots, in order to undergo the operation of roasting.

The scoriæ are rich in copper; they are added to the fusion of the calcined coarse metal of the fourth operation.

In the smelting houses of Messrs. Vivian, at Hafod, near Swansea, the fifth and sixth operations have been omitted of late years. The second matt is run into pigs, under the name of *blue metal*, to be immediately exposed to the roasting.

The disposition of the canal *a a'*, *fig.* 374., which introduces a continuous current of air to the hearth of the furnace, accelerates and facilitates the calcination of the matt; an advantage which has simplified the treatment, by diminishing the number of calculations.

Seventh operation. Roasting of the coarse copper, the product of the sixth operation. — The chief object of this operation is oxidizement; it is performed either in an ordinary roasting furnace, or in the one belonging to *fig.* 374., which admits a constant current of air. The pigs of metal derived from the preceding melting are exposed, on the hearth of the furnace, to the action of the air, which oxidizes the iron and other foreign metals with which the copper is still contaminated. The duration of the roasting varies from

12 to 24 hours, according to the degree of purity of the crude copper. The temperature should be graduated, in order that the oxidizement may have time to complete, and that the volatile substances which the copper still retains may escape in the gaseous form. The fusion must take place only towards the end of the operation.

The charge varies from a ton and a quarter to a ton and a half. The metal obtained is run out into moulds of sand. It is covered with black blisters, like steel of cementation; whence it has got the name of blistered copper. In the interior of these pigs, the copper presents a porous texture, occasioned by the ebullition produced by the escape of the gases during the moulding. The copper being now almost entirely purged from the sulphur, iron, and the other substances with which it was combined, is in a fit state to be refined. This operation affords some scoriæ; they are very heavy, and contain a great deal of oxide of copper, sometimes even metallic copper.

These scoriæ, as well as those of the third melting and of the refining, are added to the second fusion, as we have already stated, in describing the fourth operation.

In some works, the roasting is repeated several times upon the *blue metal*, in order to bring it to a state fit for refining. We shall afterwards notice this modification of the treatment.

Eighth operation. Refining or toughening. — The pigs of copper intended for refining are put upon the sole of the refining furnace through the door in the side. A slight heat is first given, to finish the roasting or oxidation, in case this operation has not already been pushed far enough. The fire is to be increased by slow degrees, so that, by the end of 6 hours, the copper may begin to flow. When all the metal is melted, and when the heat is considerable, the workman lifts up the door in the front, and withdraws with a rake the few scoriæ which may cover the copper bath. They are red, lamellated, very heavy, and closely resemble protoxide of copper.

The refiner takes then an assay with a small ladle, and when it cools, breaks it in a vice, to see the state of the copper. From the appearance of the assay, the aspect of the bath, the state of the fire, &c., he judges if he may proceed to the toughening, and what quantity of wooden spars and wood charcoal he must add to render the metal malleable, or, in the language of the smelters, bring it to the proper pitch. When the operation of refining begins, the copper is brittle or dry, and of a deep red colour approaching to purple. Its grain is coarse, open, and somewhat crystalline.

To execute the refining, the surface of the metal is covered over with wood charcoal, and stirred about with a spar or rod of birch wood. The gases which escape from the wood, occasion a brisk effervescence. More wood charcoal is added from time to time, so that the surface of the metal may be always covered with it, and the stirring is continued with the rods, till the operation of refining be finished; a circumstance indicated by the assays taken in succession. The grain of the copper becomes finer and finer, and its colour gradually brightens. When the grain is extremely fine, or *closed*, when the trial pieces half cut through and then broken, present a silky fracture, and when the copper is of a fine light red, the refiner considers the operation to be completed; but he verifies still further the purity of the copper, by trying its malleability. For this purpose, he takes out a sample in his small ladle, and pours it into a mould. When the copper is solidified, but still red-hot, he forges it. If it is soft under the hammer, if it does not crack on the edges, the refiner is satisfied with its ductility, and he pronounces it to be in its *proper state*. He orders the workmen to mould it; who then lift the copper out of the furnace in large iron ladles lined with clay, and pour it into moulds of the size suitable to the demands of commerce. The ordinary dimensions of the ingots or pigs are 12 inches broad, 18 long, and from 2 to 2½ thick.

The period of the refining process is 20 hours. In the first six, the metal heats, and suffers a kind of roasting; at the end of this time it melts. It takes four hours to reach the point at which the refining, properly speaking, begins; and this last part of the process lasts about 4 hours. Finally, 6 hours are required to arrange the moulds, cast the ingots, and let the furnace cool.

The charge of copper in the refining process depends upon the dimensions of the furnace. In the Hafod works, one of the most important in England, the charge varies from 3 to 5 tons; and the quantity of pure copper manufactured in a week is from 40 to 50 tons.

The consumption of fuel is from 15 to 18 parts of coal, for one part of refined copper in pigs.

When the copper offers difficulties in the refining, a few pounds of lead are added to it. This metal, by the facility with which it scorifies, acts as a purifier, aiding the oxidation of the iron and other metals that may be present in the copper. The lead ought to be added immediately after removing the door to skim the surface. The copper should be constantly stirred up, to expose the greatest possible surface to the action of the air, and to produce the complete oxidation of the lead; for the smallest quantity of this metal alloyed in copper, is difficult to clear up in the lamination; that is to say, the scale of oxide does not come cleanly from the surface of the sheets.

The operation of refining copper is delicate, and requires, upon the part of the workmen, great skill and attention to give the metal its due ductility. Its surface ought to be entirely covered with wood charcoal; without this precaution, the refining of the metal would *go back*, as the workmen say, during the long interval which elapses in the moulding; whenever this accident happens, the metal must be stirred up anew with the wooden pole.

Too long employment of the wooden rod gives birth to another remarkable accident, for the copper becomes more brittle than it was prior to the commencement of the refining; that is, when it was *dry*. Its colour is now of a very brilliant yellowish red, and its fracture is fibrous. When this circumstance occurs, when the refining, as the workmen say, has *gone too far*, the refiner removes the charcoal from the top of the melted metal; he opens the side door, to expose the copper to the action of the air, and it then resumes its malleable condition.

Mr. Vivian, to whom we owe the above very graphic account of the processes, has explained, in a very happy manner, the theory of refining. He conceives, we may conclude, that the copper in the *dry state*, before the refining, is combined with a small portion of oxygen, or, in other words, that a small portion of oxide of copper is diffused through the mass, or combined with it; and that this proportion of oxygen is expelled by the deoxidizing action of the wood and charcoal, whereby the metal becomes malleable. 2. That when the refining process is carried too far, the copper gets combined with a little charcoal. Thus copper, like iron, is brittle when combined with oxygen and charcoal; and becomes malleable only when freed entirely from these two substances.

It is remarkable, that copper, in the *dry state*, has a very strong action upon iron; and that the tools employed in stirring the liquid metal become very glistening, like those used in a farrier's forge. The iron of the tools consumes more rapidly at that time, than when the copper has acquired its malleable state. The metal requires, also, when *dry*, more time to become solid, or to cool, than when it is refined; a circumstance depending, probably, upon the difference in fusibility of the copper in the two states, and which seems to indicate, as in the case of iron, the presence of oxygen.

When the proper refining point has been passed, another very remarkable circumstance has been observed; namely, that the surface of the copper oxidizes more difficultly, and that it is uncommonly brilliant; reflecting clearly the bricks of the furnace vault. This fact is favourable to the idea suggested above, that the metal is in that case combined with a small quantity of carbon; which absorbs the oxygen of the air, and thus protects the metal from its action.

Copper is brought into the market in different forms, according to the purposes which it is to serve. What is to be employed in the manufacture of brass is granulated. In this condition it presents more surface to the action of zinc or calamine, and combines with it more readily. To produce this granulation, the metal is poured into a large ladle, pierced with holes, and placed above a cistern filled with water, which must be hot or cold, according to the form wished in the grains. When it is hot, round grains are obtained analogous to lead shot; and the copper in this state is called *bean shot*. When the melted copper falls into cold water perpetually renewed, the granulations are irregular, thin, and ramified; constituting *feathered shot*. The *bean shot* is the form employed in brass making.

Copper is also made into small ingots, about 6 ounces in weight. These are intended for exportation to the East Indies, and are known in commerce by the name of Japan copper. Whenever these little pieces are solidified, they are thrown, while hot, into cold water. This immersion slightly oxidizes the surface of the copper, and gives it a fine red colour.

Lastly, the copper is often reduced into sheets, for the sheathing of ships, and many other purposes. The Hafod works possess a powerful rolling mill, composed of four pairs of cylinders. It is moved by a steam engine, whose cylinder has 40 inches diameter. See the representation of the rolling mill of the Royal Mint, under GOLD.

The cylinders for rolling copper into sheets are usually 3 feet long, and 15 inches in diameter. They are uniform. The upper roller may be approached to the under one, by a screw, so that the cylinders are brought closer, as the sheet is to be made thinner.

The ingots of copper are laid upon the sôle of a reverberatory furnace to be heated; they are placed alongside each other, and they are formed into piles in a cross-like arrangement, so that the hot air may pass freely round them all. The door of the furnace is shut, and the workman looks in through a peep-hole from time to time, to see if they have taken the requisite temperature; namely, a dull red. The copper is now passed between the cylinders; but although this metal be very malleable, the ingots cannot be reduced to sheets without being several times heated; because the copper cools, and acquires, by compression, a texture which stops the progress of the lamination.

These successive heatings are given in the furnace indicated above; though, when the

sheets are to have a very great size, furnaces somewhat different are had recourse to. They are from 12 to 15 feet long, and 5 wide. See BRASS.

The copper, by successive heating and lamination, gets covered with a coat of oxide, which is removed by steeping the sheets for a few days in a pit filled with urine; they are then put upon the sole of the heating furnace. Ammonia is formed, which acts on the copper oxide, and lays bare the metallic surface. The sheets are next rubbed with a piece of wood, then plunged, while still hot, into water, to make the oxide scale off; and lastly, they are passed cold through the rolling press to smooth them. They are now cut square, and packed up for home sale or exportation.

The following estimate has been given by MM. Dufrenoy and Elie de Beaumont of the expense of manufacturing a ton of copper in South Wales.

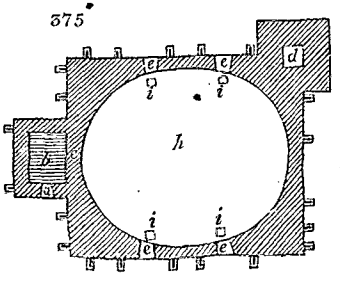
	£	s.	d.
12½ tons of ore, yielding 8½ *per cent.* of copper	55	0	0
20 tons of coals - - -	8	0	0
Workmen's wages, rent, repairs, &c. -	13	0	0
	76	0	0

The exhalations from the copper smelting works are very detrimental to both vegetable and animal life. They consist of sulphurous acid, sulphuric acid, arsenic and arsenious acids, various gases and fluoric vapours, with solid particles mechanically swept away into the air, besides the coal smoke. Mr. Vivian has invented a very ingenious method of passing the exhalations from the calcining ores and *matts* along horizontal flues or rather galleries of great dimensions, with many crossings and windings of the current, and exposure during the greater part of the circuit to copious showers of cold water. By this simple and powerful system of condensation, the arsenic is deposited in the bottoms of the flues, the sulphurous acid is in a great measure absorbed, and the nuisance is remarkably abated.

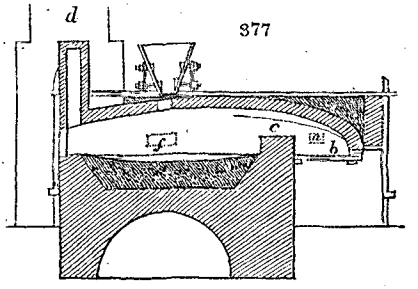
The following figures represent certain modifications of the copper calcining and smelting copper furnaces of Swansea.

Fig. 376. is the section of the roasting furnace lengthwise; *fig.* 375. the ground plan; in which *a* is the fire-door; *b* the grate; *c* the fore-bridge; *d* the chimney; *e e* working

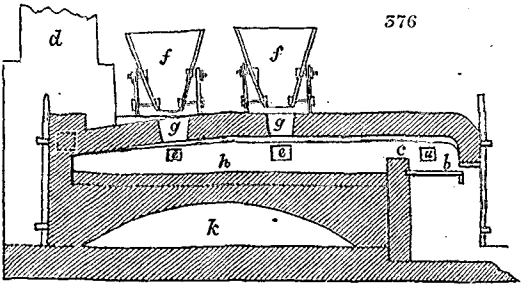
375



377



376



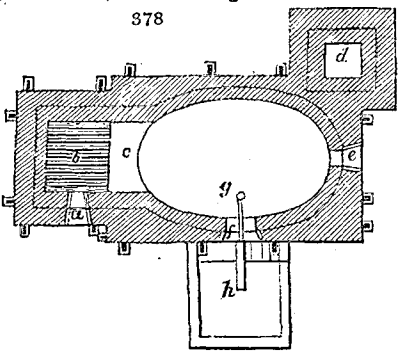
apertures on each of the long sides of the furnace, through which the ore is introduced, spread, and turned over; *f f* cast-iron hoppers; *g g* openings in the vaulted roof; *k* the hearth-sole; *i i* holes in this; *k* a vaulted space under the hearth. The hearth has a suitable oval shape, and is covered with a flat arch. Its length is 16 feet, breadth 13½, mean height 2 feet.

Fig. 377. is a longitudinal section of the melting furnace; *fig.* 378. the ground plan in which *a* is the fire door; *b* the grate; *c* the fire bridge; *d* the chimney; *e* the side openings; *f* the working doors; *g* the raking-out hole; *h* iron spouts, which conduct the melted metal into pits filled with water.

The melting furnace is altogether smaller; but its firing hearth is considerably larger

than in the roasting furnace. The long axis of the oval hearth is 14 feet; its short axis 10 feet; its mean height 2 feet.

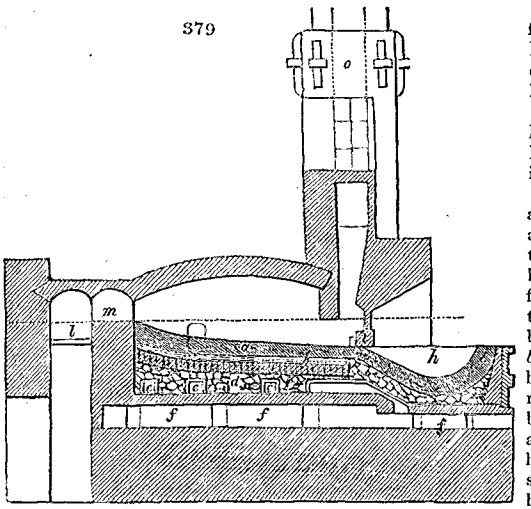
378



The principal ore smelted at Chessy is the azure copper, which was discovered by accident in 1812. Red copper ore, also, has come into operation there since 1825. The average metallic contents of the richest azure ore are from 33 to 36 per cent.; of the poorer, from 20 to 24. The red ore contains from 40 to 67 parts in 100. The ore is sorted, so that the mean contents of metal may be 27 per cent., to which 20 per cent. of limestone are added; whence the cinder will amount to 50 per cent. of the ore. A few per cents. of red copper slag, with some quicklime and *gahrslag*, are added to each charge, which consists of 200 pounds of the above mixture, and 150 pounds of coke. When the furnace (*fourneau à manche*, see the Scotch smelting hearth, under LEAD), is in good action, from 10 to 14 such charges are worked in 12 hours. When the crucible is full of metal at the end of this period, during which the cinder has been frequently raked off, the blast is stopped, and the *matt* floating over the metal being sprinkled with water and taken off, leaves the black copper to be treated in a similar way, and converted into *rosettes*. The refining of this black copper is performed in a kind of reverberatory furnace.

The cinders produced in this reduction process are either vitreous and light blue, which are most abundant; cellular, black, imperfectly fused from excess of lime; or, lastly, red, dense, blistery, from defect of lime, from too much heat, and the passage of protoxide into the cinders. They consist of silicate of alumina, of lime, protoxide of iron; the red contain some silicate of copper.

379



The copper-refining furnace at Chessy, near Lyons, is of the kind called *Spleiss-ofen* (split hearths) by the Germans. *Fig.* 379. is a section lengthwise in the dotted line A B of *fig.* 380., which is the ground plan.

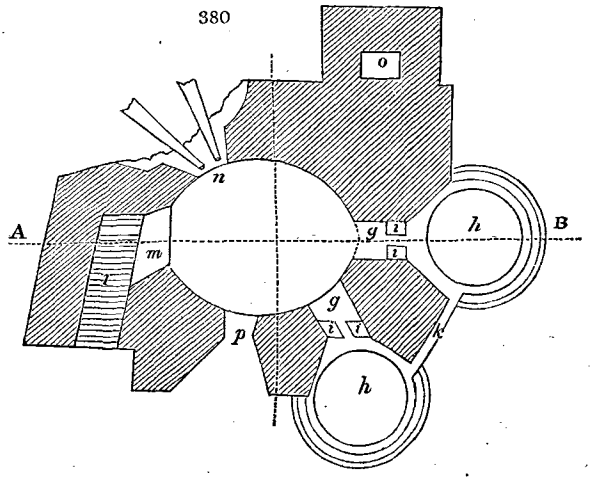
The foundation-walls are made of gneiss; the arch, the fire-bridge, and the chimney, of fire-bricks. The hearth, *a*, is formed of a dense mixture of coal-dust, upon a bottom of well-beat clay *b*, which reposes upon a bed of brickwork *c*. Beneath this there is a slag bottom *d*; *e* is the upper, and *f* the under discharge hole. The hearth is egg-shaped; the longer axis being 8 feet, the shorter $6\frac{1}{2}$ feet: in the middle it is 10 inches deep, and furnished with the outlets *g g*, which lead to each of the *Spleiss-hearths h h*, *fig.* 380. These outlets are contracted with fire-bricks *i i*, till the proper period of the discharge. The two hearths are placed in communication by a canal *k*; they are $3\frac{1}{2}$ feet in diameter, 16 inches deep; are floored with well-beat coal ashes, and receive about 27 cwt. for a charge.

l is the grate; *m*, the fire-bridge; *n*, the boshes in which the *tuyères* lie; *o*, the chimney; *p*, the working door through which the slags may be drawn off. Above this is a small chimney, to carry off the flame and smoke whenever the door is opened.

The smelting *post* or charge, to be purified at once, consists of 60 cwt. of black copper, to which a little granular copper and copper of cementation is added; the

consumption of pit-coal amounts to 36 cwt. As soon as the copper is melted, the bellows are set a-going, and the surface of the metal gets soon covered with a

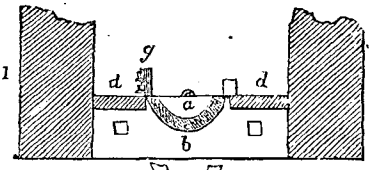
380



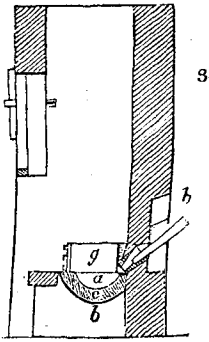
moderately thick layer of cinder, which is drawn off. This is the first skimming or *decrassage*. By and by, a second layer of cinder forms, which is in like manner removed; and this skimming is repeated, to allow the blast to act upon fresh metallic surfaces. After 4 or 5 hours, no more slag appears, and then the fire is increased. The melted mass now begins to boil or work (*travailler*), and continues so to do, for about ¾ of an hour, or an hour, after which the motion ceases, though the fire be kept up. The *gahrproof* is now taken; but the metal is seldom fine in less than ¾ of an hour after the boil is over. Whenever the metal is run off by the tap-hole into the two basins *i i*, called SPLIT-HEARTHS, a reddish vapour or mist rises from its surface, composed of an infinite number of minute globules, which revolve with astonishing velocity upon their axes, constituting what the Germans called *spratzen* (crackling) of the copper. They are composed of a nucleus of metal, covered with a film of protoxide, and are used as sand for strewing upon manuscript. The copper is separated, as usual, by sprinkling water upon the surface of the melted metal, in the state of *rosettes*, which are immediately immersed in a stream of water. This refining process lasts about 16 or 17 hours; the skimmings weigh about 50 cwt.; the refuse is from 15 to 17 per cent.; the loss from 2 to 3 per cent. The *gahrslag* amounts to 11 cwt.

The refining of the eliquated copper (called *darrlinge*) from which the silver has been sweated out by the intervention of lead, can be performed only in small hearths. The following is the representation of such a furnace, called, in German, *Kupfergahrheerd*. *Fig.* 381. is the section lengthwise; *fig.* 382. is the section across; and *fig.* 383. is the

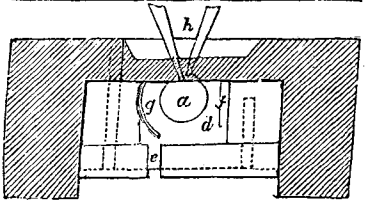
381



382



383



ground plan, in which *a* is the hearth-hollow; *b*, a massive wall; *c*, the mass out of which the hearth is formed; *d* cast-iron plates covering the hearth; *e*, opening for

running off the liquid slag; *f*, a small wall; *g*, iron curb for keeping the coals together.

The hearth being heated with a bed of charcoal, ¾ cwt. of *darrlinge* are laid over it, and covered with more fuel: whenever this charge is melted, another layer of the coal and *darrlinge* is introduced, and thus in succession till the hearth become full, or contain from 2¼ to 2½ cwt. In Neustadt 7½ cwt. of *darrlinge* have been refined in one furnace, from which 5 cwt. of *gahrcopper* has been obtained. The blast oxidizes the foreign metals, namely, the lead, nickel, cobalt, and iron, with a little copper, forming the *gahrslag*; which is, at first, rich in lead oxide, and poor in copper oxide; but, at the end, this order is reversed. The slag, at first blackish, assumes progressively a copper red tint. The slag flows off spontaneously along the channel *e*, from the surface of the hearth. The *gahre* is tested by means of a proof rod of iron, called *gahr-eisen*, thrust through the *tuyère* into the melted copper, then drawn out and plunged in cold water. As soon as the *gahrspan* (scale of copper) appears brownish red on the outside, and copper red within, so thin that it seems like a net-work, and so deficient in tenacity that it cannot be bent without breaking, the refining is finished. The blast is then stopped; the coals covering the surface, as also the cinders must be raked off the copper, after being left to cool a little; the surface is now cooled by sprinkling water upon it, and the thick cake of congealed metal (*rondelle*) is lifted off with tongs, a process called *schleissen* (slicing), or *sheibenreissen* (shaving), which is continued till the last convex cake at the bottom of the furnace, styled the *kingspiece*, is withdrawn. These *rondelles* are immediately immersed in cold water, to prevent the oxidation of the copper; whereupon the metal becomes of a cochineal red colour, and gets covered with a thin film of protoxide. Its under surface is studded over with points and hooks, the result of tearing the congealed disc from the liquid metal. Such cakes are called *rosette* copper. When the metal is very pure and free from protoxide, these cakes may be obtained very thin, one 24th of an inch for example.

The refining of two cwts. and a half of *darrlinge* takes three quarters of an hour, and yields one cwt. and a half of *gahr copper* in 36 rosettes, as also some *gahrslag*. Gahr copper generally contains from 1½ to 2½ per cent. of lead, along with a little nickel, silver, iron, and aluminum.

Smelting of the Mannsfeld copper schist, or bituminous Mergelschiefer. — The cupreous ore is first roasted in large heaps, of 2000 cwts., interstratified with brush-wood, and with some slates rich in bituminous matter, mixed with the others. These heaps are 3 ells high, and go on burning 15 weeks in fair and 20 in rainy weather. The bitumen is decomposed; the sulphur is dissipated chiefly in the form of sulphurous acid; the metal gets partially oxidized, particularly the iron, which is a very desirable circumstance towards the production of a good smelting slag. The calcined ore is diminished one-tenth in bulk, and one-eighth in weight; becoming of a friable texture and a dirty yellow gray colour. The smelting furnaces are cupolas (*schachtofen*), 14 to 18 feet high; the fuel is partly wood charcoal, partly coke from the Berlin gas-works, and Silesia. The blast is given by cylinder bellows, recently substituted for the old barbarous *Blasebälgen*, or wooden bellows of the household form.

The cupreous slate is sorted, according to its composition, into slate of lime, clay, iron, &c., by a mixture of which the smelting is facilitated. For example, 1 post or charge may consist of 20 cwt. of the ferruginous slate, 14 of the calcareous, 6 of the argillaceous, with 3 of fluor spar, 3 of rich copper slags, and other refuse matters. The nozzle at the *tuyère* is lengthened 6 or 8 inches, to place the melting heat near the centre of the furnace. In 15 hours 1 fodder of 48 cwts. of the above mixture may be smelted, whereby 4 to 5 cwts. of *matte* (crude copper, called *Kupferstein* in Germany) and a large body of slags are obtained. The *matte* contains from 30 to 40 per cent. of copper, and from 2 to 4 *loths* (1 to 2 oz.) of silver. The slags contain at times one-tenth their weight of copper.

The *matte* is composed of the sulphurets of copper, iron, silver, zinc, along with some arsenical cobalt and nickel. The slaty slag is raked off the surface of the melted *matte* from time to time. The former is either after being roasted six successive times, smelted into black copper; or it is subjected to the following concentration process. It is broken to pieces, roasted by brushwood and coals three several times in brick-walled kilns, containing 60 cwts., and turned over after every calcination; a process of four weeks' duration. The thrice roasted mass, called *spurrost*, being melted in the cupola *fig.* 385. with ore-cinder, yields the *spurstein*, or concentrated *matte*. From 30 to 40 cwts. of spurrost are smelted in 24 hours; and from 48 to 60 per cent. of *spurstein* are obtained, the slag from the slate smelting being employed as a flux. The spurstein contains from 50 to 60 per cent. of copper, combined with the sulphurets of copper, of iron, and silver.

The spurstein is now mixed with *dünnstein* (a sulphuret of copper and iron produced in the original smeltings) roasted six successive times, in a quantity of 60 cwts., with

brushwood and charcoal; a process which requires from 7 to 8 weeks. The product of this six-fold calcination is the *Gahrrost* of the Germans (done and purified); it has a colour like red copper ore, varying from blue gray into cochineal red; a granular fracture; it contains a little of the metal, and may be immediately reduced into metallic copper, called *kupfermachen*. But before smelting the mass, it is lixiviated with water, to extract from it the soluble sulphate, which is concentrated in lead pans, and crystallized.

The lixiviated *gahröste* mixed with from ¼ to ½ of the lixiviated *dünnsteinrost*, and ⅛ to ⅒ of the copper slate slag, are smelted with charcoal or coke fuel in the course of 24 hours, in a mass of 60 or 80 cwts. The product is black copper, to the amount of about ¼ the weight, and ⅛ of *dünnstein*, or *thin matte*. This black copper contains in the cwt. from 12 to 20 loths (6 to 10 oz.) of silver. The dünnstein consists of from 60 to 70 per cent. of copper combined with sulphur, sulphuret of iron and arsenic; and when thrice roasted, yields a portion of metal. The black copper lies undermost in the crucible of the furnace, above it is the *dünnstein*, covered with the stone slag, or copper cinder, resulting from the slate-smelting. The slags being raked off, and the crucible sufficiently full, the eye or nozzle hole is shut, the *dünnstein* removed by cooling the surface, and breaking the crust, which is about ¼ to ½ inch thick. The same method is adopted for taking out the black copper in successive layers. For the de-silvering of this, and similar black coppers, see SILVER.

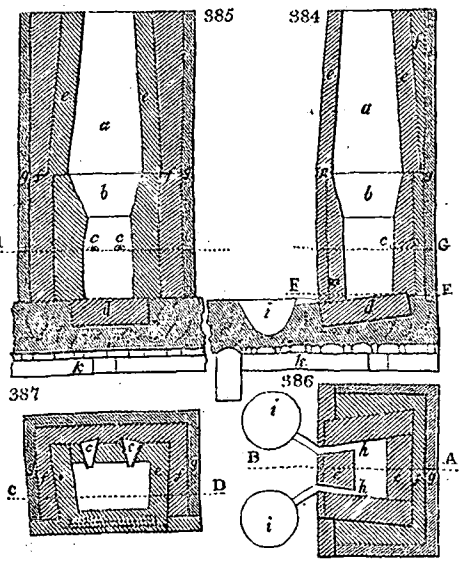


Fig. 384. is a vertical section through the form or *tuyère* in the dotted line A B of *fig.* 386. *Fig.* 385. is a vertical section in the dotted line C D of *fig.* 387. *a* is the shaft of the furnace, *b* the rest, *c c* the forms; *d* the sole or hearth-stone, which has a slope of 3 inches towards the front wall; *e e*, &c. casing walls of fire bricks; *f f*, &c. filling up walls built of rubbish stones; *g g* a mass through which the heat is slowly conducted; *h h* the two holes through one or other of which alternately the product of the smelting process is run off into the fore-hearth. Beneath the hearth-sole there is a solid body of loam; and the fore-hearth is formed with a mixture of coal-dust and clay; *k* is the discharge outlet. *Fig.* 386. is a horizontal section of the furnace through the hole or eye in the dotted line E F of *fig.* 384.; *fig.* 387. a horizontal section of the shaft of the furnace through the form in the dotted line G H of *figs.* 384 and 385. The height of the shaft, from the line E F to the top, is 14 feet; from E to G, 25 inches; from *c* to the line below *b*, 2 feet; from that line to the line opposite *g g*, 2 feet. The width at the line *g g* is 3 feet 3 inches, and at c 26 inches. The basins *i i*, *fig.* 386., are 3 feet diameter, and 20 inches deep.

The refining of copper is said to be well executed at Seville, in Spain; and, therefore, some account of the mode of operating there may be acceptable to the reader.

The first object is to evaporate in a reverberatory furnace all the volatile substances, such as sulphur, arsenic, antimony, &c., which may be associated with the sulphur; and the second, to oxidize and to convert into scoriæ the fixed substances, such as iron, lead, &c., with the least possible expense and waste. The minute quantities of gold and silver which resist oxidation cannot be in any way injurious to the copper. The hearth is usually made of a refractory sand and clay with ground charcoal, each mixed in equal volumes, and worked up into a doughy consistence with water. This composition is beat firmly into the furnace bottom. But a quartzose hearth is found to answer better, and to be far more durable; such as a bed of fire-sandstone.

Before kindling the furnace, its inner surface is smeared over with a cream-consistenced mixture of fire-clay and water.

The cast pigs, or blocks of black or crude copper, are piled upon the hearth, each successive layer crossing at right angles the layer beneath it, in order that the flame may

have access to play upon the surface of the hearth, and to heat it to a proper pitch for making the metal flow.

The weight of the charge should be proportional to the capacity of the furnace, and such that the level of the metallic bath may be about an inch above the nozzle of the bellows; for, were it higher, it would obstruct its operation, and were it too low, the stream of air would strike but imperfectly the surface of the metal, and would fail to effect, or would retard at least, the refining process, by leaving the oxidation and volatilization of the foreign metals incomplete.

As the scoriæ form upon the surface, they are drawn off with an iron rabble fixed to the end of a wooden rod.

Soon after the copper is melted, charcoal is to be kindled in three iron basins lined with loam, placed alongside the furnace, to prepare them for receiving their charge of copper, which is to be converted in them, into *rosettes*.

The bellows are not long in action before the evaporation of the mineral substances is so copious, as to give the bath a boiling appearance; some drops rise up to the roof of the reverberatory, others escape by the door, and fall in a shower of minute spherical globules. This phenomenon proves that the process is going on well; and, when it ceases, the operation is nearly completed. A small proof of copper, of the form of a watch-case, and therefore called *montre*, is taken out from time to time, upon the round end of a polished iron rod, previously heated. This rod is dipped two or three inches into the bath, then withdrawn and immersed in cold water. The copper cap is detached from the iron rod, by a few blows of a hammer; and a judgment is formed from its thickness, colour, and polish, as to the degree of purity which the copper has acquired. But these *watches* need not be drawn till the small rain, above spoken of, has ceased to fall. At the end of about 11 hours of firing, the numerous small holes observable in the first *watch* samples begin to disappear; the outer surface passes from a bright red to a darker hue, the inner one becomes of a more uniform colour, and always less and less marked with yellowish spots. It will have acquired the greatest pitch of purity that the process can bestow, when the *watches* become of a dark crimson colour.

Care must be taken to stop this refining process at the proper time; for, by prolonging it unduly, a small quantity of cupreous oxide would be formed, which, finding no oxygen to reduce it, would render the whole body of copper hard, brittle, and incapable of lamination.

The basins must now be emptied of their burning charcoal, the opening of the *tuyère* must be closed, and the melted copper allowed to flow into them through the tap-hole, which is then closed with loam. Whenever the surface is covered with a solid crust, it is bedewed with water; and as soon as the crust is about $1\frac{1}{2}$ inch thick it is raised upon hooks above the basin, to drain off any drops, and then carried away from the furnace. If these cakes, or rosettes, be suddenly cooled by plunging them immediately in water, they will assume a fine red colour, from the formation of a film of oxide.

Each refining operation produces, in about 12 hours, $1\frac{7}{10}$ tons of copper, with the consumption of about $\frac{4}{5}$ of a ton of dry wood.

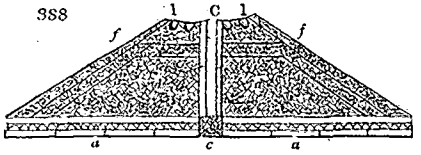
Care should be taken that the copper cake or *rosette* be all solidified before plunging it into water, otherwise a very dangerous explosion might ensue, in consequence of the sudden extrication of oxygen from the liquid metal, in the act of condensation. On the other hand, the cake should not be allowed to cool too long in the air, lest it get peroxidized upon the surface, and lose those fine red, purple, and yellow shades, due to a film of the protoxide, which many dealers admire.

When a little oxide of antimony and oxide of copper are combined with copper, they occasion the appearance of micaceous scales in the fractured faces. Such metal is hard, brittle, yellowish within, and can be neither laminated nor wire-drawn. These defects are not owing to arsenic, as was formerly imagined; but, most probably, to antimony in the lead, which is sometimes used in refining copper. They are more easily prevented than remedied.

According to M. Frèrejean, proprietor of the great copper works of Vienne, in Dauphiny, too low a temperature or too much charcoal, gives to the metal a cubical structure, or that of divergent rays; in either of which states it wants tenacity. Too high a temperature, or too rapid a supply of oxygen, gives it a brick red colour, a radiated crystallization without lustre, or a very fine grain of indeterminate form; the last structure being unsuitable for copper that is to be worked under the hammer or in the rolling-press. The form which indicates most tenacity is radiated with minute fibres glistening in mass. Melted copper will sometimes pass successively through these three states in the space of ten minutes.

Fig. 388. represents a *roasting mound* of copper pyrites in the Lower Hartz, near Goslar, where a portion of the sulphur is collected. It is a vertical section of a truncated quadrangular pyramid. A layer of wooden billets is arranged at the base of the pyramid in the line *a a*.

c, a wooden chimney which stands in the centre of the mound with a small pile of charcoal at its bottom, c; *d d* are large lumps of ore surrounded by smaller pieces; *f f*, are rubbish and earth to form a covering. A current of air is admitted under the billets by an opening, in the middle of each of the four sides of the base *a a*, so that two principal currents of air cross under the vertical axis c of the truncated pyramid, as indicated in the figure.



The fire is applied through the chimney c; the charcoal at its bottom c, and the pile *a a* are kindled. The sulphureous ores *d*, *f*, are raised to such a high temperature as to expel the sulphur in the state of vapour.

In the Lower Hartz a roasting mound continues burning during four months. Some days after it is kindled the sulphur begins to exhale, and is condensed by the air at the upper surface of the pyramid. When this seems impregnated with it, small basins 1 1 are excavated, in which some liquid sulphur collects; it is removed from time to time with iron ladles, and thrown into water, where it solidifies. It is then refined and cast into roll brimstone.

A similar roasting mound contains, in the Lower Hartz, from 100 to 110 tons of ore and 730 cubic feet of wood. It yields in four months about one ton and a half of sulphur from copper pyrites. Lead ore is treated in the same way, but it furnishes less sulphur.

There are usually from 12 to 15 roasting heaps in action at once for three smelting works of the Lower Hartz. After the first roasting two heaps are united to form a third, which is calcined anew, but under a shed; the ores are then stirred up and roasted for the third time, whence a crude mixture is procured for the smelting-house.

The most favourable seasons for roasting in the open air are spring and autumn; the best weather is a light wind accompanied with gentle rain. When the wind or rain obstruct the operation, this inconvenience is remedied by planks distributed round the upper surface of the truncated pyramid over the sulphur basins.

Manufacturing assays of copper. — The first thing is to make such a sample as will represent the whole mass to be valued; with which view, fragments must be taken from different spots, mixed, weighed, and ground together. A portion of this mixture being tried by the blow-pipe, will show, by the garlic or sulphurous smell of its fumes, whether arsenic, sulphur, or both, be the mineralizers. In the latter case, which often occurs, 100 gr. or 1000 gr. of the ore are to be mixed with one half its weight of saw-dust, then imbued with oil, and heated moderately in a crucible till all the arsenical fumes be dissipated. The residuum being cooled and triturated, is to be exposed in a shallow earthen cup to a slow roasting heat, till the sulphur and charcoal be burned away. What remains being ground and mixed with half its weight of calcined borax, one-twelfth its weight of lamp black, next made into a dough with a few drops of oil, is to be pressed down into a crucible, which is to be covered with a luted lid, and to be subjected, in a powerful air furnace, first to a dull red heat, and then to vivid ignition for 20 minutes. On cooling and breaking the crucible, a button of metallic copper will be obtained. Its colour and malleability indicate pretty well the quality, as does its weight, the relative value of the ore. It should be cupelled with lead, to ascertain if it contains silver or gold. See ASSAY, and SILVER.

If the blow-pipe trial showed no arsenic, the first calcination may be omitted; and if neither sulphur nor arsenic, a portion of the ground ore should be dried, and treated directly with borax, lamp black and oil. It is very common to make a dry assay of copper ores, by one roasting and one fusion along with 3 parts of black flux; from the weight of the metallic button the richness of the ore is inferred.

The humid assay is more exact, but it requires more skill and time.

The sulphur and the silica are easily got rid of, by the acids which do not dissolve them, but only the metallic oxides and the other earths. These oxides may then be thrown down by their appropriate reagents, the copper being precipitated in the state of either the black oxide, or pure metal. 105 parts of black oxide represent 100 of copper. Before entering upon the complete analysis of an ore, preliminary trials should be made, to ascertain what are its chief constituents. If it be sulphuret of copper, or copper pyrites, without silver or lead, 100 grains exactly of its average powder may be weighed out, treated in a matras with boiling muriatic acid for some time, gradually adding a few drops of nitric acid, till all action ceases, or till the ore be all dissolved. The insoluble matter found floating in the liquid contains most of the sulphur; it may be separated upon a filter, washed, dried, and weighed; then verified by burning away. The incombustible residuum, treated by muriatic acid, may leave an insoluble deposit, which is to be added to the former. To the whole of the filtered solutions carbonate of potash is

to be added; and the resulting precipitate, being washed, and digested repeatedly in water of ammonia, all its cupric oxide will have been dissolved, whenever the ammonia is no longer rendered blue.

Caustic potash, boiled with the ammoniacal solution, will separate the copper in the state of black oxide; which is to be thrown upon a filter, washed, dried, and weighed. The matter left undissolved by the ammonia, consists of oxide of iron, with probably a little alumina. The latter being separated by caustic potash, the iron oxide may be also washed, dried, and weighed. The powder which originally resisted the muriatic acid, is silica.

Assay of copper ores, which contain iron, sulphur, silver, lead, and antimony.

100 grains of these ores, previously sampled, and pulverized, are to be boiled with nitric acid, adding fresh portions of it from time to time, till no more of the matter be dissolved. The whole liquors which have been successively digested and decanted off, are to be filtered and treated with common salt, to precipitate the silver in the state of a chloride.

The nitric acid, by its reaction upon the sulphur, having generated sulphuric acid, this will combine with the lead oxidized at the same time, constituting insoluble sulphate of lead, which will remain mixed with the gangue. Should a little nitrate of lead remain in the liquid, it may be thrown down by sulphate of soda, after the silver has been separated. The dilute liquid being concentrated by evaporation, is to be mixed with ammonia in such excess as to dissolve all the cupric oxide, while it throws down all the oxide of iron and alumina; which two may be separated, as usual, by a little caustic potash. The portion of ore insoluble in the nitric acid, being digested in muriatic acid, every thing will be dissolved except the sulphur and silica. These being collected upon a filter, and dried, the sulphur may be burned away, whereby the proportion of each is determined.

Ores of the oxide *of copper*, are easily analyzed by solution in nitric acid, the addition of ammonia, to separate the other metals, and precipitation by potash. The *native carbonate* is analyzed by calcining 100 grains; when the loss of weight will shew the amount of water and carbonic acid; then that of the latter may be found, by expelling it from another 100 grains, by digestion in a given weight of sulphuric acid. The copper is, finally, obtained in a metallic state by plunging bars of zinc into the solution of the sulphate.

The *native arseniates of copper* are analyzed by drying them first at a moderate heat; after which they are to be dissolved in nitric acid. To this solution, one of nitrate of lead is to be added, as long as it occasions a precipitate; the deposit is to be drained upon a filter, and the clear liquid which passes through, being evaporated nearly to dryness, is to be digested in hot alcohol, which will dissolve every thing except a little arseniate of lead. This being added to the arseniate first obtained, from the weight of the whole, the arsenic acid, constituting 35 per cent., is directly inferred. The alcoholic solution being now evaporated to dryness, the residue is to be digested in water of ammonia, when the cupric oxide will be dissolved, and the oxide of iron will remain. The copper is procured, in the state of black oxide, by boiling the filtered ammoniacal solution with the proper quantity of potash.

The analysis of muriate of copper—*atacamite*—is an easy process. The ore being dissolved in nitric acid, a solution of nitrate silver is added, and from the weight of the chloride precipitated, the equivalent amount of muriate or chloride of copper is given; for 100 of chloride of silver represent 93 of chloride of copper, and 43·8 of its metallic basis. This calculation may be verified by precipitating the copper of the muriate from its solution in dilute sulphuric acid, by plates of zinc.

The phosphate of copper may be analyzed either by solution in nitric acid, and precipitation by potash; or by precipitating the phosphoric acid present, by means of acetate of lead. The phosphate of lead thus obtained, after being washed, is to be decomposed by dilute sulphuric acid. The insoluble sulphate of lead being washed, dried, and weighed, indicates by its equivalent the proportion of phosphate of lead, as also of phosphate of copper; for 100 of sulphate of lead correspond to 92·25 phosphate of lead, and 89·5 phosphate of copper; and this again to 52·7 of the black oxide.

Copper forms the basis of a greater number of important ALLOYS than any other metal. With zinc it forms Brass in all its varieties; which see.

BRONZE and BELL METAL are alloys of copper and tin. This compound is prepared in crucibles when only small quantities are required; but in reverberatory hearths, when statues, bells, or cannons are to be cast. The metals must be protected as much as possible during their combination from contact of air by a layer of pounded charcoal, otherwise two evils would result, waste of the copper by combustion, and a rapid oxidizement of the tin, so as to change the proportions and alter the properties of the alloy. The fused materials ought to be well mixed by stirring, to give uniformity to the compound. See BRONZE.

An alloy of 100 of copper and 4·17 of tin has been proposed by M. Chaudet for the ready manufacture of *medals*. After melting this alloy he casts it in moulds made of such bone-ash as is used for cupels. The medals are afterwards subjected to the action of the coining press, not for striking them, for the mould furnishes perfect impressions, but for finishing and polishing them.

By a recent analysis of M. Berthier, the bells of the *pendules*, or ornamental clocks, made in Paris, are found to be composed, of copper 72·00, tin 26·56, iron 1·44, in 100 parts.

An alloy of 100 of copper and 14 of tin is said by M. Dussaussy to furnish tools, which hardened and sharpened in the manner of the ancients, afford an edge nearly equal to that of steel.

Cymbals, gongs, and the *tamtam* of the Chinese are made of an alloy of 100 of copper with about 25 of tin. To give this compound the sonorous property in the highest degree it must be subjected to sudden refrigeration. M. D'Arcet, to whom this discovery is due, recommends to ignite the piece after it is cast, and to plunge it immediately into cold water. The sudden cooling gives the particles of the alloy such a disposition that, with a regulated pressure by skilful hammering, they may be made to slide over each other, and remain permanently in their new position. When by this means the instrument has received its intended form, it is to be heated and allowed to cool slowly in the air. The particles now take a different arrangement from what they would have done by sudden refrigeration; for instead of being ductile they possess such an elasticity, that on being displaced by a slight compression, they return to their primary position after a series of extremely rapid vibrations; whence a very powerful sound is emitted. Bronze, bell-metal, and probably all the other alloys of tin with copper present the same peculiarities.

The alloy of 100 of copper with from 60 to 33 of tin forms common *bell-metal*. It is yellowish or whitish gray, brittle, and sonorous, but not so much so as the preceding. The metal of house-clock bells contain a little more tin than that of church-bells, and the bell of a repeater contains a little zinc in addition to the other ingredients.

The bronze-founder should study to obtain a rapid fusion, in order to avoid the causes of waste indicated above. Reverberatory furnaces have been long adopted for this operation; and among these, the elliptical are the best. The furnaces with spheroidal domes are used by the bell-founders, because their alloy being more fusible, a more moderate melting heat is required; however, as the rapidity of the process is always a matter of consequence, they also would find advantage in employing the elliptical hearths (*see the form of the melting furnace, as figured under Smelting of copper ores.*) Coal is now universally preferred for fuel.

The alloy of 100 of copper with 50 of tin, or more exactly of 32 of the former with 14½ of the latter, constitutes *speculum* metal, for making mirrors of reflecting telescopes. This compound is nearly white, very brittle, and susceptible of a fine polish with a brilliant surface. The following compound is much esteemed in France for making specula. Melt 2 parts of pure copper and 1 of grain-tin in separate crucibles, incorporate thoroughly with a wooden spatula, and then run the metal into moulds. The lower surface is the one that should be worked into a mirror.

Mr. Edwards, in the Nautical Almanack for 1787, gave the following instructions for making speculum metal.

The quality of the copper is to be tried by making a series of alloys with tin, in the proportion of 100 of the former to 47, to 48, to 49, and to 50 of the latter metal; whence the proportions of the whitest compound may be ascertained. Beyond the last proportion, the alloy begins to lose in brilliancy of fracture, and to take a bluish tint. Having determined this point, take 32 parts of the copper, melt, and add one part of brass and as much silver, covering the surface of the mixture with a little black flux; when the whole is melted, stir with a wooden rod, and pour in from 15 to 16 parts of melted tin (as indicated by the preparatory trials), stir the mixture again, and immediately pour it out into cold water. Then melt again at the lowest heat, adding for every 16 parts of the compound 1 part of white arsenic, wrapped in paper, so that it may be thrust down to the bottom of the crucible. Stir with a wooden rod as long as arsenical fumes rise, and then pour it into a sand mould. While still red hot, lay the metal in a pot full of very hot embers, that it may cool very slowly, whereby the danger of its cracking or flying into splinters is prevented.

Having described the different alloys of copper and tin, I shall now treat of the method of separating these metals from each other as they exist in old cannons, damaged bells, &c. The process employed on a very great scale in France during the Revolution, for obtaining copper from bells, was contrived by Fourcroy; founded upon the chemical fact that tin is more fusible and oxidizable than copper.

1. A certain quantity of bell metal was completely oxidized by calcination in a reverberatory furnace; the oxide was raked out, and reduced to a fine powder.

2. Into the same furnace a fresh quantity of the same metal was introduced; it was

melted, and there was added to it one half of its weight of the oxide formed in the first operation. The temperature was increased, and the mixture well incorporated; at the end of a few hours, there was obtained on the one hand copper almost pure, which subsided in a liquid state, and spread itself upon the sole of the hearth, while a compound of oxide of tin, oxide of copper, with some of the earthy matters of the furnace collected on the surface of the metallic bath in a pasty form. These scoriæ were removed with a rake, and as soon as the surface of the melted copper was laid bare, it was run out. The scoriæ were levigated, and the particles of metallic copper were obtained after elutriation. By this process, from 100 pounds of bell metal, about 50 pounds of copper were extracted, containing only one *per cent.* of foreign matters.

3. The washed scoriæ were mixed with ⅛ their weight of pulverised charcoal; the mixture was triturated to effect a more intimate distribution of the charcoal; and it was then put into a reverberatory hearth, in which, by aid of a high heat, a second reduction was effected, yielding a fluid alloy consisting of about 60 parts of copper and 20 of tin; while the surface of the bath got covered with new scoriæ containing a larger proportion of tin than the first.

4. The alloy of 60 of copper with 40 of tin was next calcined in the same reverberatory furnace, but with stirring of the mass. The air in sweeping across the surface of the bath, oxidized the tin more rapidly than the copper; whence proceeded crusts of oxide that were skimmed off from time to time. This process was continued till the metallic alloy was brought to the same standard as bell metal, when it was run out to be subjected to the same operations as the metal of No. 1.

The layers of oxide successively removed in this way were mixed with charcoal, and reduced in a *fourneau à manche*, or Scotch lead smelting furnace.

I shall not prosecute any further the details of this complicated process of Fourcroy; because it has been superseded by a much better one contrived by M. Bréant. He employed a much larger quantity of charcoal to reduce the scoriæ rich in tin; and increased the fusibility by adding crushed oyster-shells, bottle glass, or even vitrified scoriæ, according to the nature of the substance to be reduced; and he treated them directly in a reverberatory furnace.

The metal, thus procured, was very rich in tin. He exposed it in masses on a sloping hearth of a reverberatory furnace, where, by a heat regulated according to the proportions of the two metals in the alloy, he occasioned an eliquation or sweating out of the tin. Metallic drops were seen to transpire round the alloyed blocks or pigs, and, falling like rain, flowed down the sloping floor of the furnace; on whose concave bottom the metal collected, and was ladled out into moulds. When the alloy, thus treated, contained lead, this metal was found in the first portions that sweated out. The purest tin next came forth, while the last portions held more or less copper in solution. By fractioning the products, therefore, there was procured:

1. Tin with lead.
2. Tin nearly pure.
3. Tin alloyed with a little copper.

A spongy mass remained, exhibiting sometimes beautiful crystallizations; this mass, commonly too rich in copper to afford tin by liquation, was treated by oxidizement. In this manner, M. Bréant diminished greatly the reductions and oxidations; and therefore incurred in a far less degree the enormous waste of tin, which flies off with the draught of air in high and long continued heats. He also consumed less fuel as well as labour, and obtained purer products of known composition, ready to be applied directly in many arts.

He treated advantageously in this manner more than a million of kilogrammes (1000 tons) of scoriæ, for every 2 cwts. of which he paid 40 *centimes* (four-pence), while several million kilogrammes of much richer scoriæ had been previously sold to other refiners at 5 *centimes* or one *sous*.

I have said that the ancients made their tools and military weapons of bronze. Several of these have been analyzed, and the results are interesting.

An antique sword found in 1799, in the peat moss of the Somme, consisted of copper 87·47; tin 12·53, in 100 parts.

The bronze springs for the balistæ, according to Philo of Byzantium, were made of copper 97, tin 3.

Hard and brittle nails afforded by analysis, 92 of copper, and 8 of tin.

Of three antique swords found in the environs of Abbeville, one was found to consist of 85 of copper to 15 of tin. The nails of the handle of this sword were flexible; they were composed of copper 95, tin 5.

Another of the swords consisted of 90 of copper and 10 of tin; and the third, of 96 copper, with 4 tin.

A fragment of an ancient scythe afforded to analysis 92·6 copper, and 7·4 tin.

The process of coating copper with tin, exemplifies the strong affinity between the two metals. The copper surface to be tinned is first cleared up with a smooth sand-

stone; then it is heated and rubbed over with a little sal ammoniac, till it be perfectly clean and bright; the tin, along with some pounded rosin, is now placed on the copper, which is made so hot as to melt the tin, and allow of its being spread over the surface with a dossil or pad of tow. The layer thus fixed on the copper is exceedingly thin; Bayen found that a copper pan, 9 inches in diameter and $3\frac{1}{4}$ inches deep, being weighed immediately before and after tinning, became only 21 grains heavier. Now as the area tinned, including the bottom, amounted to 155 square inches, 1 grain of tin had been spread over nearly $7\frac{1}{2}$ square inches; or only 20 grains over every square foot.

Copper and Arsenic form a white-coloured alloy, sometimes used for the scales of thermometers and barometers; for dials, candlesticks, &c. To form this compound, successive layers of copper clippings and white arsenic are put into an earthen crucible; which is then covered with sea salt, closed with a lid, and gradually heated to redness. If 2 parts of arsenic have been used with 5 of copper, the resulting compound commonly contains one tenth of its weight of metallic arsenic. It is white, slightly ductile, denser, and more fusible than copper, and without action on oxygen at ordinary temperatures; but, at higher heats, it is decomposed with the exhalation of arsenious acid. The white copper of the Chinese consists of 40·4 copper; 31·6 nickel; 25·4 zinc; and 2·6 iron. This alloy is nearly silver white; it is very sonorous, well polished, malleable at common temperatures, and even at a cherry red, but very brittle at a red-white heat. When heated with contact of air, it oxidizes, burning with a white flame. Its specific gravity was 8·432. When worked with great care, it may be reduced to thin leaves, and to wires as small as a needle. See GERMAN SILVER, *infra*.

Tutenag, formerly confounded with white copper, is a different composition from the above. Keir says it is composed of copper, zinc, and iron; and Dick describes it as a short metal, of a grayish colour, and scarcely sonorous. The Chinese export it, in large quanties, to India.

M. Pelouze states that an alloy of equal parts of copper and nickel is greatly preferable to an alloy which contains also zinc. Even 2 of copper and 1 of nickel form a valuable alloy.

COPPER, WHITE, or *German silver*. M. Gersdorf, of Vienna, states, that the proportions of the metals in this alloy should vary according to the uses for which it is destined. When intended as a substitute for silver, it should be composed of 25 parts of nickel, 25 of zinc, and 50 of copper. An alloy better adapted for rolling consists of 25 of nickel, 20 of zinc, and 60 of copper. Castings, such as candlesticks, bells, &c., may be made of an alloy, consisting of 20 of nickel, 20 of zinc, and 60 of copper; to which 3 of lead are added. The addition of 2 or $2\frac{1}{2}$ of iron (in the shape of tin plate?) renders the pakfong much whiter, but, at the same time, harder and more brittle.

Keferstein has given the following analysis of the genuine German silver, as made from the original ore found in Hildburghausen, near Suhl, in Henneberg: —

Copper - - -	40·4
Nickel - - -	31·6
Zinc - - -	25·4
Iron - - -	2·6
	100·0

Chinese pakfong, according to the same authority, consists of 5 parts of copper, alloyed with 7 parts of nickel, and 7 parts of zinc.

The best alloy for making plummer blocks, bushes, and steps for the steel or iron gudgeons, and pivots of machinery to run in, is said to consist of 90 parts of copper, 5 of zinc, and 5 of antimony.

A factitious protoxide of copper, of a fine red colour, may be made by melting together, with a gentle heat, 100 parts of sulphate of copper, and 50 of carbonate of soda in crystals, and continuing the heat till the mass become solid. This being pulverized, and mixed exactly with 15 parts of copper filings, the mixture is to be heated to whiteness, in a crucible, during the space of 20 minutes. The mass, when cold, is to be reduced to powder, and washed. A beautiful metallic pigment may be thus prepared, at the cost of 2*s*. a pound.

All the oxides and salts of copper are poisonous; they are best counteracted by administering a large quantity of sugar, and sulphuretted hydrogen water.

The following scientific summray of copper ores in alphabetical order may prove acceptable to many readers, amid the present perplexing distribution of the native metallic compounds in mineralogical systems.

1. *Arseniate of Copper.*

A. *Erinite*, rhomboidal arseniate of copper, micaceous copper, *kupferglimmer*. Emerald green: specific gravity 4·043; scratches calc-spar; yields water by heat; fusible at the blowpipe, and reducible into a white metallic globule. Soluble in nitric acid; the solution throws down copper by iron. It consists of arsenic acid 33·78; oxide of copper 59·24; water 5; alumina 1·77. It is found in Cornwall, Ireland, Hungary.

B. *Liroconite;* octahedral arseniate of copper; lens ore, so called from the flatness of the crystal. Blue; specific gravity 2·88; scratches calc-spar. It consists of arsenic acid 14; oxide of copper 49; water 35. It is found in Huel-Mutrel, Huel-Gorland, Huel-Unity, mines in Cornwall.

C. *Olivenite;* right prismatic arseniate of copper; olive-ore. Dull green; specific gravity 4·28; scratches fluor; yields no water by heat; fusible at the blowpipe into a glassy bead, enclosing a white metallic grain. It consists of arsenic acid 45, oxide of copper 50·62. It affords indications of phosphoric acid, which the analysts seem to have overlooked. It occurs in the above and many other mines in Cornwall.

D. *Aphanese.* Trihedral arseniate of copper. Bluish green, becoming gray upon the surface; specific gravity 4·28; scarcely scratches calc-spar; yields water with heat; and traces of phosphoric acid.

The fibrous varieties called wood copper, contain water, and resemble the last species in composition.

2. *Carbonate of Copper.*

A. *Azurite;* kupferlazur. Blue. Crystallizes in oblique rhomboidal prisms; specific gravity 3 to 3·83; scratches calc-spar, is scratched by fluor; yields water with heat, and blackens. Its constituents are, carbonic acid 25·5; oxide of copper 69·1; water 5·4. The Chessy and Banat azurite is most profitably employed to make sulphate of copper.

B. *Malachite;* green carbonate or mountain green. Crystallizes in right rhomboidal prisms; specific gravity 3·5; affords water with heat, and blackens. It consists of carbonic acid 18·5; oxide of copper 72·2; water 9·3.

C. *Mysorine;* anhydrous carbonate of copper. Dark brown generally stained green or red; conchoidal fracture; soft, sectile; specific gravity 2·62. It consists of carbonic acid 16·7; oxide of copper 60·75; peroxide of iron 19·5; silica 2·10. This is a rare mineral found in the Mysore.

3. *Chromate of Copper and Lead;* vauquelinite. Green of various shades; specific gravity 6·8 to 7·2; brittle; scratched by fluor; fusible at the blowpipe with froth and the production of a leaden bead. It consists of chromic acid 28·33; oxide of lead 60·87; oxide of copper 10·8. It occurs at Berezof in Siberia along with chromate of lead.

4. *Dioptase;* silicate of copper; emerald copper. Specific gravity 3·3; scratches glass with difficulty; affords water with heat, and blackens; infusible at the blowpipe. It consists of silica 43·18; oxide of copper 45·46; water 11·36. This rare substance comes from the government of Kirgis.

The silicate of Dillenberg is similar in composition.

5. Gray copper ore called Panabase, from the number of metallic bases which it contains; and Fahlerz. Steel gray; specific gravity 4·79 to 5·10; crystallizes in regular tetrahedrons; fusible at the blowpipe, with disengagement of fumes of antimony and occasionally of arsenic; swells up and scorifies, affording copper with soda flux. Is acted upon by nitric acid with precipitation of antimony; becomes blue with ammonia; yields a blue precipitate with ferrocyanide of potassium; as also indications frequently of zinc, mercury, silver, &c. Its composition, which is very complex, is as follows; sulphur 26·83; antimony 12·46; arsenic 10·19; copper 40·60; iron 4·66; zinc 3·69; silver 0·60. Some specimens contain from 5 to 31 per cent. of silver. The gray copper ores are very common; in Sazony; the Hartz; Cornwall; at Dillenberg; in Mexico; Peru, &c. They are important on account both of their copper and silver. *Tennantite* is a variety of Fahlerz. It occurs in Cornwall. Its constituents are, sulphur 28·74; arsenic 11·84; copper 45·32; iron 9·26.

6. *Hydrated silicate of Copper;* or Chrysocolla. Green or bluish green; specific gravity 2·03 to 2·16; scratched by steel; very brittle; affords water with heat, and blackens; is acted upon by acids, and leaves a siliceous residuum. Solution becomes blue with ammonia. Its constituents are silica 26; oxide of copper 50; water 17; carbonic acid 7.

7. *Muriate of Copper.* Atakamite; green; crystallizes in prisms; specific gravity 4·43. Its constituents are, chlorine 15·90; copper 14·22; oxide of copper 54·22; water 14·16; oxide of iron 1·50. The green sand of Peru, collected by the inhabitants of Atakama, is this substance in a decomposed state.

8. *Oxide of Copper.*

A. Black, or Melaconise; a black earthy looking substance found at Chessy and other places. It is deutoxide of copper.

B. Protoxide or red oxide of copper; ziegelerz. Crystallizes in the regular octahedron; specific gravity 5·69; scratches calc-spar; fusible at the blowpipe into the black oxide; and reducible in the smoke of the flame to copper; acted upon by nitric acid with disengagement of nitrous gas; solution is rendered blue by ammonia. Its constituents are oxygen 11·22; copper 88·78. It occurs near Chessy, and upon the eastern slope of the Altai mountains.

9. *Phosphate of Copper.* Dark green; crystallizes in octahedrons; specific gravity 3·6 to 3·8; scratches calc-spar; yields water with heat; and affords metallic copper

with soda flux; acted on by nitric acid. Its constituents are, phosphoric acid 28·7; oxide of copper 68·9; water 7·4. It occurs in the mines of Libethen in Hungary.

10. *Pyritous Copper;* Kupferkies; a metallic looking substance, of a bronze-yellow colour, crystallizing in octahedrons which pass into tetrahedrons; specific gravity 4·16; fusible at the blowpipe into beads attractable by the magnet, and which afterwards afford copper with a soda flux; soluble in nitric acid; solution is rendered blue by ammonia, and affords an abundant precipitate of iron. Its composition is, sulphur 36; copper 34·5; iron 30·5; being a combined sulphuret of these two metals. This is the most important metallurgic species of copper ores. It occurs chiefly in primitive formations, as among gneiss and mica slate, in veins or more frequently masses in very many parts of the world—Cornwall, Anglesea, Wicklow, &c. It is found among the early secondary rocks, in Shetland, Yorkshire, Mannsfeldt, &c. The finest crystallized specimens come from Cornwall, Derbyshire, Freyberg, and Saint Marie-aux-Mines in France.

11. *Seleniate of Copper*; Berzeline. Is of metallic aspect; silver white; ductile; fusible at the blowpipe into a gray bead, somewhat malleable; is acted upon by nitric acid; consists of selenium 40; copper 64.

12. *Sulphate of Copper;* Cyanose. Blue; soluble, &c. like the artificial sulphates, which see.

Brochantite is a subsulphate of copper observed in small crystals at Ekaterinenbourg in Siberia.

13. *Sulphuret of Copper*; Kupferglanz. Of a steel gray metallic aspect; crystallizes in rhomboids; specific gravity 5·69; somewhat sectile, yet brittle; fusible with intumescence at the blowpipe, and yields a copper bead with soda; soluble in nitric acid; becomes blue with ammonia, but lets fall scarcely any oxide of iron. Its constituents are, sulphur 19; copper 79·5; iron 0·75; silica 1·00. It occurs in small quantities in Cornwall, &c.

The chemical preparations of copper which constitute distinct manufactures are, Blue or Roman vitriol; for which see *Sulphate of Copper;* Scheele's green and Schweinfurth green, Verditer, and Verdigris. See these articles in their alphabetical places.

The copper mines, now so important, were so little worked until a recent period, that in 1799 we are told in a Report on the Cornish mines, "it was not until the beginning of the last century that copper was discovered in Britain." This is not correct for in 1250, a copper mine was worked near Keswick in Cumberland. Edward III. granted an indenture to John Ballanter and Walter Bolbolter, for working all "mines of gold, silver, and copper;" but that the quantity found was very small is proved from the fact that Acts of Parliament were passed in the reigns of Henry VIII. and Edward VI. to prevent the exportation of brass and copper, "lest there should not be metal enough left in the kingdom, fit for making guns and other engines of war, and for household utensils:" and in 1665 the calamine works were encouraged by the government, as "the continuing these works in England will occasion plenty of rough copper to be brought in."

At the end of the seventeenth century some "gentlemen from Bristol made it their business to inspect the Cornish mines, and bought the copper for 2*l.* 10*s.* per ton, and scarce ever more than 4*l.* a ton."

In 1700, one Mr. John Costor introduced an hydraulic engine into Cornwall, by which he succeeded in draining the mines, and "he taught the people of Cornwall also a better way of assaying and dressing the ore."

The value and importance of copper mines since that period has been regularly increasing. During a term of about 30 years 220 mines have sold their ores at the public sales. The following table (p. 490.) from a report by Sir Charles Lemon, Bart., M. P., represents the progress of copper mining, from 1771 to 1837:—

The produce of the copper mines of Cornwall since 1845, has been as follows:—

Years.	Ore in Tons.	Copper in Tons.	Money Value.
			£ s.
1845	162,557	12,883	919,934 6
1846	150,431	11,851	796,182 6
1847	155,985	12,754	889,287 0
1848	147,701	12,422	720,090 0
1849	146,326	11,683	763,614 0
1850	155,025	12,254	840,410 0

Years.	Tons of Ore.	Tons of Copper.	Total Value of Ore.	Standard Value per Ton.
			£	
1771	27,896	3,347	189,609	81
1780	24,433	2,932	171,231	83
1799	51,273	4,223	469,664	121

1827	126,700	10,311	745,178	106
1831	146,502	12,218	817,740	100
1837	140,753	10,823	908,613	119

With the improvements in the construction of the steam-engine, the facilities for working the mines have been increased. The first steam engine employed in the county was set to work at Huel Vor tin mines, near Helstone, in 1713, by Newcomen; but it was not until the reconstruction of the engine was effected by Watt that steam power was generally employed for draining the mines. The rapid advance made by Cornish engineers in the perfection of their engines will be seen by the following return of the duty, that is, the performance of each, which is reckoned by the number of millions of pounds lifted a foot high by the consumption of a bushel of coals:—

Name of Mine.	Highest Duty.
Stray Park, 1813	29,000,000
Dolcoath, 1816	40,000,000
Consolidated Mines, 1822	44,000,000
Consolidated Mines, 1827	67,000,000
Fowey Consols, 1834	97,000,000
United Mines, 1842	108,000,000

* Supplement to the Mining Journal, Feb. 28, 1838

Statistics of Copper for Cornwall in 1837.—The total quantity of ore sold was 142,089 tons (of 21 cwts.), yielding an average produce of eight per cent.; the quantity of fine copper being 11,209 tons 1 cwt.; and the average price of the ore *5l.* 15*s.* 6*d.*; the total amount of the sales for the twelve months being 822,516*l.* The standard upon the 5th of January was 127*l.* 16*s.*; this was the highest for the year. Upon the 22d of June it was at the lowest, being only 93*l.* 18*s.* It went up again to 120*l.* 10*s.* upon the 5th of October; but declined with some slight fluctuation to 107*l.* 18*s.* upon the 28th of December. The largest quantity sold at any one ticketing was 4670 tons, upon the 4th of May: and the smallest 1088, upon the 17th of August. The highest produce was nine and five-eighths per cent. upon the 13th of July; and the lowest, seven, upon the 26th of January. The greatest weekly total was 25,887*l.*, upon the 2nd of November, and the least *5694l.* upon the 17th of August. The average sum per week was *15,817l.**

Quantity of Copper produced in the several districts of Great Britain and Ireland: —

COPPERING IRON AND ZINC. The great advantages which would arise from perfecting a plan whereby the easily oxidizable metals, such as iron and zinc, could be coated with copper at a cheap rate, induced Messrs. Elsner & Philip, of Berlin, to undertake a series of experiments, to ascertain if such could not be effected more economically than by employing the cyanuret of potassium, and in this they have been successful. For coating iron the article must be well cleaned in rain or soft water, and rubbed before immersing it in the solution, which may be either chloride of potassium, chloride of sodium, with a little caustic ammonia added, or tartrate of potash, with a small portion of carbonate of potash. At the extremity of the wire, in connection with the copper, or negative pole of the battery, is fixed a thin flattened copper plate, and the article to be coated is attached to the wire from the zinc, or positive pole, and both are then immersed in the exciting solution, the copper plate only partially. The liquid should be kept at a temperature of from 15° to 20° Centigrade, and the success of the operation depends greatly on the strength and uniformity of the galvanic current. When the chlorides are employed, the coating is of a dark, natural copper colour; and with tartrate of potash, it assumes a red tinge, similar to the red oxide of copper. When sufficiently covered, the article is rubbed in sawdust, and exposed to a current of warm air to dry, when they will take a fine polish, and resist all atmospheric influence. In coating zinc with copper, the same general principles will apply as for iron, only observing that, in proportion to the size of the article, the galvanic current must be less powerful for zinc. The surfaces must be perfectly smooth, and for this reason it is well to rub them thoroughly with fine sand, and polish with a brush. Tartrate of potash is the best existing liquid for coating zinc. By very simple means large articles in iron and zinc may be coated with copper by the above cheap chemical solutions, which could not, at any former period, be effected from the high price of cyanuret of potassium.

COPPER MEDALS AND MEDALLIONS may be readily made in the following way: — Let black oxide of copper, in fine powder, be reduced to the metallic state, by exposing it to a stream of hydrogen, in a gun-barrel, heated barely to redness. The metallic powder thus obtained is to be sifted, through crape, upon the surface of the mould, to the thickness of ¼ or ⅛ of an inch, and is then to be strongly pressed upon it, first by the hand, and lastly by percussion with a hammer. The impression thus formed is beautiful; but it acquires much more solidity by exposure to a red heat, out of contact with air. Such medals are said to have more tenacity than melted copper, and to be sharply defined.

M. Bœttger proposes the following improvement upon the above plan of Mr. Osann: — He prepares the powder of copper easier and of better quality, by precipitating a boiling hot solution of sulphate of copper, with pieces of zinc, boiling the metallic powder thus obtained with dilute sulphuric acid for a little, to remove all traces of the zinc or oxide, washing it next with water, and drying it in a tubulated retort by the heat of a water bath, while a stream of hydrogen is passed over it. This cupreous precipitate possesses so energetic an affinity for oxygen, that it is difficult to prevent its passing into the state of orange oxide. If it be mixed with one-half its atomic weight of precipitated sulpher, and the two be ground together, they combine very soon into sulphuret of copper with the evolution of light.

COPPER, PURIFYING.—Copper may be purified by melting 100 parts of it with 10 parts of copper scales (black oxide), along with 10 parts of ground bottle-glass or other flux. Mr. Lewis Thompson, who received a gold medal from the Society of Arts for this invention, says, that after the copper has been kept in fusion for half an hour, it will be found at the bottom of the crucible perfectly pure; while the iron, lead, arsenic, &c., with which this metal is usually contaminated, will be oxidized by the scales, and will dissolve in the flux, or be volatilized. Thus he has obtained perfectly pure copper from brass, bell-metal, gun-metal, and several other alloys, containing from 4 up to 50 per cent. of iron, lead, antimony, bismuth, arsenic, &c. The scales of copper are cheap, being the product of every large manufactory where that metal is worked.

COPPERAS. (*Couperose verte*, Fr.; *Eisenvitriol*, Germ.) Sulphate of iron.

COPROLITES, or FOSSIL MANURE. Wherever there is an out-cropping of the upper green sand (the stratum in which coprolites are found)—and it extends a considerable distance around Cambridge—there these peculiar nodules may be met with. And this, the surface bottom of an ancient deep sea, appears to have been the receptacle of the bones and fæcal matter of its inhabitants for a long period, which matter is now, by the united penetrating researches of the chemist and geologist, brought to light, as containing the fertilizing principle and pabulum of vegetable life, verifying the axiom of chemistry, that nothing is lost in organic atoms, and that the refuse of former ages, in an indirect manner, produces the food of the present. The parish of Barnwell contains an extensive area of these coprolites or fossil dung.

The appearance of these nodules is in shape various; generally a hard, black, water-worn looking stone, with excrescences; some with convoluted marks, bearing the impress of the intestine, and rounded off at the extremities; the surface of all exhibiting lines from the decomposition of its more destructible component parts. Portions of coral, ammonites, crustacea, sponges, &c., may be found in the agglutinated mass. They vary in size from a small bird's egg to masses the size of a fist. A large selection from our own, as well as from distant localities,—the lias of Lyme, the chalk of Farnham, the slate of Newhaven, and the crag of Suffolk—are open for the inspection of those interested in most geological collections.

The process which they go through to render them available for use is as follows:—After being selected from the soil, they are well washed by rotatory machinery erected on the spot, and then conveyed by rail to the manufactory, where they are ground to a very fine powder; an operation, from their hardness, of no small difficulty, vertical granite and buhr stones being required. The powder is mixed with about an equal portion by weight of strong sulphuric acid. This is, I believe, a part of the process used in the manufactory of Mr. Lawes, who produces a very superior article, and to whom we are much indebted for his early attention to supply the increasing demand for phosphates as artificial manures, and who has been supplied with thousands of tons from digging over a four-acre field at Walton, in Suffolk, the subsoil of which was crag, producing to the farmer a much richer harvest than grain at the present free-trade prices. In an article varying, as it necessarily must, from extraneous matter, the component parts materially differ. The following analysis may be taken as an average of their composition, 100 parts containing—

Earthy phosphates	61
Carbonate of lime and iron	24
Insoluble	82
Moisture	3
	100

Mr. Lawes, from a sample from the same locality, made 7 more parts of phosphates, and Mr. Potter 4 less, than the above analysis.

There is a prevalent idea that these coprolites are almost the same as guano. This is a great mistake; for although our own production yields a larger proportion of the phosphates, it is devoid of salts of urea and ammonia, which, in combination with the phosphates, increases to a considerable extent the fertilizing principle for which that foreign article is so celebrated. It has been the object of artificial manures to supply synthetically the composition of guano at a much reduced rate.

In respect to the value of coprolites in Suffolk, besides giving employment at the slack season to many idle hands, a bonus has been given for the right of royalty over the soils, and 5*s.* per ton is paid the proprietor for all raised. This, with labour, washing,—a troublesome and tedious process,—and rail charges for delivery in London, costs from 35*s.* to 40*s.* per ton.

To show the comparative value of the different substances containing the phosphates, and that of guano, an analysis of a good sample is here given, and that of the phosphates and carbonate of lime in various bones. That portion contained in the fossil

remains of bone and coprolite is a beautiful illustration of the goodness of the Great Author of Nature — remains which, after being interred thousands of years, are by the labours of man brought again into action, that their elementary parts may be again separated and made subservient to his uses.

Silicic acid coloured red by a little undecomposed silicate of iron	5·792	6·309
	100·000 = PO^5 36·889	100·000 = PO^5 37·16

I. Fifty grains of the first specimen, in fine powder, when burnt with potash lime, furnished 0·20 gr. of platino-chloride of ammonium, which is equivalent to 0·0254 per cent. of nitrogen.

It is said that the coprolites which Mr. Lawes employs in the manufacture of his well-known "Coprolite manure," are obtained from the Suffolk coast, and are similar in character to the above.

In an excellent paper "On the Phosphoric Strata of the Chalk Formations," published in the first number of the Journal of the Royal Agricultural Society of England for last year, Mr. Way observes, that he has found the coprolites from this district to contain from 52 to 54 per cent. of bone-earth phosphate; and that Dr. Gilbert had informed him, that in several analyses which he had made of samples taken from several tons of the ground coprolites, he had found the proportion of phosphate of lime to vary between 55 and 57 per cent. Mr. Nesbit (Quart. Journ. of Chem. Soc. Part III. p. 235.) found from 22·30 to 28·74 per cent. of phosphoric acid, which is equivalent to from 48·31 to 59·07 of tribasic phosphate, in those from the tertiary deposits of this county.

II. This one was brought from the same part of the coast as the preceding; but differed from them in its irregularity of form, and in exhibiting imperfect evidences of a bony structure. The specific gravity it was found impossible to determine, on account of the numerous air cavities it contained.

Analysis showed it to possess the following per centage composition: —

Water driven off at from 300° to 350° F.	2·600
do. and organic matters expelled at a red heat	9·000
Chloride of sodium, &c.	evident traces
Carbonate of lime	39·500
do. magnesia	0·520
Sulphate of lime	distinct traces
Phosphate of lime (tribasic)	15·860 = PO^5 5·287
do. magnesia	traces
Perphosphate of iron	9·200 = PO^5 4·358
Phosphate of alumina	4·708 = PO^5 2·764
Peroxide of iron	none
Alumina	6·212
Fluoride of calcium	1·698
Silicic acid	10·601
	99·899 = PO^5 12·409

The proportion of nitrogen in this specimen was not estimated.

III. This coprolite was discovered in the lias strata of Lyme Regis.

It was rather large, being above 9 ozs. in weight, was of a grayish colour, and when broken exhibited some traces of a crystalline structure. It was considerably softer than either of the preceding, and furnished a grayish-white powder. Many scales of different extinct fishes, and other organic remains, were to be perceived on the external surface; the greater proportion of them appeared to belong to a species of fish which is known to ichthyologists by the name of *Pholidophorus limbatus*. Its specific gravity was about 2·644 or 2·700, and the composition per cent. was as follows: —

	I.	II.	Mean.	
Water driven off at from 300° to 350° F.	2·560	2·668	2·6140	
Water and organic matters expelled at a red heat	3·680	3·456	3·5680	
Chloride of sodium, with some sulphate of soda	traces	traces	traces	
Carbonate of lime	23·640	23·708	23·6740	
do. of magnesia	none	none	none	
Sulphate of lime	1·740	1·801	1·7705	
Phosphate of do. (tribasic)	60·726	60·813	60·7695 = PO^5 28·047	
do. magnesia	a little	a little	a little	
Perphosphate of iron	3·980	4·135	4·0575 = PO^5 1·922	
Phosphate of alumina	a little	a little	a little	
Peroxide of iron	2·094	1·894	1·9940	
Alumina	none	none	none	
Silicic acid, with fluoride of calcium and loss	1·580	1·525	1·5525	
	100·000	100·000	100·0000 = PO^5 29·969*	

The proportion of nitrogen in this specimen was rather large, being 0 0826 per cent. — *Thornton J. Herapath.*

CORAL (*Corail*, Fr.; *Koralle*, Germ.) is a calcareous substance, formed by a species of sea polypus, which construct in concert immense ramified habitations, consisting of an assemblage of small cells, each the abode of an animal. The coral is, therefore, a real polypary, which resembles a tree stripped of its leaves. It has no roots, but a foot not unlike a hemispherical skull-cap, which applies closely to every point of the surface upon which it stands, and is therefore difficult to detach. It merely serves as a basis or support to the coral, but contributes in no manner to its growth, like the root of an ordinary tree, for detached pieces have been often found at the bottom of the sea in a state of increase and reproduction. From the above base a stem, usually single, proceeds, which seldom surpasses an inch in diameter, and from it a small number of branches ramify in very irregular directions, which are studded over with cells, each containing an insect. The polypi, when they extend their arms, feelers, or *tentacula*, resemble flowers, whence, as well as from the form of the coral, they were classed among vegetable productions. They are now styled zoophites by the writers upon Natural History.

The finest coral is found in the Mediterranean. It is fished for upon the coasts of Provence, and constitutes a considerable branch of trade at Marseilles. The coral is at-

* In the first of these analyses, the phosphoric acid was estimated by M. Schulze's method, as perphosphate of iron; in the second, as phosphate of lead.

tached to the submarine rocks, as a tree is by the roots, but the branches, instead of growing upwards, shoot downwards towards the bottom of the sea; a conformation favourable to breaking them off and bringing them up. For this kind of fishing, eight men, who are excellent divers, equip a felucca or small boat, called commonly a coral line. They carry with them a large wooden cross, with strong, equal, and long arms, each bearing a stout bag-net. They attach a strong rope to the middle of the cross, and let it down horizontally into the sea, having loaded its centre with a weight sufficient to sink it. The diver follows the cross, pushes one arm of it after another into the hollows of the rocks, so as to entangle the coral in the nets. Then his comrades in the boat pull up the cross and its accompaniments.

Coral fishing is nearly as dangerous as pearl fishing, on account of the number of sharks which frequent the seas where it is carried on. One would think the diving-bell in its now very practicable state might be employed with great advantage for both purposes.

Coral is mostly of a fine red colour, but occasionally it is flesh-coloured, yellow, or white. The red is preferred for making necklaces, crosses, and other female ornaments. It is worked up like precious stones. See LAPIDARY.

CORK (*Liège*, Fr.; *Kork*, Germ.) is the bark of the *quercus liber*, Linn., a species of oak-tree, which grows abundantly in the southern provinces of France, Italy and Spain. The bark is taken off by making coronal incisions above and below the portions to be removed; vertical incisions are then made from one of these circles to another, whereby the bark may be easily detached. It is steeped in water to soften it, in order to be flattened by pressure under heavy stones, and next dried at a fire which blackens its surface. The cakes are bound up in bales and sent into the market.

There are two sorts of cork, the white and the black; the former grows in France and the latter in Spain. The cakes of the white are usually more beautiful, more smooth, lighter, freer from knots and cracks, of a finer grain, of a yellowish-gray colour on both sides, and cut more smoothly than the black. When this cork is burnt in close vessels it forms the pigment called *Spanish black*.

This substance is employed to fabricate not only bottle corks, but small architectural and geognostic models, which are very convenient from their lightness and solidity.

The cork-cutters divide the boards of cork first into narrow fillets, which they afterwards subdivide into short parallelopipeds, and then round these into the proper conical or cylindrical shape. The bench before which they work is a square table where four workmen are seated, one at every side, the table being furnished with a ledge to prevent the corks from falling over. The cork-cutter's knife is a broad blade, very thin, and fine edged. It is whetted from time to time upon a fine-grained dry whetstone. The workman ought not to draw his knife edge over the cork, for he would thus make misses, and might cut himself, but rather the cork over the knife edge. He should seize the knife with his left hand, rest the back of it upon the edge of the table, into one of the notches made to prevent it from slipping, and merely turns its edge sometimes upright and sometimes to one side. Then holding the squared piece of cork by its two ends, between his finger and his thumb, he presents it in the direction of its length to the edge; the cork is now smoothly cut into a rounded form by being dexterously turned in the hand. He next cuts off the two ends, when the cork is finished and thrown into the proper basket alongside, to be afterwards sorted by women or boys.

Of late years a much thicker kind of cork boards have been imported from Catalonia, from which longer and better corks may be made. In the art of cork-cutting the French surpass the English, as any one may convince himself by comparing the corks of their champagne bottles with those made in this country.

Cork, on account of its buoyancy in water, is extensively employed for making floats to fishermen's nets, and in the construction of life-boats. Its impermeability to water has led to its employment for inner soles to shoes.

When cork is rasped into powder, and subjected to chemical solvents, such as alcohol, &c., it leaves 70 per cent. of an insoluble substance, called *suberine*. When it is treated with nitric acid, it yields the following remarkable products: — White fibrous matter 0·18, resin 14·72, oxalic acid 16·00, suberic acid (peculiar acid of cork) 14·4 in 100 parts.

Machine cork-cutting.—A patent was obtained some years ago by Sarah Thomson for this purpose. The cutting of the cork into slips is effected by fixing it upon the sliding bed of an engine, and bringing it, by a progressive motion, under the action of a circular knife, by which it is cut into slips of equal widths. The nature or construction of a machine to be used for this purpose may be easily conceived, as it possesses no new mechanical feature, except in its application to cutting cork. The motion communicated to the knife by hand, steam, horse, or other power, moves at the same time the bed also, which carries the cork to be cut.

The second part of the invention, viz., that for separating the cork into square pieces, after it has been cut into slips as above, is effected by a moving bed as before, upon which

the slips are to be placed and submitted to the action of a cutting lever, which may be regulated to chop the cork into pieces of any given length.

The third part of the invention, viz., that for rounding or finishing the corks, consists of an engine to which is attached a circular knife that turns vertically, and a carriage or frame upon its side that revolves on its axle horizontally.

This carriage or frame contains several pairs of clamps intended respectively to hold a piece of the square cut cork by pressing it at the ends, and carrying it lengthways perpendicularly; which clamps are contrived to have a spindle motion, by means of a pinion at the lower end of their axles, working into a spur-wheel.

The machinery, thus arranged, is put in motion by means of bands and drum-wheels, or any other contrivance which may be found most eligible; and at the same time that the circular knife revolves vertically, the frame containing the clamps with the pieces of cork, turns horizontally, bringing the corks, one by one, up to the edge of the knife, when, to render each piece of cork cylindrical, the clamps, as above described, revolve upon their axes, independently of their carriage, by which means the whole circumference of the cork is brought under the action of the knife, the superfluous parts are uniformly pared off, and the cork finished smooth and cylindrical. The quantity entered for home consumption amounts to about 2200 tons per annum.

CORROSIVE SUBLIMATE; bichloride of mercury.

CORUNDUM. This mineral species includes sapphire, corundum stone, and emery. It consists of pure alumina coloured from admixture with oxide of iron.

	Blue Sapphire, China.		Corundum, Bengal.	Emery, Naxos.
Alumina -	98·5	84·0	89·5	86·0
Lime - -	0·5	0·0	0·0	3·0
Silica - -	0·0	6·5	5·5	3·0
Oxide of iron -	1·0	7·5	1·25	4·0
	100·0 Klapr.	98·0 Chen.	98·2 Tennent.	96·0 Tennent.

The perfectly white crystals of sapphire are pure alumina.

There are two varieties of the perfect corundum; the sapphire so called, and the Oriental ruby; of which the latter has a rather less specific gravity, being 3·9 against 3·97. Their form is a slightly acute rhomboid, which possesses double refraction, and is inferior in hardness only to the diamond. The sapphire occurs also in 6-sided prisms.

COTTON DYEING, (*Teinture de Coton*, Fr.; *Baumwollenfärberei*, Germ.) Cotton and linen yarns and cloths have nearly the same affinity for dyes, and may therefore with propriety be treated, in this respect, together. After they have acquired the proper degree of whiteness (see BLEACHING) they are still unfit to receive and retain the dyes in a permanent manner. It is necessary before dipping them into the dye-bath, to give them a tendency to condense the colouring particles within their cavities or pores, and to communicate such chemical properties as will fix these particles so that they will not separate, to whatever ordinary trial they may be subjected. All the colours which it would be desirable to transfer to these stuffs unfortunately do not possess this permanence. Men of science engaged in this important art have constantly aimed at the discovery of some new processes which may transfer into the class of fast colours those dyes which are at present more or less fugitive. Almost all the goods manufactured of cotton, flax, or hemp, are intended to be washed, and ought, therefore, to be so dyed as to resist the alkaline and soapy solutions commonly used in the laundry. Vitalis distinguished dyed cottons into three classes; 1. the *fugitive*, or fancy-coloured (*petit teint*), which change their hue or are destroyed by one or two boils with soap; 2. those which resist five or six careful washings with soap are *good* dyes, (*bon teint*); and those which were still more durable, such as Turkey reds, may be called fast colours (*grand teint*). The colours of Brazil wood, logwood, annotto, safflower, &c., are *fugitive*; those made with madder without an oily base are *good*; and those of madder, with an oily mordant, are *fast*. It is, however, possible to point out certain processes for giving these different orders of dyes a greater degree of fixity.

I shall describe, in the five following paragraphs, the operations conducive to the fixation of colours upon cotton and linen.

1. *Galling*. Either gall nuts alone, or sumach alone, or these two substances united, are employed to give to cotton the fast dye preparation. 2 or 3 ounces of galls for every pound of cotton, being coarsely pounded, are to be put into a copper containing about 30 gallons of water for every 100 pounds of cotton, and the bath is to be boiled till the bits

of galls feel pasty between the fingers. The fire being withdrawn, when the bath becomes moderately cool, it is passed through a hair-cloth sieve. If during this operation the liquor should become cold, it must be made once more as hot as the hand can bear. A portion of it is now transferred into another vessel, called a *back*, in which the cotton is worked till it be well penetrated with the decoction. It is then taken out, wrung at the peg or squeezed in a press, and straightway hung up in the drying house. Some more of the fresh decoction being added to the partially exhausted liquor in the back, the process is resumed upon fresh goods.

The manipulation is the same with sumach, but the bath is somewhat differently made; because the quantity of sumach must be double that of galls, and must be merely infused in very hot water, without boiling. When galls and sumach are both prescribed, their baths should be separately made and mixed together.

2. *Aluming.* Alum is a salt which serves to prepare cotton for receiving an indefinite variety of dyes. Its bath is made as follows: For 100 pounds of scoured cotton, about 30 gallons of water being put into the copper, are heated to about 122° F., when 4 ounces of alum, coarsely pounded, are thrown in for every pound of cotton, and instantly dissolved. Whenever the heat of the bath has fallen to about 98° F., the cotton is well worked in it, in order that the solution may thoroughly penetrate all its pores. It is then taken out, wrung at the peg or squeezed in the press, and dried in the shade. The solution of alum is of such constant employment in this kind of dyeing, that it should be made in large quantities at a time, kept in the alum tun, where it can suffer no deterioration, and drawn off by a spigot or stop-cock as wanted.

There are certain colours which require alum to be deprived of a portion of its acid excess, as a supersalt; which may be done by putting 1 ounce of crystals of soda into the tun for every pound of alum. But so much soda should never be used as to cause any permanent precipitation of alumina. When thus prepared, it is called *saturated alum*, though it is by no means neutral to litmus paper; but it crystallizes differently from ordinary alum.

Cotton does not take up at the first aluming a sufficient quantity of alum; but it must receive a second, or even a third immersion. In every case the stuff should be thoroughly dried, with an interval of one or two days between each application; and it may even be left for 10 or 12 hours moist with the alum bath before being hung in the air. When the cotton is finally dry, it must be washed before being plunged into the dye bath; otherwise, the portion of alum, not intimately combined with the cotton, but adhering externally to its filaments, would come off by the heat, mix with the bath, alter the colour by dissolving in it, and throw it down to the bottom of the copper, in the form of a lake, to the great loss of the dyer. Madder red, weld yellows, and some other colours, are more brilliant and faster when acetate of alumina, prepared with acetate of lead, alum, and a little potash, is used, than even saturated alum. This mordant is employed cold, and at 4° Baumé.

3. *Mordants.* See this article in its alphabetical place; and CALICO PRINTING.

4. *Dye baths,* are distinguished into two classes; the colouring bath, and the dyeing bath. The former serves to extract the colouring matters of the different substances, with the exception of madder, which is always used in substance, and never as an extract, infusion, or decoction. In all these cases, when the colour is extracted, that is, when the dye bath is completed by the degree of heat suited to each substance, it is then allowed to cool down a certain way, and the cotton is worked or winched through it, to get the wished-for tint. This is what is called the dye bath. Several colouring baths are made in the cold; and they serve to dye also in the cold; but the greater part require a heat of 90° or 100° to facilitate the penetration of the stuffs by the colouring particles. The description of the several dye baths is given under the individual dyes.

5. *Of the washing after the dyeing.* — The washing of the cottons after they have received the dyes, is one of the most important operations in the business. If it is not carefully performed, the excess of colour not combined with the fibres is apt to stain whatever it touches. This inconvenience would be of little consequence, if the friction carried off the colour equally from all the points; but it does not do so, and hence the surface appears mottled. A well-planned dye-house should be an oblong gallery, with a stream of water flowing along in an open conduit in the middle line, a series of dash wheels arranged against the wall, at one side, and of dyeing coppers, furnished with self-acting winces or reels, against the other. In such a gallery, the washing may be done either by hand, by the rinsing machine, or by the dash wheel, according to the quality of the dye, and the texture of the stuffs. And they may be stripped of the water either by the jack and pin, by the squeezing roller, or by the press. Wooden pins are placed in some dye-houses on each side of the wash cistern or pool. They are somewhat conical, $1\frac{1}{2}$ foot high, $3\frac{1}{2}$ inches in diameter at the base, $1\frac{1}{2}$ at the top, are fixed firmly upright, and at a level of about 3 feet above the bottom of the cistern, so as to be handy for the

workmen. See BRAZIL WOOD, FUSTIC, MADDER, BLACK DYE, BROWN DYE, &c., as also BLEACHING, BRAN, CALICO PRINTING, DUNGING, DYEING, &c.

Cotton may be distinguished from Linen in a cloth fabric by means of a good microscope; the former fibres being flat, riband-like and more or less contorted or shrivelled, and the latter straight, round, and with cross knots at certain distances. These two fibrous matters may be also distinguished by the action at a boiling heat of a strong caustic lye, made by dissolving fused potash in its own weight of water. By digestion in this liquor, linen yarn becomes immediately yellow, while the cotton yarn remains white. The best way of operating is to immerse a square inch of the cloth to be tested for two minutes in the above boiling hot caustic lye, to lift it out on a glass rod, press it dry between folds of blotting-paper, and then to pull out a few of the warp and weft threads — when the linen ones will be found of a deep yellow tint, but the cotton, white or very pale yellow.

COTTON (*Alkalized*). The *mercurized* cotton, as it has been called, is chemically identical with the natural, but instead of having its fibres flattened and twisted, it has them cylindrical, as seen in the microscope. In fact, the moment they are touched by the alkaline lye they untwist themselves, contract in length, and retain the rounded form after the soda is removed by washing. We can thus conceive how a larger quantity of dye may be imbibed, as the substance becomes more porous. The formula of the sodaed cotton is given by Mr. Gladstone as $C_{24}\,H_{20}\,O_{20}\,KO$, when potash is the alkali employed.

COTTON FACTORY (*General Construction of*). — There is no textile substance whose filaments are so susceptible of being spun into fine threads of uniform twist, strength, and diameter, as cotton wool. It derives this property from the smoothness, tenacity, flexibility, elasticity, peculiar length, and spiral form of the filaments; hence, when a few of them are pulled from a heap with the fingers and thumb, they lay hold of and draw out many others. Were they much longer they could not be so readily attenuated into a fine thread, and were they much shorter the thread would be deficient in cohesion. Even the differences in the lengths of the cotton staple are of advantage in adapting them to different styles of spinning and different textures of cloth.

If we take a tuft of cotton wool in the left hand, and seizing the projecting fibres with the right, slowly draw them out, we shall perceive with what remarkable facility they glide past each other, and yet retain their mutual connexion, while they are extended and arranged in parallel lines, so as to form a little riband susceptible of considerable elongation. This demonstration of the ductility, so to speak, of cotton wool, succeeds still better upon the carded fleece in which the filaments have acquired a certain parallelism; for in this case the tiny riband in being drawn out by the fingers to a moderate length, may at the same time receive a gentle twist to preserve its cohesion till it becomes a fine thread.

Hence we may imagine the steps to be taken or the mechanical processes to be pursued in cotton spinning. After freeing the wool of the plant from all foreign substances of a lighter or a heavier nature, the next thing is to arrange the filaments in lines as parallel as possible, then to extend them into regular ribands, to elongate these ribands by many successive draughts, doubling, quadrupling, or even octupling them meanwhile, so as to give them perfect equality of size, consistence and texture, and at the same time to complete the parallelism of the fibres by undoing the natural convolutions they possess in the pod. When the rectilinear extension has been thus carried to the fineness required by the spinner, or to that compatible with the staple, a slight degree of torsion must accompany the further attenuation; which torsion may be either momentary, as in the tube roving machine, or permanent, as in the bobbin and fly frame. Finally, the now greatly attenuated soft thread, called a *fine roving*, is drawn out and twisted into finished cotton yarn, either by continuous indefinite gradations of drawing and twisting, as in the throstle, or by successive stretches and torsions of considerable lengths at a time, as in the mule.

Mechanical spinning consists in the suitable execution of these different processes by a series of different machines. After the carding operation, these are made to act simultaneously upon a multitude of ribands and spongy cords or threads by a multitude of mechanical hands and fingers. However simple and natural the above described course of manufacture may appear to be, innumerable difficulties stood for ages in the way of its accomplishment, and so formidable were they as to render their entire removal of late years in the cotton factories of England one of the greatest and most honourable achievements of human genius.

1. The *cleaning* and opening up or loosening the flocks of cotton wool, as imported in the bags, so as to separate at once the coarser and heavier impurities as well as those of a lighter and finer kind.

2. The *carding*, which is intended to disentangle every tuft or knot, to remove every remaining impurity which might have eluded the previous operation, and finally to prepare for arranging the fibres in parallel lines, by laying the cotton first in a fleecy web, and then in a riband form.

3. The *doubling* and *drawing out* of the card-ends or ribands, in order to complete the parallelism of the filaments, and to equalize their quality and texture.

4. The *roving* operation, whereby the *drawings* made in the preceding process are greatly attenuated, with no more twist than is indispensable to preserve the uniform continuity of the spongy cords; which twist either remains in them, or is taken out immediately after the attenuation.

5. The *fine roving* and *stretching* come next; the former operation being effected by the fine bobbin and fly frame, the latter by the stretcher mule.

6. The *spinning* operation finishes the extension and twist of the yarn, and is done either in a continuous manner by the water twist and throstle, or discontinuously by the mule; in the former, the yarn is progressively drawn, twisted, and wound upon the bobbins; in the latter, it is drawn out and twisted in lengths of about 56 inches, which are then wound all at once upon the spindles.

7. The seventh operation is the winding, doubling, and singeing of the yarns, to fit them for the muslin, the stocking, or the bobbin net lace manufacture.

8. The *packing press*, for making up the yarn into bundles for the market, concludes this series.

9. To the above may be added the operations of the dressing machines, and,

10. The power-looms.

The site of the factory ought to be carefully selected in reference to the health of the operatives, the cheapness of provisions, the facilities of transport for the raw materials, and the convenience of a market for the manufactured articles. An abundant supply of labour, as well as fuel and water for mechanical power, ought to be primary considerations in setting down a factory. It should therefore be placed, if possible, in a populous village, near a river or canal, but in a situation free from marsh malaria, and with such a slope to the voider stream as may ensure the ready discharge of all liquid impurities. These circumstances happily conspire in the districts of Stockport, Hyde, Stayleybridge, Duckenfield, Bury, Blackburn, &c., and have eminently favoured the rapid extension of the cotton manufactures for which these places are pre-eminent.

Mr. Orrell's Cotton Factory.—The mill consists of a main body with two lateral wings, projecting forwards, the latter being appropriated to store-rooms, a counting-house, rooms for winding the yarn on bobbins, and other miscellaneous purposes. The building has 6 floors besides the attic story. The ground-plan comprehends a plot of ground 280 feet long by 200 feet broad, exclusive of the boiler sheds.

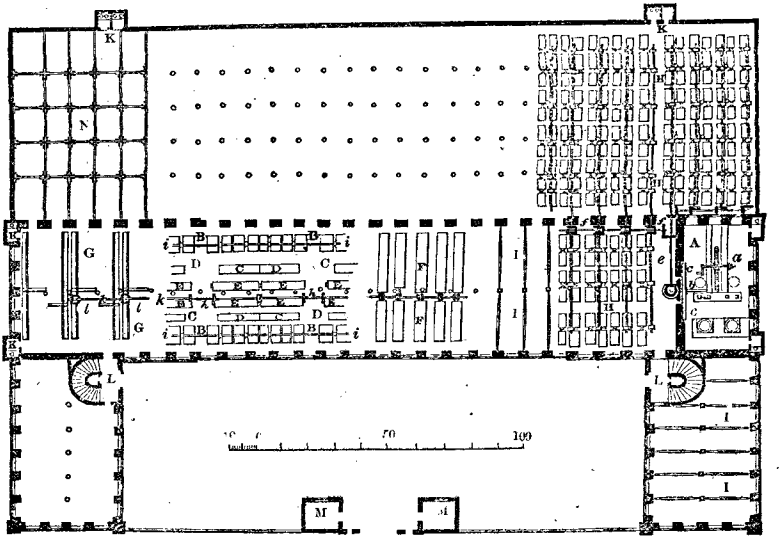
The right-hand end, A (*fig.* 389.) of the principal building, is separated from the main body by a strong wall, and serves in the three lower stories for accommodating two ninety-horse steam engines, which are supplied with steam from a range of boilers contained in a low shed exterior to the mill.

The three upper stories over the steam engine gallery are used for unpacking, sorting, picking, cleaning, willowing, batting, and lapping the cotton wool. Here are the willow, the blowing, and the lap machines, in a descending order, so that the lap machine occupies the lowest of the three floors, being thus most judiciously placed on the same level with the preparation room of the building. On the fourth main floor of the factory there are, in the first place, a line of carding engines arranged, near and parallel to the windows, as shown at B, B, in the ground plan, (*fig.* 389.) and, in the second place, two rows of drawing frames, and two of bobbin and fly frames, in alternate lines, parallel to each other, as indicated by D, C, D, C, for the drawing frames, and E, E, E, E, for the bobbin and fly frames in the ground plan. The latter machines are close to the centre of the apartment.

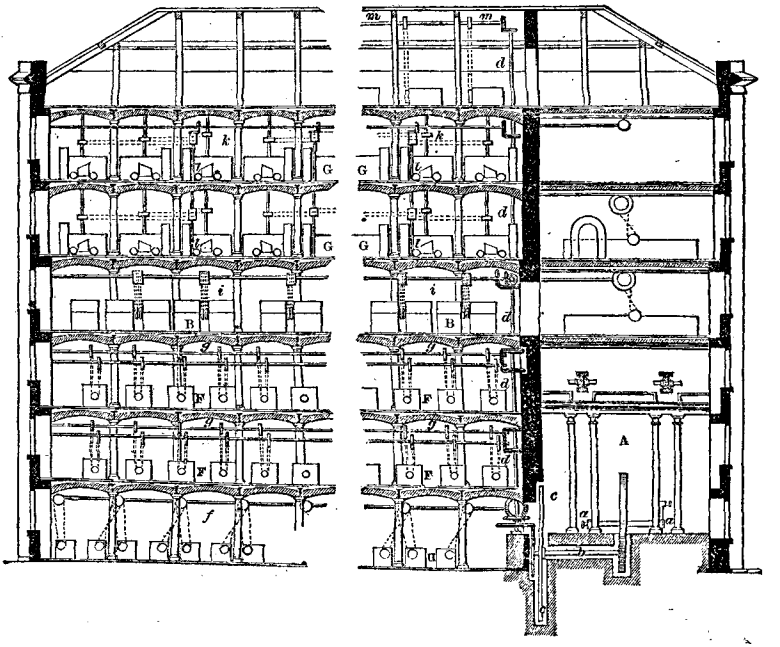
The two stories next *under* the preparation room are occupied with throstle frames, distributed as shown at F, F, in the ground plan. They stand in pairs alongside of each other, whereby two may be tended by one person. These principal rooms are 280 feet long, and nearly 50 feet wide. The two stories *over* the preparation room, viz., the fifth and sixth floors from the ground, are appropriated to the mule jennies, which are placed in pairs fronting each other, so that each pair may be worked by one man. Their mode of distribution is shown at G G, in the ground-plan. The last single mule is seen standing against the end wall, with its head-stock projecting in the middle.

The ground floor of the main building, as well as the extensive shed abutted behind it, marked by N, H, H in the plan, is devoted to the power looms, the mode of placing which is plainly seen at H, H, H.

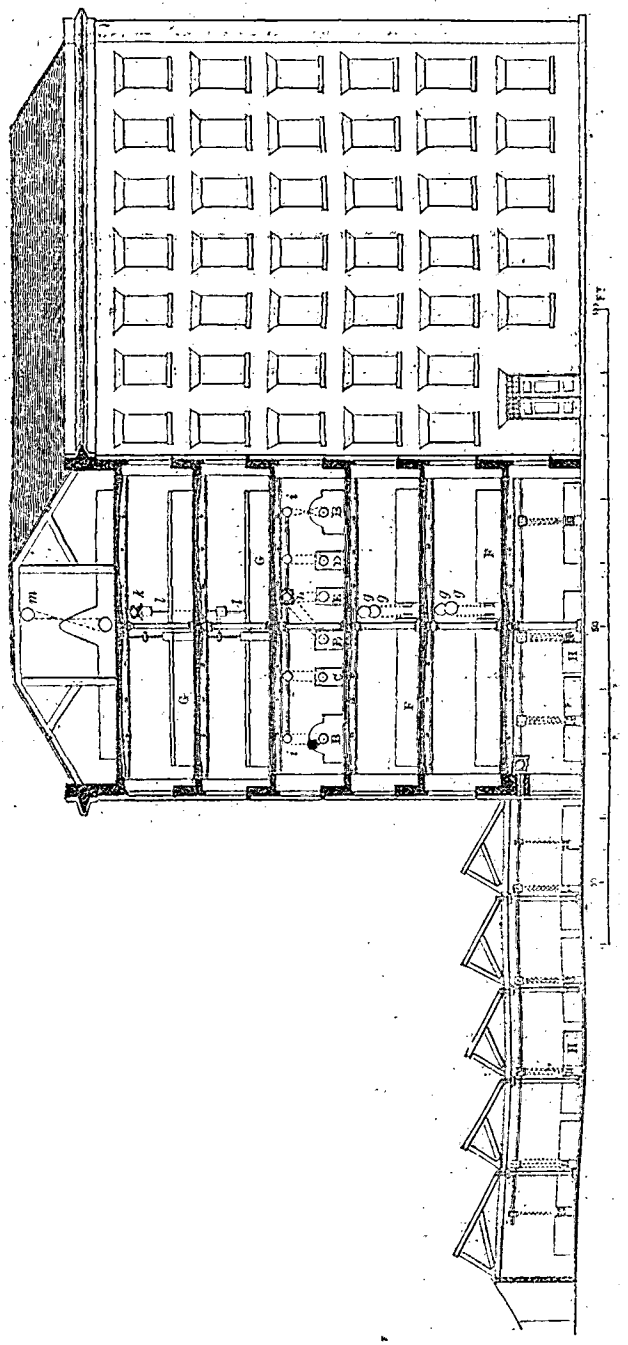
389



390



391



The attic story accommodates the warping mills, and the warp dressing machines subservient to power weaving.

The winding machines, and some extra mules (self-actors), are placed in the wings; the five winding machines being in the two top rooms of the left wing.

We shall briefly sum up the references in the ground-plan as follows:—

A, the grand apartment for the steam engines.

B, the distribution of the carding engines, the moving shaft or axis running in a straight line through them, with its pulleys for receiving the driving bands.

C, C, the drawing frames.

D, D, the jack, or coarse bobbin and fly frames.

E, E, the fine roving or bobbin and fly frames.

F, the arrangement of the throstle frames, standing in pairs athwart the gallery, in the 2nd and 3rd flats.

G, the mules are here represented by their roller beams, and the outlines of their head-stocks, as placed in the 5th and 6th stories.

H, the looms, with their driving pulleys projecting from the ends of their main axes. Sometimes the looms are placed in parallel straight lines, with the rigger pulleys of the one alternately projected more than the other, to permit the free play of the driving-belts; sometimes the looms are placed, as generally in this engraving, alternately to the right and left, by a small space, when the pulleys may all project equally. The former plan is the one adopted in Mr. Orrell's mill.

I, represents the cast-iron girders which support the floors of this fire-proof building.

K, K, are closets placed in each floor, in the recesses of a kind of pilasters built against the outside of the edifice. These hollow shafts are joined at top by horizontal pipes, which all terminate in a chest connected with the suction axes of a fan, whereby a constant draught of air circulates up the shafts, ventilates the apartments, and prevents the reflux of offensive effluvia from the water-closets, however careless the work-people may be. The tunnels towards the one end of the building are destined for the men; towards the other for the women.

L, L, are the staircases, of a horse-shoe form, the interior space or shaft in the middle being used for the teagle or hoist. In the posterior part of the shaft a niche or groove is left for the counter-weight to slide in, out of the way of the ascending and descending platform.

M, M, are the two porters' lodges, connected to the corner of each wing by a handsome iron balustrade. They are joined by an iron gate.

It will be observed that the back loom-shed has only one story, as shown in section, (*fig.* 391.) In the ground-plan of the shed, N represents the roofing, of wood-work. The rafters of the floors rest at their ends upon an iron plate, or shoe with edges (as it is called), for the girders to bear upon.

The two steam engines, of fully 90 horse power each, operate by cranks, which stand at right angles upon the shaft marked *a* both in the plan and section. In the centre, between the bearings, is a large cog-wheel, driving a smaller one upon the shaft marked *b* in both figures, to which the fly-wheel *c* belongs. That prime motion wheel is magnificent, and possesses a strength equal to a strain of 300 horses. From this shaft motion is given to the main or upright shaft *d*, in the section, by two bevel wheels, visible at the side and on the top of the great block of stone, about 5 tons weight, (*fig.* 391.) which gives a solid basis to the whole moving apparatus.

The velocity of the piston in these steam engines is 240 ft. per minute.

The first shaft makes 44·3 revolutions per minute; the main upright shaft 58·84 per minute. The steam engines make 16 strokes per minute; and the length of their stroke is 7 ft. 6 in.

As the one engine exerts its maximum force when the other has no force at all, and as the one increases as the other diminishes in the course of each pair of strokes, the two thus cooperate in imparting an equable impulsion to the great geering and shafts, which, being truly made, highly polished, and placed in smooth bearings of hard brass, revolve most silently and without those vibrations which so regularly recurred in the old factories, and proved so detrimental to the accurate performance of delicate spinning frames.

To the horizontal ramifications from the upright shaft any desired velocity of rotation may be given by duly proportioning the diameters of the bevelled wheels of communication between them; thus, if the wheel on the end of the horizontal shaft have one-half or one-third the diameter of the other, it will give it a double or a triple speed.

In the lowest floor, the second bevel wheel above the stone block drives the horizontal shaft *e*, seen in the ground plan; and thereby the horizontal shaft *f*, at right angles to the former, which runs throughout the length of the building, as the other did through its breadth, backwards. The shaft *f* lies alongside of the back window wall, near the

ceiling; and from it the transverse slender shafts proceed to the right and left in the main building, and to the shed behind it, each of them serving to drive two lines of looms. These slender or branch shafts are mounted with pulleys, each of which drives four looms by four separate bands.

In the second and third floors, where the throstles are placed, the shaft *d* is seen in the section to drive the following shafts:—

Upon the main upright shaft *d*, (*fig.* 390.) there are in each of these stories two horizontal bevel wheels, with their faces fronting each other (shown plainly over *d d*), by which are moved two smaller vertical bevel wheels, on whose respective axes are two parallel shafts, one over each other, *g*, *g*, which traverse the whole length of the building. These two shafts move therefore with equal velocities, and in opposite directions. They run along the middle space of each apartment; and wherever they pass the rectangular line of two throstle frames (as shown at F in the ground plan) they are each provided with a pulley; while the steam pulleys on the axes of two contiguous throstles in one line are placed as far apart as the two diameters of the said shaft-pulleys. An endless strap goes from the pulley of the uppermost horizontal shaft *g*, round the steam or driving-pulley of one throstle frame; then up over the pulley of the second or lower shaft, *g*; next up over the steam pulley of a second throstle; and, lastly, up to the pulley of the top shaft, *g*. See *g g* in the throstle floors of the cross section.

In the preparation room, three horizontal shafts are led pretty close to the ceiling through the whole length of the building. The middle one, *h* (see the plan *fig.* 389.), is driven immediately by bevel wheels from the main upright shaft *d* (*fig.* 390.) The two side ones *i*, *i*, which run near the window walls, are driven by two horizontal shafts, which lead to these side shafts. The latter are mounted with pulleys, in correspondence with the steam pulleys of the two lines of carding engines, as seen between the cards in the plan. The middle shaft *h*, drives the two lines of bobbin and fly frames, E, E, E, E (see cross section), and short shafts *i*, *i*, seen in the cross section of this floor, moved from the middle shaft *h*, turning in gallows fixed to the ceiling, over the drawing and jack frames, give motion to the latter two sets of machines. See C D in the cross section.

To drive the mules in the uppermost story, a horizontal shaft *k* (see longitudinal and cross sections, as well as ground plan) runs through the middle line of the building, and receives motion from bevel wheels placed on the main upright shaft, *d*, immediately beneath the ceiling of the uppermost story. From that horizontal shaft, *k*, at every second mule, a slender upright shaft, *l*, passing through both stories, is driven (see both sections). Upon these upright branch shafts are pulleys in each story, one of which serves for two mules, standing back to back against each other. To the single mules at the ends of the rooms the motions are given by still slenderer upright shafts, which stand upon the head stocks, and drive them by wheel-work, the steps (top bearings) of the shafts being fixed to brackets in the ceiling.

In the attic, a horizontal shaft, *m m*, runs lengthwise near the middle of the roof, and is driven by wheel work from the upright shaft. This shaft, *m*, gives motion to the warping mills and dressing machines.

This cotton mill having been erected according to plans devised and executed by that very eminent engineer, Mr. Fairbairn, of Manchester, may be justly reckoned a model of factory architecture. It is mounted with 1,100 power looms, of which 100 require steam power equivalent to 25 horses to impel them, inclusive of the preparation and spinning operations competent to supply the looms with yarn. A third steam engine is added.

Ten looms, with the requisite dressing, without spinning, are considered to be equivalent to 1 horse power in a steam engine. Steam power equivalent to 1 horse will drive—

500 mule spindles,
300 self-actor spindles,
180 throstle spindles of the common construction; in which estimate the requisite preparation processes are included.

In Mr. Orrell's mill there are 6,474 spindles in each of the throstle-frame floors - - -	12,948	spindles
And 14 pairs of mules in each of the 2 mule floors, containing altogether - - -	24,928	„
19 self-actors in the wing, containing - -	7,984	„
Total yarn spindles -	45,860	

One of the most compact and best regulated modern factories, on the small scale, which I visited in Lancashire, consisted of the following system of machines: —

1 willow, 1 blowing machine, 1 lap machine, capable, together, of cleaning and lapping 9,000 pounds of cotton per week, if required.
21 cards, breakers, and finishers, which carded 5,000 lbs. of cotton every week of 69 hours' work, being about 240 lbs. per card.
3 drawing-frames, of 3 heads each.
3 coarse bobbin and fly frames.
7 fine do. No stretcher mule.
12 self-actor mules, of Sharp and Roberts's construction, of 404 spindles each = 4,848 mule spindles.
10 throstle frames, of 236 spindles each = 2,360 spindles.
7 dressing machines.
236 power looms.
2 warping mills.
300 winding spindles for winding the warp.

The rovings have 4 hanks in the pound, and are spun into yarn No. 38. on the throstle, as well as the mule.

One bobbin of the roving (compressed) lasts 5 days on the self-actors, and 6 days on the throstles.

According to the estimate of Peile & Williams, of Manchester, 66 horses power of a steam engine are equivalent to 396 power looms, including 16 dressing machines; the cloth being 36 inches wide upon the average, and the yarn varying in fineness from 12's to 40's, the mean being 26's. Here, the spinning and preparation not being included, the allowance of power will appear to be high. The estimate given above assigns 10 looms, with the requisite dressing, to 1 horse; but the latter assigns no more than 6.

For the following experimental results, carefully made with an improved steam-engine *indicator*, upon the principle of Mr. Watt's construction, I am indebted to Mr. Bennet, an eminent engineer in Manchester. His mode of proceeding was to determine, first of all, the power exerted by the factory steam engine when all the machines of the various floors were in action; then to detach, or throw out of geer, each system of machines, and to note the diminution of force now exercised. Finally, when all the machines were disengaged, he determined the power requisite to move the engine itself, as well as the great geering-wheels and shafts of the factory.

He found at the factory of S. A. Beaver, Esq., in Manchester, that 500 calico looms (without dressing) took the power of 33 horses, which assigns 15 looms to 1 horse power.

At Messrs. Birlie's factory, in Manchester, he found that 1,080 spindles in 3 self-actor mules took 2·59 horses, being 417 spindles for 1 horse power; that 3,960 spindles in 11 self-actors took 8·33 horses, being 475 spindles per horse power; 1,080 spindles in 3 self-actors took 2 horses, being 540 spindles per horse.

At Messrs. Clarke & Sons, in Manchester, that 585 looms for weaving fustians of various breadths took 54 horses power, exclusive of dressing machines, being 11 looms to 1 horse.

At J. A. Beaver's, on another occasion, he found that 1,200 spindles, of Danforth's construction, took 21 horses, being 57 spindles per horse power; and that in a second trial the power of 22 horses was required for the same effect, being 54 Danforth's spindles per horse power.

An excellent engine of Messrs. Bolton & Watt, being tried by the indicator, afforded the following results in a factory: —

A 60 horse boat-engine (made as for a steam boat) took 14½ horses power to drive the engine with the shafts	14·5
3½ blowing machines, with their three fans	21·55
10 dressing machines	10·25
12 self-actor mules, of 360 spindles each (720 spindles per horse power)	6·00
6 Danforth throstle frames, containing 570 spindles (96 in each), being 93 spindles to 1 horse power	6·20

At Bollington, in a worsted mill, he found that 106⅔ spindles, including preparation, took 1 horse power upon throstles. N. B. There is no carding in the long wool or worsted manufacture for merinos: —

At Bradford, in Yorkshire, he found that a 40 horse power boat-engine, of Bolton & Watt's, drove 598 calico looms, 6 dressing machines (equivalent to dress warp for 180 of the said looms), and 1 mechanics' workshop, which took 2 horses power. Other engineers estimate 200 common throstle spindles, by themselves, to be equivalent to the power of 1 horse.

The shafts which drive the cards revolve about 120 times per minute, with a driving pulley of from 15 to 17 inches in diameter.

The shafts of the drawing, and the bobbin and fly frames, revolve from 160 to 200 times per minute, with pulleys from 18 to 24 inches in diameter.

The shafts of throstle frames in general turn at the rate of from 220 to 240 times per minute, with driving pulleys 18 inches in diameter, when they are spinning yarn of from No. 35. to 40. The shafts of mules revolve about 130 times per minute, with pulleys 16 inches in diameter.

The shafts of power looms revolve from 110 to 120 times per minute, with pulleys 15 inches in diameter.

The shafts of dressing machines revolve 60 times per minute, with pulleys 14 inches in diameter.

Before quitting the generalities of the cotton manufacture I may state the following facts communicated also by Mr. Bennet: —

A waggon-shaped boiler, well set, will evaporate 12 cubic ft. of water with 1 cwt. of coals; and a steam boiler with winding flues will evaporate 17 cubic ft. with the same weight of fuel: $7\frac{2}{10}$ lbs. of coals to the former boiler are equivalent to 1 horse power exerted for an hour, estimating that a horse can raise 33,000 lbs. 1 foot high in a minute.

The first cotton mill upon the fire-proof plan was erected, I believe, by the Messrs. Strutt, at Belper, in the year 1797; that of Messrs. Phillips & Lee, at Manchester, in 1801; that of H. Houldsworth, Esq., of Glasgow, in 1802; and that of James Kennedy, at Manchester, in 1805; since which time all good factories have been built fire-proof, like Mr. Orrell's.

The heating of the apartments of cotton factories is effected by a due distribution of cast-iron pipes, of about 7 or 8 inches diameter, which are usually suspended a little way below the ceilings, traverse the rooms in their whole length, and are filled with steam from boilers exterior to the building. It has been ascertained that one cubic foot of boiler will heat fully more than 2,000 cubic ft. of space in a cotton mill, and maintain it at the temperature of about 75° Fahr. If we reckon 25 cubic ft. contents of water in a waggoned-shaped steam boiler as equivalent to 1 horse power, such a boiler would be capable of warming 50,000 cubic ft. of space; and therefore a 10 horse steam boiler will be able to heat 500,000 cubic ft. of air from the average temperature, 50°, of our climate, up to 75°, or perhaps even 80° Fahr.

It has been also ascertained that in a well-built cotton mill, one superficial foot of exterior surface of cast-iron steam pipe will warm 200 cubic ft. of air. In common cases for heating churches and public rooms, I believe that one-half of the above heating surface will be found adequate to produce a sufficiently genial temperature in the air. The temperature of the steam is supposed to be the same with that in Mr. Watt's low-pressure engines, only a few degrees above 212° — the boiling point of water.

The pipes must be freely slung, and left at liberty to expand and counteract under the changes of temperature, having one end at least connected with a flexible pipe of copper or wrought iron, of a swan-neck shape. Through this pipe the water of condensation is allowed to run off. The pipes should not be laid in a horizontal direction, but have a sufficient slope to discharge the water. The pipes are cast from half an inch to three-quarters thick in the metal. In practice the expansion of steam pipes of cast-iron may be taken at about one-tenth of an inch in a length of 10 feet, when they are heated from a little above the freezing to the boiling point of water. The upper surface of a horizontal steam pipe is apt to become hotter than the bottom, if the water be allowed to stagnate in it; the difference being occasionally so great, as to cause a pipe 60 feet long to be bent up 2 inches in the middle.

In arranging the steam pipes provision ought to be made not only for the discharge of the water of condensation, as above stated, but for the ready escape of the air; otherwise the steam will not enter freely. Even after the pipes are filled with steam, a little of it should be allowed to escape at some extreme orifice, to prevent the re-accumulation of air discharged from the water of the steam boiler. In consequence of water being left in the pipes serious accidents may happen; for the next time the steam is admitted into them, the regularity of heating and expansion is impeded, some part of the pipe may crack, or a violent explosion may take place, and the joints may be racked to a very considerable distance, every way, from the place of rupture, by the alternate expansions and condensations. The pipes should therefore be laid, so as to have the least possible declivity, in the direction of the motion of the steam.

Formerly, when drying rooms in calico printing works were heated by iron stoves, or cockles, their inmates were very unhealthy, and became emaciated; since they have been heated by steam pipes the health of the people has become remarkably good, and their appearance frequently blooming.

COTTON MANUFACTURE. (*Filature de Coton*, Fr.; *Baumwollenspinnerie*,

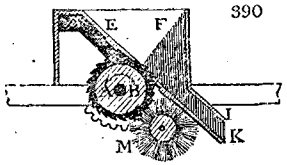
Germ.) Cotton is a filamentous down, which invests the seeds of the plant called *gossypium* by Linnæus, and placed by him in the class *monadelphia* and order *monandria*, but belonging to the natural family of *malvaceæ*. It has a cup-shaped calyx, obtusely five-toothed, inclosed in a three-cleft exterior calyx; the leaflets are united at their base, of a heart shape and toothed; stigmas three to five; capsule three to five celled and many-seeded; seeds bearing a downy wool. Thirteen species are described by Decandolle, but their characters are very uncertain, and no botanist can assign to a definite species of the plant, the very dissimilar staples of the cotton filaments found in commerce. The leaves are generally palmate and hairy; and the blossoms are large, and of a beautiful yellow. The *gossypium religiosum* of Tranquebar has white blossoms in some of its varieties, to which, probably, the white cotton of Rome, cultivated in the Jardin des Plantes at Paris, belongs. The filaments differ in length, flexibility, tenacity, and thickness, in different cottons, whence the great differences of their value to the cotton-spinner, as the prices current in the market show. Thus, at Liverpool, on the 1st of December, 1835, the following values were assigned to the following cottons: —

	s.	d.		s.	d.
Sea-island	1	6	to	2	6
Demerara and Berbice	0	9		1	0
Pernambuco	0	$10\frac{3}{4}$		1	$1\frac{1}{2}$
Egyptian	0	$11\frac{1}{2}$		1	$2\frac{1}{2}$
New Orleans	0	$7\frac{1}{8}$		1	0
Bahia	0	$8\frac{1}{2}$		0	10
Upland Georgia	0	$7\frac{1}{8}$		0	$11\frac{1}{2}$
West Indian	0	$7\frac{3}{4}$		0	9
Surat	0	$6\frac{1}{8}$		0	8
Madras	0	$6\frac{1}{2}$		0	8
Bengal	0	$5\frac{1}{4}$		0	$6\frac{1}{4}$

But it is to be observed, that there are varieties of the Sea-island Georgian cotton, so highly prized by the spinner of fine yarn, as to fetch 3*s.*, 4*s.*, or even 5*s.* per pound.

The filaments of cotton, when examined with a good microscope, are seen to be more or less ribbon-like, and twisted; having a breadth varying from $\frac{1}{800}$ of an inch in the strongest Smyrna or candle-wick cotton of the Levant, to $\frac{1}{2500}$ of an inch in the finest Sea-island.

The main distinction between cottons in the pod, is that of the black seeded, and the green seeded; for the former part with their downy wool very readily to a pair of simple rollers, made to revolve nearly in contact, by the power of the human arm; while the latter retain the wool with much force, and require to be ginned, as the operation is called, by a powerful revolving circular saw-mechanism, usually driven by horse or water power. After the cotton wool is thus separated from the seeds, it is packed in large canvas bags, commonly with the aid of a screw or hydraulic press, into a very dense bale, for the convenience of transport. Each of the American bags contains about 340 lbs. of cotton wool. When this cotton is delivered to the manufacturer, it is so foul and flocky, that he must clean and disentangle it with the utmost care, before he can subject it to the carding operation.



390

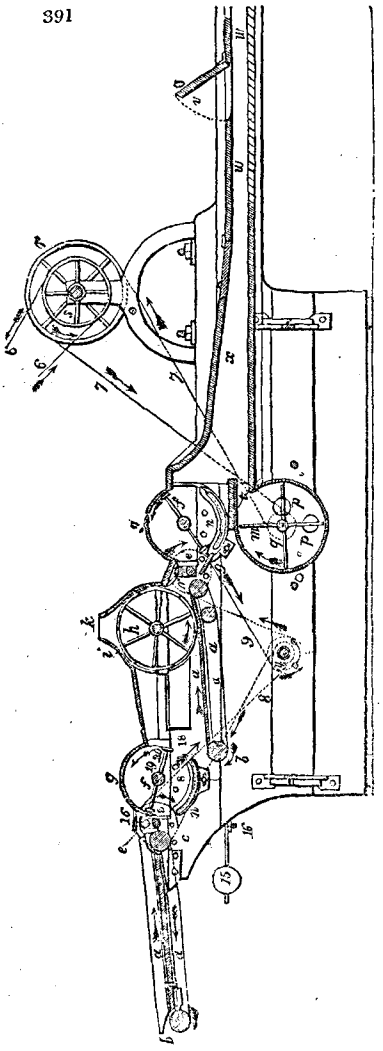
Fig. 390. A B, is a roller, about 9 inches in diameter, which revolves in the direction of the arrow. This cylinder consists of a parallel series of oblique pointed circular saws made fast to one axis, and parted from each other by wooden rings nearly one inch and a half in thickness. Above the cylinder is a kind of hopper E F, into which ginner throws the seed cotton, which falls upon a grating, up though which small segments of the saw-teeth project, so as to lay hold of the fibres in their revolution, and pull them through, while the seeds being thus separated, roll down the slope of the grid, to be discharged from the spout I K. M is a cylindrical brush placed below the grating, which revolves against the saw teeth, so as to clear them of the adhering cotton filaments.

The *willow*, which was originally a cylindrical willow basket, whence its name, but is now a box made of wood, with revolving iron spikes, is the first apparatus to which cotton wool is exposed, after it has been opened up, picked, and sorted by hand or a rake, in what is called a *bing*. The willow exercises a winnowing action, loosens the large flocks, and shakes out much of the dirt contained in them. The frame of the willow is about 2 feet wide, and turns with its spikes at the rapid rate of 600 revolutions per minute, whereby it tosses the cotton about with great violence. The heavy impurities fall down through the grid bottom. It is exposed, however, for only a few minutes to the action of this machine. For factories which work up chiefly the coarser and fouler cottons of India, and Upland Georgia, the conical self-acting willow, as

constructed by Mr. Lillie at Manchester, is much employed. In it, the cotton is put in at the narrow end of the truncated cone, which, being spiked, and revolving rapidly within a nearly concentric case upon a horizontal axis, wafts it on towards the wide end, while its impurities are partly shaken out through the grid or perforated bottom, and partly sucked up through revolving squirrel wire cages, by the centrifugal action of a fan. This is a powerful automatic engine, deserving the study of the curious, and is as safe as it is powerful. The cone of this huge machine makes from 400 to 600 turns per minute, and will clean 7200 pounds, or 24 bags, in a day.

After shaking out the grosser impurities by the willow, the cotton spinner proceeds to separate each individual filament of cotton wool from its fellow, so as to prepare it for carding, and to free it from every particle of foreign matter, whether lighter or heavier than itself. This second operation is performed by what are called batting *(beating)*, scutching, and blowing machines, which are all now much the same, whatever difference of signification the name may have. Indeed, each machine not only beats, scutches, but blows. *Fig.* 391. exhibits a longitudinal section of a good blowing engine of modern construction. The machine is about 18 or 19 feet long, and three feet across within the case. The whole frame is made of cast-iron, lined with boards, forming a close box, which has merely openings for introducing the raw cotton wool, for taking out the cleansed wool, and removing the dust as it collects at the bottom. These doors are shut during the operation of the machine, but may be opened at pleasure, to allow the interior to be inspected and repaired.

391

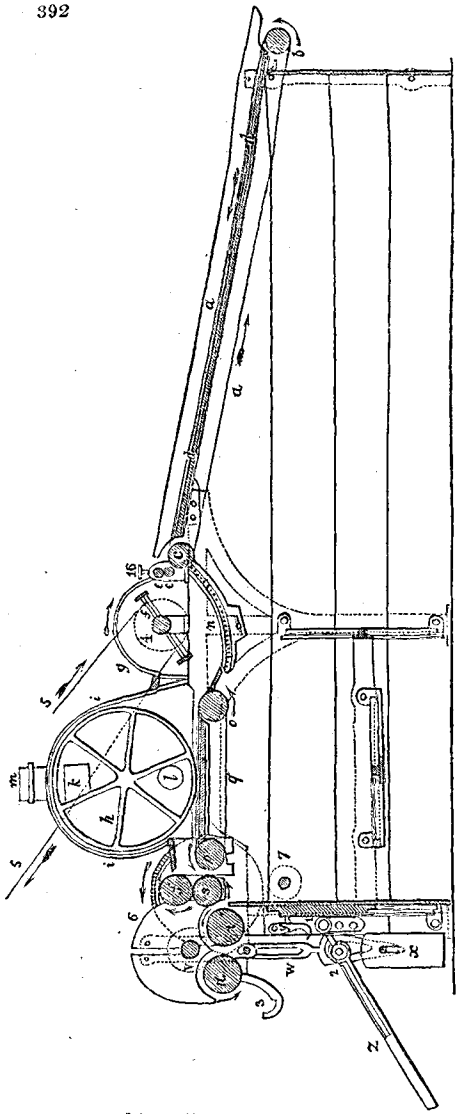


The introduction of the cotton is effected by means of an endless cloth or double apron, which moves in the direction of the arrow *a a*, at the left end of the figure, by passing round the continually revolving rollers at *b* and *c*. The two rollers at *e*, being the ones which immediately introduce the cotton into the jaws, as it were, of the machine, are called the feed rollers. The batting arm, or revolving diameter, *f e*, turns in the direction of the arrow, and strikes the flocks violently as they enter, so as to throw down any heavy particles upon the iron grating or grid at *n*, while the light cotton filaments are wafted onwards with the wind, from the rotation of the scutcher in the direction of arrow *a'*, along the second travelling apron, upon which the squirrel cage cylinder presses, and applies the cotton in the form of a lap. Above the cylindric cage *h*, which turns in the direction of its arrow, there is a pipe *k*, the continuation of the case *i*. This pipe, though broken off in the figure, communicates by a branch pipe with an air-sucking fan ventilator, not seen in this figure, but explained under Foundry. The cage *h*, by its rotation, presses down, as we have said, the half-cleaned cotton upon the cloth *a'*, which carries it forward to the second scutcher *f'*, by the second set of feed rollers *e'*. The second scutcher throws down the heavy dust upon the second grid *n'*, through which it falls upon the bottom of the case. The first scutcher makes about 1280 strokes of each of its two arms in a minute; the second 1300. The feed rollers for each are fluted. The feed cloth is either sustained by a board, or is made of parallel spars of wood, to secure it against bagging, which would render the

delivery of the cotton irregular. The feed rollers make 8 turns in the minute, and as their diameter is 1½ inches, they will introduce 8 times their circumference, or 37·7 inches of the cotton spread upon the apron in that time. Upon every 12th part of an inch of the cotton, therefore, nearly 3 blows of the scutcher arm will be applied. The second feed rollers move relatively with more slowness, so that for every 2·4 blows of the scutcher, only one twelfth of an inch of cotton wool is presented.

The fan is inclosed in a cylindrical case. The wings or vanes revolve from 120 to 150 times in the minute; and while they throw the air out with nearly this velocity at their excentric outlet in the circumference, they cause it to enter, with equal velocity, at the centre. With this centre the squirrel cage is connected by a pipe, as above stated. The sound filaments of the cotton are arrested by the sieve surface of the cylindric cage, and nothing but the broken fragments and the light dust can pass through.

392



The cotton wool in the blowing machine is wafted by the second scutcher into the space *x*, *w w*, provided with a fine grid bottom; or it is cometimes wound up there by rollers into a lap.

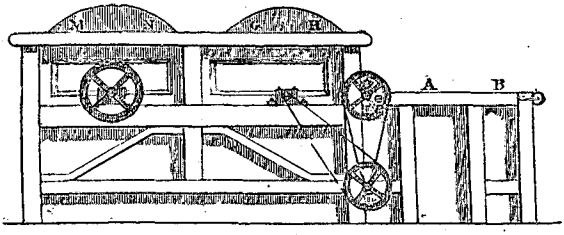
In *fig.* 391. an additional ventilator is introduced beneath at *m*, *o o*, to aid the action of the scutchers in blowing the cotton onwards into the oblong trough *a*. The outlet of that fan is at *t*; and it draws in the air at its axis *q*. *u* and *v*, are two doors or lids for removing the cleaned cotton wool. This last fan is suppressed in many blowing machines, as the scutching arms supply a sufficient stream of air. The dotted lines show how the motion is transmitted from the first mover at *s*, to the various parts of the machine. 6′ 6′ represent the bands leading to the main shafting of the mill. A machine of this kind can clean fully 600 pounds of short-stapled cotton wool in a day, with the superintendence of one operative, usually a young woman, to distribute the cotton upon the first feed cloth.

The second Blowing machine is usually called a *lap* machine, because, after blowing and scutching the cotton, as above described, it eventually coils the fleece upon a wooden roller at the delivering end of the apparatus. It is sometimes also called a *spreading machine*. A section of it is shown in *fig.* 392. The breadth of this machine is about 3 feet as the lap formed is prepared for the usual breadth of the breaker cards, namely 3 feet. Where the cards are only 18 inches broad, the lap machine is also made of the same breadth. In the figure we see the feed-cloth, the scutching barrel, the squirrel suction, and spreading cage, and the rollers for coiling up the lap. The lever shown below is for removing the pressure weight from the axis of the lap

rollers, when a full one is to be removed, and replaced by an empty one. *m*, at the top, is the commencement of the pipe which leads to the suction fan, or ventilator. The thickness of the lap in this machine must be nicely regulated, as it determines, in a great measure, the grist of the card ends, and even the rovings. In 12 hours such a lap machine will prepare 650 pounds of cotton.

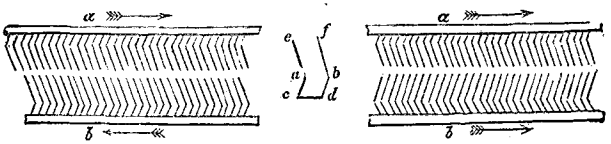
Fig. 393. is the first scutching machine, now never seen except in the oldest factories. A B is the feed cloth; G H and M N are the two scutcher frames.

393



Carding is the next operation in a cotton factory. Cards are destined to disentangle the individual filaments from each other, and to lay them lengthwise, instead of being doubled up and convoluted, as they usually are in leaving the blowing and lap machines. Carding consists in the mutual action of two opposite surfaces, which are studded thick with oblique angled hooks. The wires of which these hooks are made must be very hard drawn in order to render them stiff and elastic. The middle part of the figures shows one of the staples or double teeth, the structure of which has been partly

394



395

explained under CARD. Suppose *a*, *fig.* 394. to be a piece of a card fillet, and *b* to be another piece, each being made fast with pins to a board; the teeth of these two cards are set in opposite directions, but are very near together, and parallel. Now suppose a flock or tuft of cotton placed between two such bristling surfaces. Let *a* be moved in the direction of its arrow, and let *b* be moved in the opposite direction, or even let it remain at rest. Every filament of the cotton will be laid hold of by each set of teeth, when their surfaces are thus drawn over each other; the teeth of *a* will pull them in a forward direction, while those of *b* will tend to retain them, or to pull them backwards. The loops or doublings will, by both movements, be opened or drawn out, so that the flocks will be converted into rows of parallel filaments, lying alongside or before each other. Each tooth will secure to itself one or more of them, and by the friction of its sides, as well as the hooks of its points, will draw them to their utmost elongation. Though one stroke of the opposite cards be inadequate to produce this equable arrangement, yet many repeated strokes must infallibly accomplish the end in view, of laying the fibres parallel.

Let us suppose this end effected, and that all the fibres have been transferred to the card *a*, a transverse stroke of *b* will draw over to it a certain number of them, and indeed at each stroke there will be a new partition between the two cards, with increased parallelism, but still each card will retain a great deal of the cotton. To make one card strip another, the teeth of one of them must be placed in a reverse position, as shown in *fig.* 395.

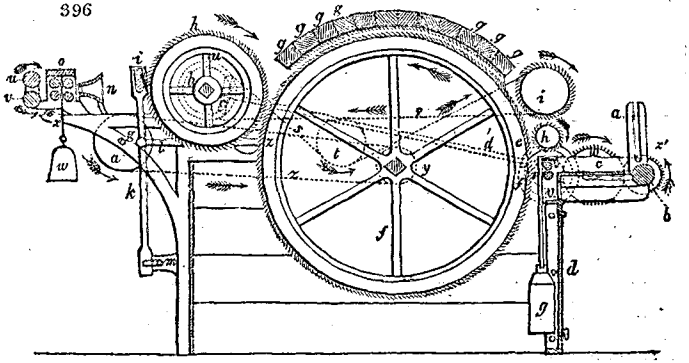
If *a* be now drawn in the direction of its arrow along the face of *b*, it will inevitably comb out all, or almost all, the filaments from it, since the hooks of *b* have, in this position, no power of retaining them. Even the doubled fibres or loops will slip over the sloping point of *b*, in obedience to the traction of *a*. By considering these two relative positions of the cards, which take place in hand cards, simply by reversing one of them, any person will be able to understand the play of a cylinder card against its flat top, or against another cylinder card, the respective teeth being in what we may call the teazing position of *fig.* 394.; and also the play of a cylinder card against the doffer cylinder, in what may be called the stripping position of *fig.* 395.

Cylinder cards, so essential to the continuity and dispatch of cotton factory labour, were the ingenious invention of Lewis Paul of Northampton, but were greatly improved and brought into nearly their present operative state by Sir Richard Arkwright. A

carding engine consists of one or more cylinders, covered with card-leather (sometimes called card cloth), and a set of plane surfaces similarly covered, made to work against each other, but so that their points do not come into absolute contact. Some cards consist entirely of cylinders, the central main cylinder being surrounded by a series of smaller ones called urchins or squirrels. These are used solely for preparing the coarser stapled cotton, and sheep's wool for the wool spinner.

Fig. 396. represents a card of excellent construction, which may be called a *breaker* and *finisher*, as it is capable of working up the fleece roll of the lapping machine directly into a card-end or riband fit for the drawing machine. In fine spinning mills there are always, however, two cards; one coarser, called a breaker, which turns off

396



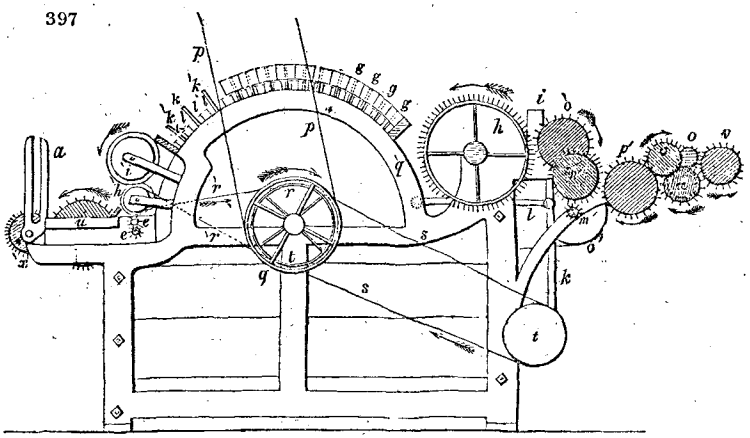
the cotton in a broad fleece of extreme thinness, which is lapped round a cylinder; and constitutes the material presented to the finisher card, which has teeth of a finer construction.

a is one of the two upright slots, which are fixed at each side of the engine for receiving the iron gudgeons of the wooden cylinders round which the fleece of the lapping machine is rolled. The circumference of this coil rests upon a roller *b*, which is made to turn slowly in such a direction as to aid the unfolding of the lap by the fluted cylinders *c*. The lap proceeds along the table seen beneath the letter *c*, in its progress to the fluted rollers, which are an inch and one-sixth in diameter, and have 28 flutings in their circumference. *g* is a weight which hangs upon the axis of the upper roller, and causes it to press upon the under one: *f* is the main card drum; *g g g*, the arch formed by the flat top cards; *h*, the small card cylinder for stripping off the cotton, and therefore called the doffer, as we have said; *i*, the doffer-knife or comb for stripping the fleecy web from the doffer; *k l q m*, the lever mechanism for moving these parts. At *d* there is a door for permitting the tenter to have access to the interior of the engine, and to remove whatever dirt, &c. may happen to fall into it. In *fig.* 397. we see the manner of fixing the flat tops *g g* over the drum; and for making the matter clearer, three of the tops are removed. Upon the arched cast-iron side of the frame, a row of strong iron pins *k* are made fast in the middle line; and each top piece has, at each of its ends, a hole, which fits down upon two such opposite pins. *l l* are screws whose heads serve as supports to the tops, by coming into contact with the bottom of the holes, which are not of course bored through the wood of the tops. By turning the heads of these screws a little the one way or the other, the pins may be lengthened or shortened in any degree, so as to set the tops very truly in adjustment with the drum teeth revolving beneath them. *h'* is the small runner or urchin, and *i'* the large runner; both of which are spirally covered from end to end with narrow card fillets, in the same manner as the doffer. The main drum is on the contrary covered with card cloth, in strips laid on parallel to its axis, with interjacent parallel smooth leather borders. The teeth of these several cards are set as represented in the figure, and their cylinders revolve as the arrows indicate. The runners as well as the doffer cylinder may be set nearer to or farther from the drum *f*; but the screws intended for this adjustment are omitted in the drawings, to avoid confusion of the lines.

The card-end or fleece taken off the doffer *h* by the crank and comb mechanism *i k m*, passes through the tin plate or brass funnel *n*, *fig.* 396., whereby it is hemmed in and contracted into a riband, which is then passed through between a pair of drawing rollers *o*. It is next received by the rollers *u v*, which carry it off with equable velocity, and let it fall into the tin cans placed below, or conduct it over a friction pulley, to be wound along with many other card-ends upon a lap roller or large bobbin. The latter mechanism is not shown in this figure. A sloping curved tin or brass plate, channelled or

ridged along its surface, conducts the card ribands separately; there are two smooth iron rollers for condensing the several ribands, and a wooden pin round which the ribands are lapped, resting between two leather-covered rollers, one of which receives

397



motion from mill geering, and imparts it by friction to the lap roller over it. The iron ends of the lap roller lie in upright slots, which allow them freedom to rise as the roller gets filled with fleece.

The two pairs of rollers at *o*, effect the extension of the card-end, and reduce its size. The under rollers are made of iron and fluted; the upper ones are also made of iron, but they are covered with a coat of leather, nicely glued on over a coat of flannel, which two coats render them both smooth and elastic. Two weights, *w*, press the upper cylinders steadily down upon the under ones. Between the first and second pair there is a certain interval, which should be proportioned to the length of the cotton staple. The second, or that furthest from the funnel, revolves with greater velocity than the first, and therefore turns out a greater length of riband than it receives from its fellow; the consequence is a corresponding extension of the riband in the interval between the two pairs of rollers.

The motions of the several parts of the engine are effected in the following way. The band, *p p*, *fig.* 397., which comes down from the pulley upon the main shaft near the ceiling of the work-room, drives, by means of the pulley *q*, the drum *f*, *fig.* 396., with a velocity of from 120 to 140 revolutions in a minute. From another pulley *r*, on the axis of the drum, the axis of *t* is driven by the band *s* working round the pulley *t* on its end. This shaft drives the crank and lever mechanism of the stripper knife *i*. A third pulley of the same size as *r* is fixed just within the frame to the other end of the drum, and from it a crossed or close band *r'* goes to a pulley upon the small runner *h'*, to give this its rapid rotation. Upon the opposite end of the engine in *fig.* 396., these wheels and pulleys are marked with dotted lines. Here we may observe, first, a pulley *y* upon the drum, and a pulley *a'*, which receives motion from it by means of the band *z*. The axis of *a'*, carries in front a pinion *m'*, which sets in motion the wheel *n'*. The latter imparts motion, by means of a pinion and intermediate wheel *o'*, to the wheel *h* on the doffer cylinder, and consequently to that cylinder on the one hand; and it turns, by the carrier wheel *p'*, a wheel *x*, whose axis is marked also with *x* in *fig.* 396., upon the other hand. The axis of *x'*, *fig.* 396., carries, towards the middle of the engine, a very broad wheel, which is represented by a small dotted circle. The toothed wheel *v* of the smooth roller *v'*, *fig.* 396., and the two toothed wheels *o o*, *fig.* 397., of the under rollers *o o*, *fig.* 396., work into that broad wheel. The wheel of the second or delivery fluted roller is seen to be smaller than that of the first, by which means the difference of their velocities is obtained. The large runner *i* is driven from the main drum pulley, by means of the band *s'*, and the pulley *u'*, *fig.* 396. The said band is crossed twice, and is kept in tension by the pulley *t'*, round which it passes. The motion of the fluted rollers *e*, which feed in the cotton fleece, is effected by means of a bevel wheel *b'* on the end of the doffer, which works into a similar wheel *c'* on the oblique axis *d'* (dotted lines across the drum), of the pinion *e'* upon the lower end of the same axis which turns the wheel *f'*, upon the under feed roller.

Each of the feed rollers, *fig.* 397., bears a pinion *e e* at one end, so that the upper roller turns round with the under one. The roller *b*, *fig.* 396., is set in motion by means of

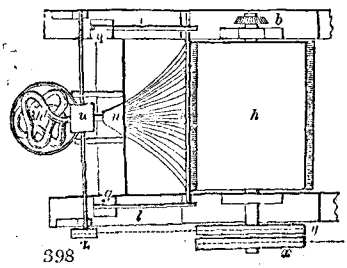
its wheel x'; which is driven by a wheel v' on the other end of the under feed roller, through the intervention of the large carrier wheel w'. The original or first motion of b must be as quick as that of the fluted feed rollers e, in order that the former may uncoil as much lap as the latter can pass on.

The annexed table exhibits the proper velocities of the different cylinders and rollers of the carding engine, which, however, are not invariable, but may be modified according to circumstances, by changing the pinions e', *fig.* 396., and w', according to the quality or length of the cotton staple. The velocities stated in the table will be obtained when the pulley a', *fig.* 396., is made greater than y in the proportion of 3 to 2, and the wheels and pinions have the following number of teeth: m', 18; n', 50; its pinion, 18; h, 128; x, 24; the broad wheel upon the shaft of x, 37 teeth; the wheel o of the first fluted roller, 35; that of the second, 21; v, 44; b' and e', 54; e', 10; f', 63.

Names of the parts.	Diameter in inches.	Circumference in inches.	Revolutions in one minute.	Velocity.
Drum f - - -	35	109·9	130	142·87
Doffer h - - -	14	43·96	4·38	192·5
Runner or urchin i' -	6·25	19·62	5·	98·1
Ditto h' - - -	3·5	11·	470·	5170·
Fluted feed roller e -	1·167	3·664	0·696	2·55
First drawing roller o -	1·	3·14	68·71	215·75
Second ditto - -	1·167	3·664	114·52	419·6
Smooth delivery roller v	2·5	7·85	54·66	429·08

The operation of the runners, h' and i', becomes very plain on comparing their speed with one another and with that of the main-drum, and taking into account the direction of the card teeth. The cotton wool, taken off from the feed-rollers by the drum, is caught by the opposite teeth of the large runner i', which, on account of its slower surface rotation (98 inches per minute) may be considered to be at rest with reference to the drum, and therefore, by holding the cotton in its teeth, will commence its carding. The small runner h', in consequence of its greater surface velocity (5170 inches per minute) will comb the cotton-wool back out of the teeth of the large runner, but it will give it up in its turn to the swifter teeth of the drum, which, in carrying it forwards, encounters the teeth of the top cards, and delivers up the filaments to their keeping for some time. We thus see how essential the runners are to the perfection as well as to the acceleration of the carding process for ordinary cotton wool, though for the slenderer and longer filaments of the sea-island kind they are not so well adapted. In cleaning the carding-engines the little runner must be looked to every time that the drum is examined. The large runner and the doffer require to be cleaned together. The quantity of cotton spread upon the feed-cloth, the velocity of it, and of the drawing-rollers, must all be carefully adjusted to the grist of the yarn intended to be spun.

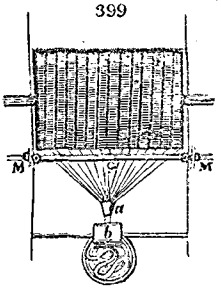
Suppose the sizes and velocities to be as represented in the preceding table, that the engine is a double card 36 inches broad, and that it is furnished with a lap from the lap-machine of which 30 feet in length weigh 5 lbs. In one minute the surface of the feed-rollers, e, passes 2·55 inches of that lap onwards; in the same time the main drum f will work it off. To card the whole 30 feet, therefore, 141 minutes, or 2 hours and 21 minutes will be required. In this time the circumference of the rollers, u v, moves through a space of 141 × 42,908 in. = 5042 ft., and delivers a card-end of that length, weighing 5 lbs., *minus* 6 per cent. for waste, that is 4 lbs. 11½ oz. One pound will form a riband 1072 feet long, being, according to the English mode of counting, about number ⅓, or 0·357. The extension of the cotton-fleece to this degree proceeds as follows: — In the 141 minutes which the feed-rollers take to introduce the 30 feet of lap, the doffer, h, makes 617·58 revolutions, and the comb, or doffer knife, i, detaches from the doffer teeth, a thin fleecy web of 2262 feet in length. The first drawing pair of fluted rollers, by its quick motion, with the aid of the funnel, m, converts this fleece into a riband 2535 feet long. The second pair of the fluted rollers extends this riband to 4390 feet, since their surface velocity is greater than the first pair in that proportion. The slight elongation (of only 112 feet, or about $\frac{1}{41}$) which takes place between the delivery fluted rollers and the smooth cylinders, v, u, serves merely to keep the card-end steadily upon the stretch without folding. *Fig.* 398. is a plan of the card and the fleece, where h is the cylinder, n is the funnel, u the pressing rollers, and h' the card-ends in the can.



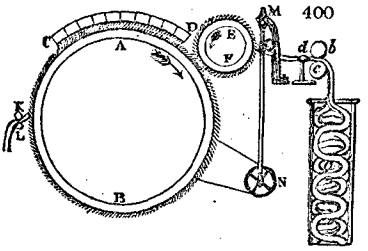
398

Figs. 399, 400. represent skeletons of the old cards to facilitate the comprehension of these complex machines. *Fig.* 399. is a plan; F is the main drum; M M is the doffer

399



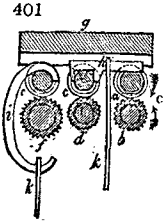
400



knife or comb; G, the carded fleece hemmed in by the funnel *a*, pressed between the rollers *b*, and then falling in narrow fillets into its can. *Fig.* 400. K L are the feed rollers; A B, the card drum; C D, the tops; E F, the doffer card; M N, the doffer knife; *d*, *b*; *c*, the card-end passing between compressing rollers into the can *a*.

The drawing and doubling are the next operation. The ends, as they come from the cards, are exceedingly tender and loose, but the filaments of the cotton are not as yet laid so parallel with each other as they need to be for machine spinning. Before any degree of torsion therefore be communicated, a previous process is required to give the filaments a level arrangement in the ribands. The drawing out and doubling accomplish this purpose, and in a manner equally simple and certain. The means employed are drawing-rollers, whose construction must here be fully explained, as it is employed in all the following machines; one example of their use occurred, indeed, in treating of the cards.

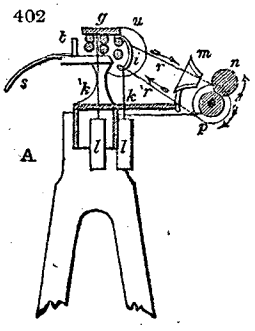
401

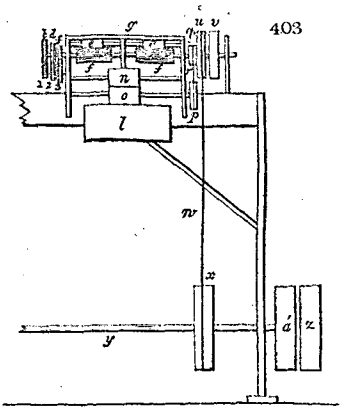


Let *a* and *b*, *fig.* 401., represent the section of two rollers lying over each other, which touch with a regulated pressure, and turn in contact upon their axes, in the direction shown by the arrows. These rollers will lay hold of the fleecy riband presented to them at *a*, draw it through between them, and deliver it quite unchanged. The length of the piece passed through in a given time will be equal to the space which a point upon the circumference of the roller would have percured in the same time; that is, equal to the periphery of one of the rollers multiplied by the number of its entire revolutions. The same thing holds with regard to the transmission of the riband through between a second pair of rollers, *c*, *d*, and a third, *e*, *f*. Thus the said riband issues from the third pair exactly the same as it entered at *a*, provided the surface speed of all the rollers be the same. But if the surface speed of *c* and *d* be greater than that of *a* and *b*, then the first-named pair will deliver a greater length of riband than the last receives and transmits to it. The consequence can be nothing else in these circumstances than a regulated drawing or elongation of the riband in the interval betwixt *a*, *b*, and *c*, *d*, and a condensation of the filaments as they glide over each other, to assume a straight parallel direction. In like manner the drawing may be repeated by giving the rollers, *e*, *f*, a greater surface speed than that of the rollers, *c* and *d*. This increase of velocity may be produced, either by enlarging the diameter, or by increasing the number of turns in the same time, or finally by both methods conjoined. In general the drawing-machine is so adjusted, that the chief elongation takes place between the second and third pair of rollers, while that between the first and second is but slight and preparatory. It is obvious, besides, that the speed of the middle pair of rollers can have no influence upon the amount of the extension, provided the speed of the first and third pair remains unchanged. The rollers, *a*, *b*, and *c*, *d*, maintain towards each other continually the same position, but they may be removed with their frame-work, more or less, from the third pair, *e*, *f*, according as the length of the cotton staple may require. The distance of the middle point from *b* and *d*, or its line of contact with the upper roller, is, once for all, so calculated, that it shall exceed the length of the cotton filaments, and thereby that these filaments are never in danger of being torn asunder by the second pair pulling them while the first holds them fast. Between *d* and *f*, where the greatest extension takes place, the distance must be as small as it can be without risk of tearing them in that way; for thus will the uniformity of the drawing be promoted. If the distance between *d* and *f* be very great, a riband passing through will become thinner, or perhaps break in the middle; whence we see that the drawing is more equable, the shorter is the portion submitted to extension at a time, and the nearer the rollers are to each other, supposing them always distant enough not to tear the staple.

The under rollers *b d f* are made of iron, and, to enable them to lay firmer hold of the filaments, their surfaces are fluted with triangular channels parallel to their axes. The upper rollers, *a c e*, are also made of iron, but they are smooth, and covered with a double coating, which gives them a certain degree of softness and elasticity. A coat of flannel is first applied by sewing or gluing the ends, and then a coat of leather in the same way. The junction edges of the leather are cut slanting, so that when joined by the glue (made of isinglass dissolved in ale) the surface of the roller may be smoothly cylindrical. The top rollers are sometimes called the *pressers*, because they press by means of weights upon the under ones. These weights are suspended to the slight rods *k k'*; of which the former operates on the roller *e* alone, the latter on the two rollers *a* and *e* together. For this purpose the former is hung to a c shaped curve *i*, whose upper hook embraces the roller *e*; the latter to a brass saddle *h*, which rests upon *a* and *c*. A bar of hard wood, *g*, whose under surface is covered with flannel, rests, with merely its own weight, upon the top rollers, and strips off all the loose hanging filaments. Similar bars with the same view are made to bear up under the fluted rollers *b d f*, and press against them by a weight acting through a cord passing over a pulley. Instead of the upper dust-covers, light wooden rollers covered with flannel are occasionally applied.

Were the drawing of a riband continued till all its fibres acquired the desired degree of parallelism, it would be apt, from excessive attenuation, to tear across, and thereby to defeat the purpose of the spinner. This dilemma is got rid of in a very simple way, namely, by laying several ribands together at every repetition of the process, and incorporating them by the pressure of the rollers. This practice is called *doubling*. It is an exact imitation of what takes place when we draw a tuft of cotton wool between our fingers and thumb in order to ascertain the length of the staple, and replace the drawn filaments over each other, and thus draw them forth again and again, till they are all parallel and of nearly equal length. The doubling has another advantage, that of causing the inequalities of thickness in the ribands to disappear, by applying their thicker to their thinner portions, and thereby producing uniformity of substance.





The drawing frame, as shown in section in *figs.* 401. 403., and in a back view in *fig.* 402., will require, after the above details, little further explanation. *l l* are the weights which press down the top rollers upon the under ones, by means of the rods *k k'* and hook *i*. Each fluted roller is, as shown at *f*, *fig.* 402., provided in the middle of its length with a thinner smooth part called the *neck*, whereby it is really divided into two fluted portions, represented by *e e* in the figure. Upon this middle neck in the pressure rollers, the hook *i* and the saddle *h* immediately bear, as shown in the former *fig.* 401. The card-ends, to the number probably of six, are introduced to the drawing frame either from tin cans, placed at *e e*, *fig.* 403., and at A, *fig.* 402., or from lap-bobbins; and, after passing through it, the ribands or slivers are received either into similar tin cans, as *g*, or upon other lap-bobbins upon the other side. These appendages may be readily conceived, and are therefore not exhibited in all the drawings. Three of the slivers being laid together, are again introduced to the one fluted portion *a b*, *fig.* 401., and three other slivers to the other portion. The sloping curved tin or brass plate *s*, *fig.* 402., with its guide pins *t*, serves to conduct the slivers to the rollers. When the two threefold slivers have passed through between the three pairs of rollers, and been thereby properly drawn, they run towards each other in an oblique direction, behind the last roller pair *e f*, *fig.* 401., and unite, on issuing through the

conical funnel *m*, *fig.* 402., into a single riband or spongy sliver; which is immediately carried off with equable velocity by two smooth cast-iron rollers, *n o*, *fig.* 402. and 403. and either dropped into a can, or wound upon a large bobbin. The surface speed of these rollers is made a trifle greater than that of the delivery drawing rollers, in order to keep the portion of sliver between them always in an extended state. Four fluted drawing portions are usually mounted in one drawing frame, which are set a-going or at rest together. To save all unnecessary carrying of the cans from the back to the front of the frame, the drawing heads are so placed, that the first and third, discharge their slivers at the one side, and the second and fourth at the other. By this arrangement, the cans filled behind one head, are directly pushed aside in front of the next drawing head; by which alternate distribution the work goes on without interruption.

The *fast* pulley *u*, *fig.* 403., by which the whole machine is driven, derives its motion from the main shaft of the mill by means of the band *w*. The similar pulley *z*, which sits loose upon the axis, and turns independently of it, is called the loose pulley; both together being technically styled *riggers*. When the operative desires to stop the machine, he transfers the band from the fast to the loose pulley by means of a lever, bearing a fork at its end, which embraces the band. Upon *y*, four pulleys such as *x* are fixed, each of which sets in motion a drawing head, by means of a band like *w* going round the pulleys *x* and *u*. On account of the inverted position of the heads, which requires the motion of *u* to be inverted, the bands of the first and third heads are open, but those of the second and fourth are crossed. Every head is provided with a loose pulley *v*, as well as the fast pulley *u*, in order to make the one stop or move without affecting the others. The shaft of the pulley *u* is the prolonged shaft of the backmost fluted roller *f*. It carries besides a small pulley *q*, which, by means of the band *r*, and the pulley *p*, *fig.* 402., sets in motion the undermost condensing roller *o*. The upper roller *n*, presses with its whole weight upon it, and therefore turns by friction. The toothed wheel-work, by which the motions are communicated from the backmost fluted roller to the middle and front ones, are seen in *fig.* 403.

The wheel *f*, *fig.* 401., of 20 teeth, works in a 44-toothed carrier-wheel, on whose axis there are two smaller wheels; 2 with 26 teeth, and 1 with 22 teeth. The wheel *d*, *fig.* 403., of the middle roller, and the wheel *b* of the front roller, are set in motion by other carrier wheels; the first has 27 teeth, and the last 40. For every revolution of *b*, the roller *d* makes nearly $1\frac{3}{4}$ turns, and the roller *f*, 4 revolutions. The top rollers revolve, as we have stated, simply by the friction of contact with the lower ones. Now suppose the diameter of the rollers *b* and *d* to be 1 inch or 12 lines, that of *f*, $1\frac{1}{4}$ inches or 15 lines, the surface velocities of the three pairs of rollers in the series will be as 1, $1\frac{3}{4}$, and 5. Every inch of the cotton sliver will be therefore extended between the first and second pair of rollers into $1\frac{3}{4}$ inches, and between the second and third or delivery pair into 5 inches; and after the sliver has passed through all the four drawing heads, its length will be increased 625 times $= 5 \times 5 \times 5 \times 5$.

The further the drawing process is pushed, the more perfectly will its object be accomplished; namely the parallelism of the filaments. The fineness of the appearance of the sliver after the last draught depends upon the number of doublings conjointly with the original fineness and number of drawings. The degree of extension may be increased or diminished, by changing the wheels in *fig.* 403., for others with a different number of teeth. Thus the grist or fineness of the sliver may be modified in any desired degree; for, when the subsequent processes of the mill remain the same, the finer the drawings the finer will be the yarn. For spinning coarse numbers or low counts, for example, six card-ends are usually transmitted through the first drawing head, and converted into one riband. Six such ribands again form one in the second draught; six of these again go together into the third sliver; and this sliver passes five-fold through the last draught. By this combination 1080 of the original card-ends are united in the finished drawn sliver $= 6 \times 6 \times 6 \times 5$. The fineness of the sliver is, however, in consequence of these doublings not increased but rather diminished. For, by the drawing, the card-end has been made 625 times longer, and so much smaller; by the doubling alone it would have become 1080 times thicker; therefore the original grist is to the present as 1, to the fraction $\frac{625}{1080}$; that is, supposing 1072 feet of the riband delivered by the card to weigh one pound, 625 feet, the sliver of the last drawing, will also weigh a pound, which corresponds in fineness to number 0·24, or nearly $\frac{1}{4}$.

The rearmost or last drawing roller has a circumference of nearly 4 inches, and makes about 150 revolutions per minute; hence, each of these drawing heads may turn off 35,000 feet of sliver in 12 hours.

Some manufacturers have lately introduced a double roller beam, and a double draught at the same doubling, into their drawing frames. I have seen this contrivance working satisfactorily in mills where low counts were spun, and where the tube roving frame was employed; but I was informed by competent judges, that it was not advisable where a level yarn was required for good printing calicoes.

The loss which the cotton suffers in the drawing frame is quite inconsiderable. It consists of those filaments which remain upon the drawing rollers, and collect, in a great measure, upon the flannel facing of the top and bottom cleaner bars. It is thrown among the top cleanings of the carding engine. When from some defect in the rollers, or negligence in piecing the running slivers, remarkably irregular portions occur in the ribands, these must be torn off, and returned to the lap machine to be carded anew.

The fifth operation may be called the *first spinning process*, as in it, the cotton sliver receives a twist; whether the twist be permanent as in the bobbin and fly frame, or be undone immediately, as in the tube-roving machine. In fact, the elongated slivers of parallel filaments could bear little further extension without breaking asunder, unless the precaution were taken to condense the filaments by a slight convolution, and at the same time to entwine them together. The twisting should positively go no further than to fulfil the purpose of giving cohesion, otherwise it would place an obstacle in the way of the future attenuation into level thread. The combination of drawing and twisting is what mainly characterizes the spinning processes, and with this fifth operation therefore commences the formation of yarn. As however a sudden extension to the wished-for fineness is not practicable, the draught is thrice repeated in machine spinning, and after each draught a new portion of torsion is given to the yarn, till at last it possesess the degree of fineness and twist proportioned to its use.

The preliminary spinning process is called *roving*. At first the torsion is slight in proportion to the extension, since the solidity of the still coarse sliver needs that cohesive aid only in a small degree, and looseness of texture must be maintained to facilitate to the utmost the further elongation.

404

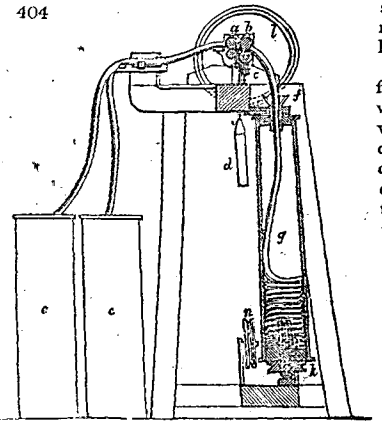


Fig. 404. is a section of the can roving frame, the ingenious invention of Arkwright, which till within these 14 years was the principal machine for communicating the incipient torsion to the spongy cord furnished by the drawing heads. It differs from that frame in nothing but the twisting mechanism; and consists of two pairs of drawing rollers, *a* and *b*, between which the sliver is extended in the usual way; *c* are brushes for cleaning the rollers; and *d* is the weight which presses the upper set upon the lower. The wiping covers (not shown here) rest upon *a b*. The surface speed of the posterior or second pair of rollers is 3, 4, or 5 times greater than that of the front or receiving pair, according to the desired degree of attenuation. Two drawn slivers were generally united into one by this machine, as is shown in the figure, where they are seen coming from the two cans *e e*, to be brought together by the pressure rollers, before they reach the drawing rollers *a b*. The sliver, as it escapes from these rollers, is conducted into the revolving conical lantern *g*, through the funnel *f* at its top. This lantern-can receives its motion by means of a cord passing over a pulley *k*, placed a little way above the step on which it turns. The motion is steadied by the collet of the funnel *f*, being embraced by a brass busk. Such a machine generally contained four drawing heads, each mounted with two lanterns; in whose side there was a door for taking out the conical coil of roving.

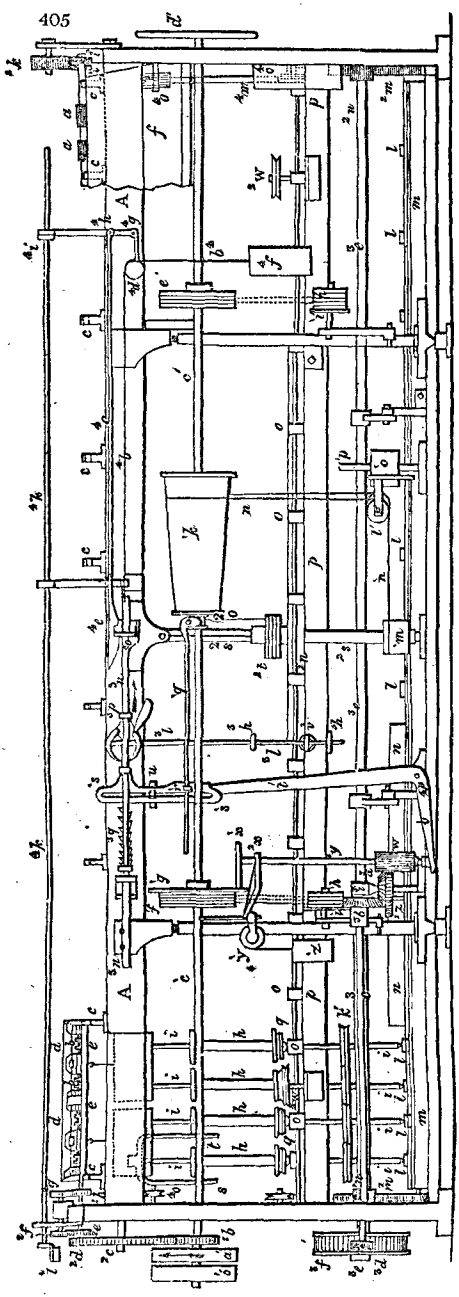
The motion imparted to the back roller by the band pulley or rigger *m*, was conveyed to the front one by toothed wheel work.

The vertical guide pulley at bottom *n*, served to lead the driving band descending from the top of the frame round the horizontal whorl or pulley upon the under end of the lantern. The operation of this can-frame was pleasing to behold; as the centrifugal force served both to distribute the soft cord in a regular coil, and also to condense a great deal of it most gently within a moderate space. Whenever the lantern was filled, the tenter carried the roving to a simple machine, where it was wound upon bobbins by hand. Notwithstanding every care in this transfer, the delicate texture was very apt to be seriously injured, so as to cause corresponding injuries in every subsequent operation, and in the finished yarn. Messrs. Cocker and Higgins, of Salford, had the singular merit, as I have said, of superseding that beautiful but defective mechanism, which had held a prominent place in all cotton mills from almost the infancy of the factory system, by the following apparatus.

The Bobbin and Fly frame is now the great roving machine of the cotton manufac-

ture; to which may be added, for coarse spinning, the tube roving frame. Of such a complicated machine as the bobbin and fly frame, it is not possible to give an adequately detailed description in the space due to the subject in this Dictionary. Its mechanical combinations are however so admirable as to require such an account as will make its functions intelligible by the general reader.

405



406

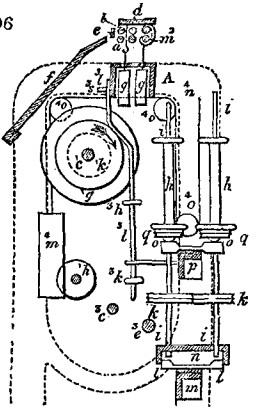


Fig. 405. exhibits a back view of this machine; and *fig.* 406. a section of some of the parts not very visible in the former figure. The back of the machine is the side at which the cotton is introduced between the drawing rollers.

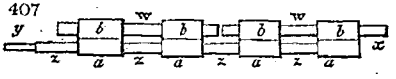
The cans, or lap-bobbins filled with slivers at the drawing frame, are placed in the situation marked B, *fig.* 406., in rows parallel with the length of the machine. The sliver of each can or the united slivers of two contiguous cans are conducted upwards along the surface of a sloping board *f*, and through an iron staple or guide *e*, betwixt the usual triple pair of drawing rollers, the first of which is indicated by *a*, *b*. In *fig.* 405., for the purpose of simplifying the figure, the greater part of these rollers and their subordinate parts are omitted. After the slivers have been sufficiently extended and attenuated between the rollers, they proceed forwards, towards the spindles *i i i*, where they receive the twist, and are wound upon the bobbins *h*. The machine delineated contains thirty spindles, but many bobbin and fly frames contain double or even four times that number. Only a few of the spindles are shown in *fig.* 405., for fear of confusing the drawing.

With regard to the drawing functions of this machine, I have already given abundant

explanation, so far as the properties and operation of the rollers are concerned. The frame-work of this part of the machine, called the *roller-beam*, is a cast iron bench, upon which nine bearers *c* are mounted for carrying the rollers. The fluted rollers *a a a*, *fig.* 407., are constructed in four pieces for the whole length, which are parted from each other by thinner smooth cylindric portions *z*, called necks. Seven such partings for four rollers, and one parting for two rollers, constitute together the 30 fluted rollers of which the whole series consists. The coupling of these roller subdivisions into one cylinder, is secured by the square holes *x*, and square pins *y*, *fig.* 407., which fit into the holes of the adjoining subdivision.

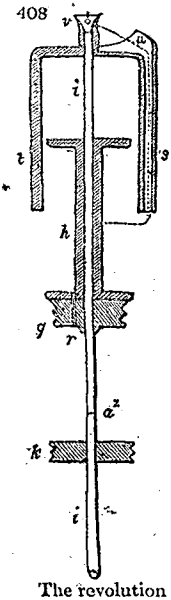
407



The top or pressure rollers *b*, are two-fold over the whole set; and the weighted saddle presses upon the neck *w*, which connects every pair, as was already explained under *fig.* 402. These weights *g*, *g*, *fig.* 406., are applied in this as in the *drawing frame*; *d*, are the bars faced with flannel for cleaning the top rollers. A similar bar is applied beneath the rollers, to keep the flutings clean.

The structure and operation of the spindles *i*, may be best understood by examining the section *fig.* 408. They are made of iron, are cylindrical from the top down to a^2, but from this part down to the steel tipt rounded points they are conical. Upon this conical portion there is a pulley *k*, furnished with two grooves in its circumference, in which the cord runs that causes the spindle to revolve. The wooden bobbin *h*, is slid upon the cylindrical part, which must move freely upon it, as will be presently explained. To the bobbin another two-grooved pulley or whorl *g* is made fast by means of a pin *r*, which passes through it; by removing this pin, the bobbin can be instantly taken off the spindle. The upper end of the spindle bears a fork *s t*, which may be taken off at pleasure by means of its left-handed screw; this fork or flyer, has a funnel-formed hole at *v*. One arm of the fork is a tube *s*, *u*, open at top and bottom; the leg *t*, is added merely as a counterpoise to the other. In *fig.* 406., for the sake of clearness, the forks or flyers of the two spindles here represented are left out; and in *fig.* 405. only one is portrayed for the same reason. It is likewise manifest from a comparison of these two figures that the spindles are alternately placed in two rows, so that each spindle of the back range stands opposite the interval between two in the front range. The object of this distribution is economy of space, as the machine would need to be greatly longer if the spindles stood all in one line. If we suppose the spindles and the bobbins (both of which have independent motions) to revolve simultaneously and in the same direction, their operation will be as follows: The sliver properly drawn by the fluted rollers, enters the opening of the funnel *v*, proceeds thence downwards through the hole in the arm of the fork, runs along its tube *u*, *s*, and then winds round the bobbin. This path is marked in *fig.* 408. by a dotted line.

408



The revolution of the spindles in the above circumstances effects the twisting of the sliver into a soft cord; and the flyer *s*, *t*, or particularly its tubular arm *s*, lays this cord upon the bobbin. Were the speed of the bobbins equal to that of the spindles, that is, did the bobbin and spindle make the same number of turns in the same time, the process would be limited to mere twisting. But the bobbin anticipates the flyers a little, that is, it makes in a given time a somewhat greater number of revolutions than the spindle, and thereby effects the continuous winding of the cord upon itself. Suppose the bobbin to make 40 revolutions, while the spindle completes only 30; 30 of these revolutions of the bobbin will be inoperative towards the winding-on, because the flyers follow at that rate, so that the cord or twisted sliver will only be coiled 10 times round the bobbin, and the result as to the winding-on will be the same as if the spindle had stood still, and the bobbin had made $40 - 30 = 10$ turns. The 30 turns of the spindles serve, therefore, merely the purpose of communicating twist.

The mounting and operation of the spindles are obviously the same as they are upon the household flax wheel. In the bobbin and fly frame there are some circumstances which render the construction and the winding-on somewhat difficult, and the mechanism not a little complicated. It may be remarked in the first place, that as the cord is wound on, the diameter of the bobbin increases very rapidly, and therefore every turn made round it causes a greater length of roving to be taken up in succession. Were the motions of the bobbins to continue unchanged in this predicament, the increased velocity of the winding-on would require an increased degree of extension, or it would

occasion the rupture of the cord, because the front fluted rollers move with uniform speed, and therefore deliver always the same length of sliver in the same time. It is therefore necessary to diminish the velocity of the bobbins, or the number of their turns, in the same proportion as their diameter increases, in order that the primary velocity may remain unchanged. Moreover, it is requisite for the proper distribution of the cord upon the bobbin, and the regular increase of its diameter, that two of its successive convolutions should not be applied over each other, but that they should be laid close side by side. This object is attained by the up and down sliding motion of the bobbin upon the spindle, to the same extent as the length of the bobbin barrel. This up and down motion must become progressively slower, since it increases the diameter of the bobbin at each range, by a quantity equal to the diameter of the sliver. What has now been stated generally, will become more intelligible by an example.

Let it be assumed that the drawing rollers deliver, in 10 seconds, 45 inches of roving, and that this length receives 30 twists. The spindles must, in consequence, make 30 revolutions in 10 seconds, and the bobbins must turn with such speed, that they wind up the 45 inches in 10 seconds. The diameter of the bobbin barrels being $1\frac{1}{4}$ inches, their circumference of course $4\frac{1}{2}$ inches, they must make 10 revolutions more in the same time than the spindles. The effective speed of the bobbins will be thus $30+10=40$ turns in 10 seconds. Should the bobbins increase to 3 inches diameter, by the winding-on of the sliver, they will take up 9 inches at each turn, and consequently 45 inches in 5 turns. Their speed should therefore be reduced to $30+5=35$ turns in 10 seconds. In general, the excess in number of revolutions, which the bobbins must make over the spindles, is inversely as the diameter of the bobbins. The speed of the bobbins must remain uniform during the period of one ascent or descent upon the spindle, and must diminish at the instant of changing the direction of their up and down motion; because a fresh range of convolutions then begins with a greater diameter. When, for example, 30 coils of the sliver or roove are laid in one length of the bobbin barrel, the bobbin must complete its vertical movement up or down, within 30 seconds in the first case above mentioned, and within 60 seconds in the second case.

The motions of the drawing rollers, the spindles, and bobbins, are produced in the following manner: — A shaft c', *fig.* 405. and 406., extending the whole length of the machine, and mounted with a fly wheel d', is set in motion by a band from the running pulley upon the shaft of the mill, which actuates the pulley a'. b' is the loose pulley upon which the band is shifted when the machine is set at rest. Within the pulley a', but on the outside of the frame, the shaft c' carries a toothed wheel b^2 with 50 teeth, which by means of the intermediate wheel c^2 turns the wheel d^2 upon the prolonged shaft of the backmost fluted roller (m^2, *fig.* 406.) This wheel d^2 has usually 54 teeth; but it may be changed when the roove is to receive more or less twist; for as the spindles revolve with uniform velocity, they communicate the more torsion the less length of sliver is delivered by the rollers in a given time. Upon the same shaft with d^2, a pinion e^2 of 32 teeth is fixed, which works in a wheel f^2 of 72 teeth. Within the frame a change pinion g^2 is made fast to the shaft of f^2. This pinion, which has usually from 24 to 28 teeth, regulates the drawing, and thereby the fineness or *number* of the roving. It works in a 48-toothed wheel h^2 upon the end of the backmost fluted roller a, *fig.* 406. The other extremity of the same roller, or, properly speaking, line of rollers, carries a pinion l^2, furnished with 26 teeth, which, by means of the broad intermediate wheel k^2, sets in motion the pinion i'^2 of 22 teeth upon the middle roller. When the diameter of all the drawing rollers is the same, suppose 1 inch, their proportional velocities will be, with the above number of teeth in the wheel work, if g^2 have 24 teeth, as $1 : 1{\cdot}18 : 4{\cdot}5$; and the drawn sliver will have $4\frac{1}{2}$ times its original length. The front or delivery roller of the drawing frame is of late years usually made $1\frac{1}{4}$ or $1\frac{3}{8}$ inches in diameter. If 625 feet of the sliver from the drawing frame weighed one pound, 2790 feet of the roving will now go to this weight, and the number will be $1{\cdot}12$; that is, 1 hank and 12 hundredths to the pound. The front pair of fluted rollers makes about 90 revolutions, and delivers $282{\cdot}6$ inches of roving in the minute, when of one inch diameter.

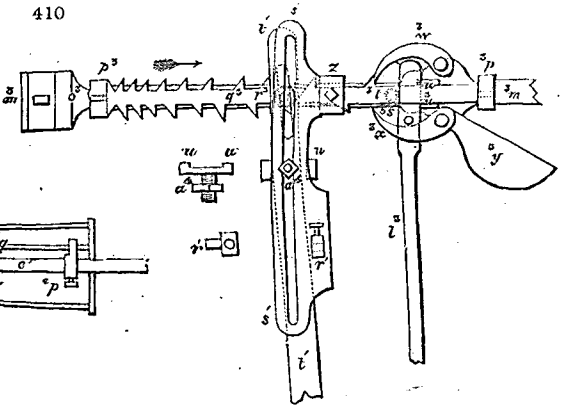
The spindles i, (*fig.* 405. and 406.), rest, with their lower ends, in steps l, which are fixed in an immoveable beam or bar m. To protect it from dust and cotton filaments, this beam is furnished with a wooden cover n, in which there are small holes for the passage of the spindles right over the steps. In *fig.* 405., two of the eight covers n, which compose the whole range m, are removed to let the steps be seen. The cylindrical part of each spindle passes through a brass ring o; and all these 30 rings, whose centres must be vertically over the steps l, are made fast to the copping beam p. This beam is so called, because it is destined not merely to keep the spindles upright by the rings attached to it, but, at the same time, to raise and lower along the spindles the bobbins

which rest on these rings; for which purpose the two racks, or toothed bars m^2 m^2, made fast to it, are designed, as will be presently explained. To effect the revolution of the spindles, there are attached to the main shaft c' two whorls or pulleys e' f', each bearing four grooves of equal diameter. Each of these pulleys puts one half of the spindles in motion, by means of a cord, which, after going round the whorls h, turns four times about the pulleys of the shaft c'. Two guide pulleys h', each four-grooved, and two others i', with a single groove, which turn independently of the others, upon the above shaft, serve to give the whorl cords the proper direction, as well as to keep them tight. The spindles revolve 200 times or thereby in the minute; and therefore impart two turns or twists to every three inches of the roving.

The revolution of the bobbins is independent of that of the spindles, although it likewise proceeds from the shaft c', and differs from it in being a continually retarded motion. The simplest method of effecting this motion, is by means of the wooden or tin plate cone h'', which revolves equally with the shaft c', and at the same time slides along it.

The manner in which this operates is shown in section in *fig.* 409. Here we perceive the rod q^2, which extends from the base towards the narrow end of the truncated cone, and p^2 a forked bearer or carrier made fast to the shaft c' by a screw, which compels the cone by means of that rod, to obey the movements of c'. In the large end

410



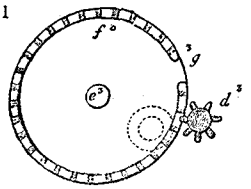
409

of the cone there is an aperture, through which the bearer can be got at. The smaller end carries outside a projection o^2, provided with a groove, which is embraced by the forked end of a rod q', *fig.* 410., that serves to shove the cone along upon the shaft c'. Directly under the cone, there is an upright round pillar p', upon which the holder o' of the two guide pulleys l' is adjustable. A bar r^2 placed along-side of the holder, prevents its turning round, but allows it to slide along p' by friction. The weight of the holder and the pulley is sufficient to distend the endless band n', which runs from the cone h', through under the pulley l', and round the small drum m' on the shaft s^2. A pulley or whorl t^2 with four grooves, is made fast by means of a tube to this shaft, and slides along it backwards and forwards, without ever ceasing to follow its revolutions. The shaft possesses for this purpose a long fork, and the interior of the tube a corresponding tongue or catch. There is besides upon the tube beneath the pulley, at u^2, a groove that goes round it, in which the staple or forked end of an arm like v^2, *fig.* 406. made fast to the copping beam p, catches. By the up and down movement of that beam, the pulley t^2 takes along with it the arm that embraces the tube, which therefore rises and falls equally with the bobbins h', and their pulleys or whorls q. This is requisite, since the bobbins are made to revolve by the pulleys t^2, by means of 2 endless cords or bands.

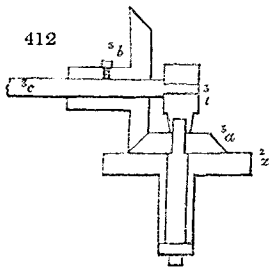
The most intricate part of the mechanism is the adjustment, by which the revolution of the bobbins is continually retarded, and their up and down, or copping motion, along the spindles, is also retarded in like proportion. The vertical pulley f', (towards the left end of the shaft c') has at its right side a somewhat larger *disc* or sheave g', with a perfectly uniform, but not a very smooth surface. Upon this sheave, a smaller horizontal pulley x' rubs, whose upper face is covered with leather to increase the friction. The under end of the shaft y^2 of the pulley x' turns in a step, which is so connected with the arm v' of the large bent lever t' v', that it always stands horizontally, whatever direction the arms of that lever may assume. The shaft y^2 is steadied at top by an

annular holder or bush, which embraces the fast arm x^2 with its forked end. Upon its opposite side, this arm carries a pulley y^2, upon which a cord goes, that is made fast to the holder of the shaft y'^2, and loaded with the weight z'. The weight presses the pulley x' against the surface of g', in such wise as to effect the degree of friction necessary in order that the revolution of g' may produce an uninterrupted revolution in x'. A pinion w', whose length must be equal at least to the semi-diameter of the sheave g', is placed upon the under end of the shaft y^2. It has 22 teeth, and takes into a 62-toothed horizontal wheel z^2. Upon the upper end of this wheel the conical pinion a^3 is made fast, which may be changed for changing the speed, but usually has from 28 to 30 teeth. By this pinion the conical wheel b^3 is turned, which has 30 teeth, and whose shaft is c^3. This shaft carries upon its opposite end a six-leaved pinion, d^3, which takes into the calender wheel f^3, formed with cogs like a trundle, upon the long shaft e^3. In *fig.* 411. the wheel f^3 is exhibited with its pinion d^3. Here we may remark that in the circumference of the wheel there is a vacant place, g^3, void of teeth. When by the motion of the wheel, the pinion comes opposite to this opening, it turns round about the last tooth of the wheel, falls into the inside of the toothed circle marked by the dotted lines, and thus gives now an inverse movement to the wheel f^3, while itself revolves always in the same direction. This reversed motion continues till the opening g^3 comes once more

411



412



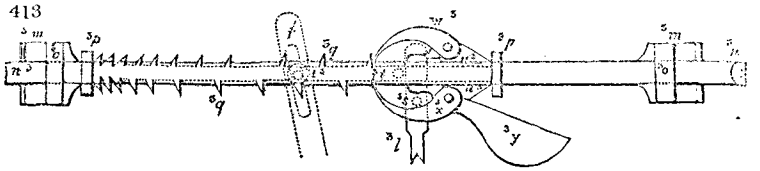
opposite to the pinion, when this turns round about the last tooth of that side, and begins again to work in the exterior teeth. Thus, by the uniform motion of d^3 and its dependent parts, the wheel f^3, with its shaft e^3, revolves alternately to the right hand and the left. That this result may ensue, the shaft c^3 of the pinion must be able to slide endwise, without losing its hold of a^3 and b^3. This adjustment is effected by placing the end of the said shaft, nearest b^3, in a box or holder i^3, in which it can turn, and which forms a vertical tube to this box, as a downward prolongation which is fixed to the tail of the conical pinion a^3. *Fig.* 412. shows this construction in section upon an enlarged scale. The second bearer of the shaft nearest d^3, must possess likewise the means of lateral motion. When therefore the pinion d^3 shifts through the opening of the wheel f^3 outwards or inwards, its shaft c^3, makes a corresponding small angular motion upon the pivot of a^3, by means of the tube i^3; a^3 and b^3 remain thereby completely in geer with one another.

The above-described alternate revolutions of the wheel f^3 serve to produce the up and down motions of the bobbins. The shaft e^3 has for this purpose two pinions n^2 n^2, which work in the rack teeth m^2 m^2 of the copping rail p, and thus alternately raise and sink it with the bobbins which rest upon it. The weight of the copping beam and all its dependent parts, is poised by two counterweights m^4, whose cords run over the pulleys o^4 o^4 o^4, *fig.* 405., and have their ends made fast to the frame, so as to make the upwards motion as easy as the downwards. The two upper pulleys out of the three of each weight, are fixed to the frame; the under one, round which the cord first runs, is attached to the copping beam, rising and falling along with it.

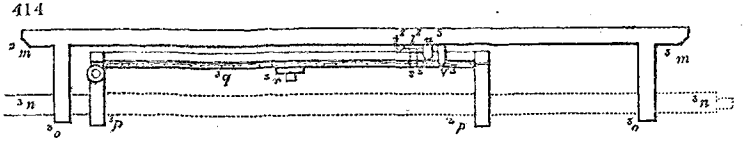
As long as the friction disc x' remains at the same height, the pulley g' derives its motion from the same circle of the said disc, and the up and down motion of the copping beam is also uniform. But when that disc ascends so as to describe with its edge a small circle upon the face of g', its motion must become proportionally more slow. This is the method, or principle of retarding the copping motions of the bobbins. It has been shown, however, that the rotation of the bobbins should be also retarded in a progressive manner. This object is effected by means of the cone k', which, as the band n' progressively approaches towards its smaller diameter, drives the pulleys or whorls q of the bobbins with decreasing speed, though itself moves uniformly quick with the shaft c'. To effect this variation, the cone is shifted lengthwise along its shaft, while the band running upon it remains continually in the same vertical plane, and is kept distended by the weight of the pulley o'. The following mechanism serves to shift the cone, which may be best understood by the aid of the figures 413., 414., and 410. A long cast iron bar m^3

which bears two horizontal projecting puppets, o^3 o^3, is made fast to the front upright face of the copping beam A. Through the above puppets a cylindrical rod n^3 passes freely,

413



414



which is left out in *fig.* 410., that the parts lying behind it may be better seen. Upon this rod there is a kind of fork, p^3 p^3, to which the alternating rack bars q^3 are made fast. The teeth of these racks are at unequal distances from each other, and are so arranged, that each tooth of the under side corresponds to the space between two teeth in the upper side. Their number depends upon the number of coils of roving that may be required to fill a bobbin; and consists in the usual machines of from 20 to 22. The rod n^3 may be shifted in the puppet o^3, like the fork p^3 of the rack-rod, upon the rod n^3, and along the surface of m^3, where two wings u^3 u^3 are placed, to keep the fork in a straight direction. Upon the bar m^3, there are the pivots or fulcra of two stop catches w^3 x^3, of which the uppermost presses merely by its own weight, but the undermost by means of a counterweight y^3, against the rack, and causes them thus to fall in between the teeth. In *fig.* 414., v^3 shows the pivot of the catch or detent w^3 by itself, the detent itself being omitted, to render the construction plainer. A pushing rod l^3, upon which there is a pin above at s^3, that passes behind the rack rod, between this and the bar m^3, has for its object to remove at pleasure the one or the other of the two catches; the upper, when the upper end of the rod pushes against it; the under, by means of the above mentioned pin s^3. Both the catches are never raised at once, but either the under or the upper holds the rack bar fast, by pressing against one of the teeth. The vertical motion up or down, which the rod l^3 must take to effect the lifting of the catches, is given to it from the copping beam p; since upon it a horizontal arm v^2, *fig.* 414., is fixed, that lays hold of that rod. Upon the pushing rod are two rings, h^3 and h^3, each made fast by a screw. When the copping beam is in the act of going up, the arm v^3 at the end of this movement, pushes against the ring h^3, raises up the rod l^3, and thus removes the catch w^3, *fig.* 410., from the teeth of the rod q^3, before which it lies flat. At the descent of the copping rail, v^2 meets the ring h^3, when the motion in this direction is nearly completed, draws down the rod l^3 a little, by means of the same, and thereby effects the removal of the catch x^3, *fig.* 414., from the rod q^3. Every time that one of the catches is lifted, the rack recovers its freedom to advance a little bit in the direction of the arrow; so far, namely, till the other catch lays hold upon the tooth that next meets it. The reason is thus manifest why the teeth of the upper and under sides of the bar q^3 are not right opposite to each other, but in an alternate position.

From the rack-bar, the sliding of the cone k', and the raising of the shaft y^2, each by minute steps at a time, is produced as follows: —

A large rectangular lever t^1, v^1, whose centre of motion is at p^4, has at the upper end of its long arm t^1, a long slot through which a stud r^3 upon the rack q^3 goes (*fig.* 413., 414., 410.,) so that the lever must follow the motions of the rack bar. The end of the short arm of the lever bears, as already mentioned, the step of the shaft y^2; hence the friction disc x^1 will be raised in proportion as the rack bar advances, and will come nearer to the middle point of g^1; consequently, its revolution and the shifting of the bobbins will become slower. Upon the cylindrical rod n^3, the piece s^1 s^1 furnished with a long slot is made fast, by means of a tube z^3, (*fig.* 410.) and a screw. A fork u u, which by means of the screw nut a^4 is made fast in the slot, embraces the arm t^1 of the bent lever; and a tube r^1 rivetted to the surface of s^1, is destined to take up the draw rod q^1 of the cone k^1, *fig.* 410. A weight f^4, whose cord b^1 is made fast to the cylindrical rod n^3, endeavours to draw this rod continually in the direction of the arrow. In consequence of this arrangement, every time that the pushing bar l^3 lifts up one of the catches, the cone k^1, the lever t^1 v^1, and by it the rack bar q^3, are set in motion. It is

obvious, that the motion of the cone may be made greater or less, according as the fork *u u* is fixed further up or down in the slot of s^1.

The number of the teeth upon the bar q^3 is so ordered, that the bobbins are quite full when the last tooth has reached the catch and is released by it. The rack bar, being restrained by nothing, immediately slides onwards, in consequence of the traction of the weight f^4 and brings the machine to repose by this very movement, for which purpose the following construction is employed. A rectangular lever which has its centre of motion in g^4 is attached to the side face of the beam A, and has at the end of its horizontal arm a pulley d^4, over which the cord b^4 of the counterweight f^4 is passed. The end of the perpendicular arm is forked and embraces the long and thin rod k^4, to whose opposite end the fork l^4 is made fast. Through this fork the band which puts the machine in motion passes down to the pulley a^1. With the bent lever another rod c^4 is connected at h^4, which lies upon the puppet e^3 with a slot at e^4, and hereby keeps the lever g^4 in its upright position notwithstanding the weight f^4. In the moment when, as above stated, the rack bar q^3 becomes free, the arm p^3 of its fork pushes in its rapid advance against the under oblique side of e^4, raises this rod, and thereby sets the lever g^4 free, whose upright arm bends down by the traction of the weight, drives the rod k^4 before it into the ring i^4 fastened to it, and thus by means of the fork l^4 shifts the band upon the loose pulley b^1. But the machine may be brought to repose or put out of geer at any time merely by shifting the rod k^4 with the hand.

The operation of the bobbin and fly frame may be fully understood from the preceding description. A few observations remain to be made upon the cone k^1, the rack-bar q^3, and the speed of the work.

When we know the diameter of the empty bobbins, and how many turns they should make in a given time in order to wind-on the sliver delivered by the fluted rollers and the spindles; when we consider the diameters of the spindle pullies q, and l^2, as also the drum m^1, *fig.* 405., we may easily find the diameter which the cone must have for producing that number of turns. This is the diameter for the greatest periphery of the base. The diameter of the smaller is obtained in the same way, when the diameter of the bobbins before the last winding-on, as well as the number of turns necessary in a given time, are known.

A bobbin and fly frame of the construction just described delivers from each spindle in a day of twelve hours, from 6 to 8 lbs of roving of the fineness of $1\frac{1}{2}$ English counts. One person can superintend two frames, piece the broken slivers, and replace the full bobbins by empty ones. The loss of cotton wool in this machine consists in the portions carried off from the torn slivers, and must be returned to the lapping machine.

The fine bobbin and fly frame does not differ essentially from the preceding machine. The rovings from the coarse bobbin and fly frame are placed in their bobbins in a frame called the *creel*, behind and above the roller beam, two bobbins being allowed for one fluted portion of the rollers. These rovings are united into one, so as to increase the uniformity of the slivers.

The invention of the beautiful machine above described is due to Messrs. Cocker and Higgins of Manchester, and as lately improved by Henry Houldsworth, junr. Esq., it may be considered the most ingeniously combined apparatus in the whole range of productive industry.

In the fine roving frame the sliver is twisted in the contrary direction to that of the coarse roving frame. For this reason the position of the cone is reversed, so as to present in succession to the band or strap, diameters continually greater, in order that the rotation of the bobbins may be accelerated in proportion as their size is increased, because here the flyer and the bobbin turn in the same direction, and the winding-on is effected by the precession of the bobbin; but if the winding-on took place by its falling behind, as in the coarse bobbin and fly frame, that is, if the flyer turned less quickly than the bobbin, the rotatory speed of the bobbin would be uniformly retarded; in which case the cone would be disposed as in the coarse frame.

When by any means whatever an uniform length of thread is delivered by the rollers in a given time, the bobbin must wind it up as it is given out, and must therefore turn with a speed decreasing with the increase of its diameter by successive layers of thread. Hence proceeds the proposition, that the velocity of the bobbin must be in the inverse ratio of its diameter, as already explained.

With respect to the bobbin and fly frame, the twist is given to the sliver by means of a spindle or flyer which turns in the same direction with the bobbin, but quicker or slower than it, which establishes two predicaments. The first case is where the flyer turns faster than the bobbin. Here the winding-on goes in advance, as in the coarse roving frame, or as in throstle spinning, where the yarn is wound on merely in consequence of the friction of the lower disc or washer of the bobbin upon the copping rail, and of the drag of the yarn. The second case is where the flyer revolves more slowly than the bobbin. Here the winding goes on in arrear, and as the bobbin

turns faster, it must receive a peculiar motion, which is uniformly retarded in the ratio of its increase of diameter. This is the case with the fine bobbin and fly frame. When the cone is placed as in *fig.* 405, the winding-on, in either the coarse or fine frame, results from the difference, whether greater or less, between the rotatory speed of the flyer and bobbin.

The motion of the bobbin and spindle is simultaneous, and takes place in the same direction, with a difference varying more or less with the varying diameters of the bobbins. To render the matter still clearer, suppose for a moment the spindle to be motionless, then the bobbin must revolve with such a speed, as to lap-on the roving as fast as the rollers deliver it. The sliver comes forward uniformly; but the bobbin, by its increase of diameter, must revolve with a speed progressively slower. Now, suppose the spindle set a-whirling, it is obvious that the bobbin must add to the movement requisite for winding-on the sliver, that of the spindle in the case of winding-on in arrear, or when it follows the flyers, and subtract its own motion from the twisting motion of the spindles, in the case of winding-on in advance, that is, when the bobbin precedes or turns faster than the flyers; for the diameter of the bobbin being $1\frac{1}{2}$ inch, 10 turns will take up 45 inches. Deducting these 10 turns from the 30 made by the spindle in the same time, there will remain for the effective movement of the bobbin only 20 turns; or when the diameter of the bobbin becomes 3 inches, 5 turns will take up the 45 inches, if the spindle be at rest; but if it makes 30 turns in the time, the effective velocity of the bobbin will be 25 turns, = 30 — 5. Hence in the fine bobbin and fly frame, the number of turns of the spindle, *minus* the number of turns made by the bobbin in equal times, is in the inverse ratio of the diameter of the bobbin. We thus perceive, that in the coarse frame the bobbin should move faster than the spindle, and that its speed should always diminish; whilst in the fine frame the bobbin should move slower than the spindle, but its speed should always increase. It is easy to conceive, therefore, why the cones are placed in reverse directions in the two machines. Not that this inversion is indispensably necessary; the cone of the fine roving frame might, in fact, be placed like that of the coarse roving frame; but as the torsion of the roving becomes now considerable, and as on that account the bobbin would need to move still faster, which would consume a greater quantity of the moving power, it has been deemed more economical to give its movement an opposite direction.

We mentioned that the twist of the sliver in the fine roving frame was the reverse of that in the coarse; this is a habit of the spinners, for which no good reason has been given.

The divisions of the rack-bar, and the successive diameters of the cone, must be nicely adjusted to each other. The first thing to determine is how much the rack should advance for every layer or range of roving applied to the bobbin, in order that the cone may occupy such a place that the strap which regulates the pulley barrel may be at the proper diameter, and thus fulfil every condition. The extent of this progressive movement of the rack depends upon the greater or less taper of the cone, and the increase which the diameter of the bobbin receives with every transverse, that is, every layer of roving laid on. But care should be taken not to taper the cone too rapidly, especially in the fine roving frame, because in its progress towards the smaller end, the strap would not slide with certainty and ease. We have already shown that the number of effective turns of the bobbin is inversely, as the diameter of the bobbin, or directly, as the successive diameters of the different points of the cone.

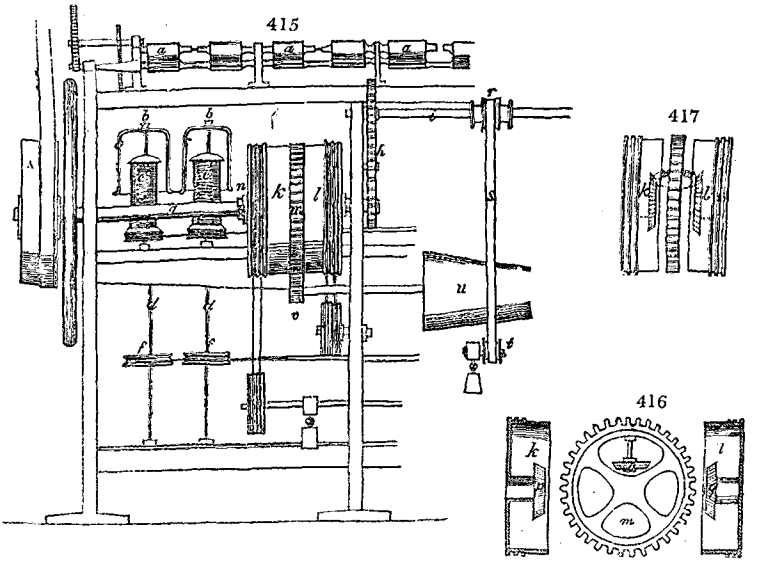
H. Houldsworth, jun. Esq. has introduced a capital improvement into the bobbin and fly frame, by his differential or equation-box mechanism, and by his spring fingers, which, by pressing the soft sliver upon the bobbin, cause at least a double quantity to be wound upon its barrel. With the description of his patent equation-box, I shall conclude the description of the bobbin and fly frame.

Fig. 415. represents a portion of a fly frame with Mr. Houldsworth's invention. *a a a* are the front drawing rollers, turning upon bearings in the top of the machine, and worked by a train of toothed wheels, in the way that drawing rollers are usually actuated.

From the drawing rollers, the filaments of cotton or other material, *b b*, are brought down to, and passed through the arms of the flyers *c c*, mounted on the tops of the spindles *d d*, which spindles also carry the loose bobbins *e e*. In the ordinary mode of constructing such machines, the spindles are turned by cords or bands passing from a rotatory drum round their respective pulleys or whirls *f*, and the loose bobbins *e*, turn with them by the friction of their slight contact to the spindle, as before said; in the improved machine, however, the movements of the spindles and the bobbins are independent and distinct from each other, being actuated from different sources.

The main shaft of the engine *g*, turned by a band and rigger A as usual, communicates motion by a train of wheels *h*, through the shaft *i*, to the drawing rollers at the reverse end of the machine, and causes them to deliver the filaments to be twisted.

Upon the main shaft *g*, is mounted a cylindrical hollow box or drum-pulley, whence one cord passes to drive the whirls and spindles *f* and *d*, and another to drive the bobbins *e*.



This cylindrical box pulley is made in two parts, *k* and *l*, and slipped upon the axle with a toothed wheel *m*, intervening between them. The box and wheel are shewn detached in *fig.* 416., and partly in section at *fig.* 417. That portion of the box with its pulley marked *l*, is fixed to the shaft *g*; but the other part of the box and its pulley *k*, and the toothed wheel *m*, slide loosely round upon the shaft *g*, and when brought in contact and confined by a fixed collar *n*, as in the machine shewn at *fig.* 415., they constitute two distinct pullies, one being intended to actuate the spindles, and the other the bobbins.

In the web of the wheel *m*, a small bevel pinion *o*, is mounted upon an axle standing at right angles to the shaft *g*, which pinion is intended to take into the two bevel pinions *p* and *q*, respectively fixed upon bosses, embracing the shaft in the interior of the boxes *k* and *l*. Now it being remembered that the pinion *q*, and its box *l*, are fixed to the shaft *g*, and turn with it, if the loose wheel *m* be independently turned upon the shaft, with a different velocity, its pinion *o*, taking into *q*, will be made to revolve upon its axle, and to drive the pinion *p*, and pulley box *k*, in the same direction as the wheel *m*; and this rotatory movement of the box *k* and wheel *m*, may be faster or slower than the shaft *g*, and box *l*, according to the velocity with which the wheel *m* is turned.

Having explained the construction of the box pullies *k* and *l*, which are the peculiar features of novelty claimed under this patent, their office and advantage will be seen by describing the general movements of the machine.

The main shaft *g*, being turned by the band and rigger A, as above said, the train of wheels *h*, connected with it, drives the shaft *i*, which at its reverse end has a pinion (not seen in the figure,) that actuates the whole series of drawing rollers *a*. Upon the shaft *i* there is a sliding pulley *r*, carrying a band *s*, which passes down to a tension pulley *t*, and is kept distended by a weight. This band *s*, in its descent, comes in contact with the surface of the cone *u*, and causes the cone to revolve by the friction of the band running against it. The pulley *r* is progressively slidden along the shaft *i*, by means of a rack and weight not shown, but well understood as common in these kind of machines, and which movement of the pulley is for the purpose of progressively shifting the band *s* from the smaller to the larger diameter of the cone, in order that the speed of its rotation may gradually diminish as the bobbins fill by the winding-on of the yarns.

At the end of the axle of the cone *u* a small pinion *v* is fixed, which takes into the teeth of the loose wheel *m*, and, as the cone turns, drives the wheel *m* round upon the shaft *g*, with a speed dependent always upon the rapidity of the rotation of the cone. Now the box pulley *l*, being fixed to the main shaft *g*, turns with one uniform speed, and by cords passing from it over guides to the whorls *f*, drives all the spindles and flyers, which twist the yarns with one continued uniform velocity; but the box pulley *k*,

being loose upon the shaft, and actuated by the bevel pinions within, as described, is made to revolve by the rotation of the wheel *m*, independent of the shaft, and with a different speed from the pulley box *l*; cords passing from this pulley box *k*, over guides to small pullies under the bobbins, communicate the motion, whatever it may be, of the pulley box *k*, to the bobbins, and cause them to turn, and to take up or wind the yarn with a speed derived from this source, independent of, and different from, the speed of the spindle and flyer which twist the yarn.

It will now be perceived, that these parts being all adjusted to accommodate the taking up movements to the twisting or spinning of any particular quality of yarn intended to be produced, any variations between the velocities of the spinning and taking up, which another quality of yarn may require, can easily be effected, by merely changing the pinion *v*, for one with a different number of teeth, which will cause the wheel *m*, and the pulley box *k*, to drive the bobbins faster or slower, as would be required in winding-on fine or coarse yarn, the speed of the twisting or spinning being the same.

The rovings or spongy cords, of greater or less tenuity, made on the bobbin and fly, or tube roving frame, are either spun immediately into firm cohesive yarn, or receive a further preparation process in the stretching frame, which is, in fact, merely a mule-jenny, without the second draught and second speed, and therefore need not be described at present, as it will be in its place afterwards.

The *finishing machines* of a cotton mill, which spin the cohesive yarn, are of two classes; 1. the water-twist or throstle, in which the twisting and winding are performed simultaneously upon progressive portions of the roving; and, 2. the mule, in which the thread is drawn out and stretched, with little twist, till a certain length of about 5 feet is extended, then the torsion is completed, and the finished thread is immediately wound upon the spindles into double conical coils called cops.

The water-twist frame, so called by its inventor, Sir R. Arkwright, because it was first driven by water, is now generally superseded by the throstle frame, in which the mechanical spinning fingers, so to speak, are essentially the same, but the mode of communicating the motion of the mill-geering to them is somewhat different. *Fig.* 418. exhibits a vertical section of the throstle. This machine is double, possessing upon each side of its frame, a row of spindles with all their subsidiary parts. The bobbins, filled with rovings from the bobbin and fly, or the tube frame, are set up in the creel *a a*, in two ranges. *b, c, d*, are the three usual pairs of drawing rollers, through which the yarn is attenuated to the proper degree of fineness, upon the principles already explained. At its escape from the front rollers, every thread runs through a guide eyelet *e* of wire, which gives it the vertical direction down towards the spindles *f, g*. The spindles which perform at once and uninterruptedly the twisting and winding-on of the thread delivered by the rollers, are usually made of steel, and tempered at their lower ends. They stand at *g* in steps, pass at *v* through a brass bush or collet which keeps them upright, and revolve with remarkable speed upon their axes. The bobbins *h*, destined to take up the yarn as it is spun, are stuck loosely upon the spindles, and rest independently of the rotation of the spindles upon the copping beam *l*, with a leather washer between. Upon the top of the spindles an iron-wire fork, called a fly or flyer, *i, k*, is made fast by a left-hand screw, and has one of its forks turned round at the end into a little ring. The branch of the flyer at *f* is tubular, to allow the thread to pass through, and to escape by a little hole at its side, in order to reach the eyelet at the end of that fork. From this eyelet *i*, it proceeds directly to the bobbin. By the twirling of the spindle, the twisting of the portion of thread between the front roller *d*, and the nozzle *f*, is effected. The winding-on takes place in the following way: — Since the bobbin has no other connection with the spindle than that of the thread, it would but for it remain entirely motionless, relatively to the spindle. But the bobbin is pulled after it by the thread, so that it must follow the rotation of the spindle and fly. When we consider that the thread is pinched by the front roller *d*, and is thereby kept fully upon the stretch, we perceive that the rotation of the bobbin must be the result. Suppose now the tension to be suspended for an instant, while the rollers *d*, deliver, for example, one inch of yarn. The inertia or weight of the bobbin, and its friction upon the copping beam *l*, by means of the leather washer, will, under this circumstance, cause the bobbin to hang back in a state of rest, till the said inch of yarn be wound on by the whirling of the fly *i*, and the former tension be restored. The delivery of the yarn by the drawing rollers, however, does not take place inch after inch, by starts, but at a certain continuous rate; whence results a continuous retardation or loitering, so to speak, of the bobbins behind the spindles, just to such an amount that the delivered yarn is wound up at the same time during the rotation.

This process in spinning is essentially the same as what occurs in the fine bobbin and fly frame, but is here simplified, as the retardation regulates itself according to the diameter of the bobbin by the drag of the thread. In the fly frame the employment

of this tension is impossible, because the roving has too little cohesion to bear the strain; and hence it is necessary to give the bobbins that independent movement of rotation which so complicates this machine.

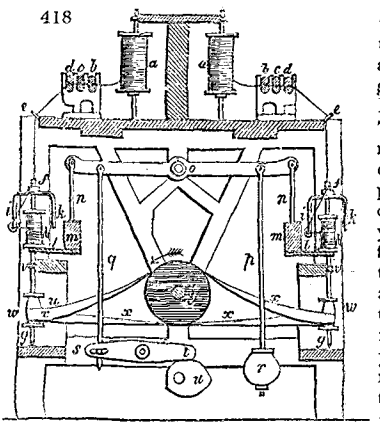
The up and down motion of the bobbins along the spindles, which is required for the equal distribution of the yarn, and must have the same range as the length of the bobbin barrels, is performed by the following mechanism. Every copping rail *l*, is made fast to a bar *m*, and this, which slides in a vertical groove or slot at the end of the frame, is connected by a rod *n*, with an equal-armed, moveable lever *o*. The rod *p* carries a weight *r*, suspended from this lever; another rod *q*, connects the great lever *o* with a smaller one *s*, *t*, upon which a heart-shaped disc or pulley *u*, works from below at *t*. By the rotation of the disc *u*, the arm *t*, being pressed constantly down upon it by the reaction, the weight *r* must alternately rise and fall; and thus the copping rail *l* must obviously move with the bobbins *h* up and down; the bobbins upon one side of the frame rising, as those upon the other sink. Strictly considered, this copping motion should become slower as the winding-on proceeds, as in the fly roving frame; but, on account of the smallness of the finished thread, this construction, which would render the machine complicated, is without inconvenience neglected, with the result merely that the coils of the yarn are successively more sparsely laid on, as the diameter of the bobbin increases.

The movement of the whole machine proceeds from the shaft of a horizontal drum, which drives the spindles by means of the endless bands *x x*. Each spindle is mounted with a small pulley or wharf *w*, at its lower part, and a particular band, which goes round that wharf or whorl, and the drum *y*. The bands are not drawn tense, but hang down in a somewhat slanting direction, being kept distended only by their own weight. Thus every spindle, when its thread breaks, can readily be stopt alone, by applying a slight pressure with the hand or knee, the band meanwhile gliding loosely round the whorl.

The velocities of rotation of the three drawing rollers are, according to this arrangement, in the proportion of 1 : 1½ : 8; and as their diameters are the same, namely, one inch, the elongation of the yarn in spinning is eight-fold. If, for example, the roving was of the number 4½, the yarn would become No. 36. The extension of the thread may be changed by changing the wheels of the drawing rollers. To perceive the power of this change, let us put, for example, in the place of the 18-toothed wheel of the back rollers, a wheel with 16 teeth; we shall find that the elongation will amount, in that case, only to 7½ times, whence the number of the yarn would come out 32 = 7½ × 4½. The extension by the throstle is extremely various; it amounts, in some cases, to only 4 times; at others to 10, 12, or even 15.

The copping motion of the bobbins is produced in consequence of a bevel pinion working in a small bevel wheel upon an upright shaft; while this wheel gives a slow motion by means of a worm screw to the wheel of the heart-shaped pulley *u*, *fig.* 418.

418



The driving pulley makes about 600 turns in a minute; and as the diameter of the drum *y*, *fig.* 418., is six times the diameter of the spindle wharves *w*, it will give 3600 turns to the spindle in that time. If the pulley be driven faster, for example 700 times in a minute, it will increase the revolutions of the spindles to 4200. The degree of twist which will be thereby imparted to the yarn, depends, with like speed of spindles, upon the rate at which the soft yarn is delivered by the drawing rollers; for the quicker this delivery, the quicker is the winding-on, and the less twist goes into a given length of yarn. If, for example, the front rollers *d*, turn 24 times in a minute, giving out of course 72 inches of yarn in this time, upon which the 3600 revolutions of the spindle are expended, there will be 50 twists to every inch of yarn. By changing the wheel-work of *fig.* 418., or by sticking greater or smaller wharves upon the spindles, the proportion between their velocity and that of the drawing rollers, and thence the degree of twist can be modified at pleasure.

The number of spindles in a throstle frame 12 feet long, is about 60 on each side. The drawing rollers are coupled together as in the bobbin and fly frame, so that each row forms one continuous cylinder. There is a complete roller beam on each side; each of the rollers of the front row is pressed by its top rollers with a weight of ten or

twelve pounds; but those of the middle and back rows bear weights of only one pound In the throstles, there is a guide bar which traverses a small way horizontally to the left and right, in front of the roller beam, to lead the thread along different points of the rollers, and thus prevent the leather of the top ones from being grooved by its constant pressure in one line.

For the service of 240 spindles, in two double frames, one young woman, and an assistant piecer are sufficient. They mend the broken ends, and replace the empty bobbins in the creel with full ones, and the full bobbins of the throstle by empty ones. The average quantity of yarn turned off in a week of 69 hours is about 24 hanks per spindle of 30's twist. Throstle yarn is of a firm wiry quality, adapted to the warps of fustians and other strong stuffs, as well as to the manufacture of stockings and sewing thread.

There are many modifications of the throstle system besides the one above described; the most celebrated of which are Danforth's, called the American throstle, Montgomery's, and Gore's. I must refer for an account of them to my work entitled "The Cotton Manufacture of Great Britain," where they are minutely described and illustrated with accurate figures.

Mule-spinning.—The general principles of the mule have been already stated. This machine is so named because it is the offspring, so to speak, of two older machines, the jenny and the water-frame. A mule is mounted with from 240 to 1000 spindles, and spins of course as many threads.

419

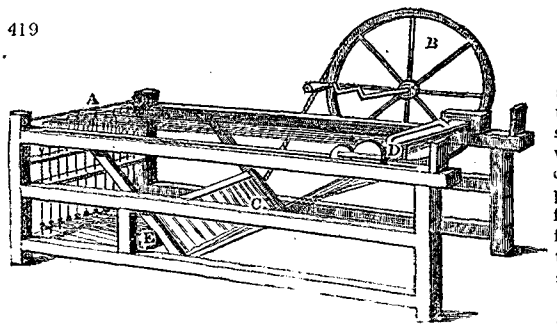


Fig 419. represents the original *jenny* of Hargreaves, by which one person was enabled to spin from 16 to 40 threads at once. The soft cords of rovings wound in double conical cops upon skewers were placed in the inclined frame at C; the spindles for first twisting and then winding-on the spun yarn were set upright in steps and bushes at A, being furnished near their lower ends with whorls, and endless cords, which were driven by passing round the long-revolving drum of tin plate E. D is the clasp or clove, having a handle for lifting its upper jaw a little way, in order to allow a few inches of the soft roving to be introduced. The compound clove D being now pushed forward upon its friction wheels to A, was next gradually drawn backward, while the spindles were made to revolve with proper speed by the right hand of the operative turning the fly-wheel B. Whenever one *stretch* was thereby spun, the clove frame was slid home towards A; the spindles being simultaneously whirled slowly to take up the yarn, which was laid on in a conical cop by the due depression of the faller wire at A with the spinner's left hand.

420

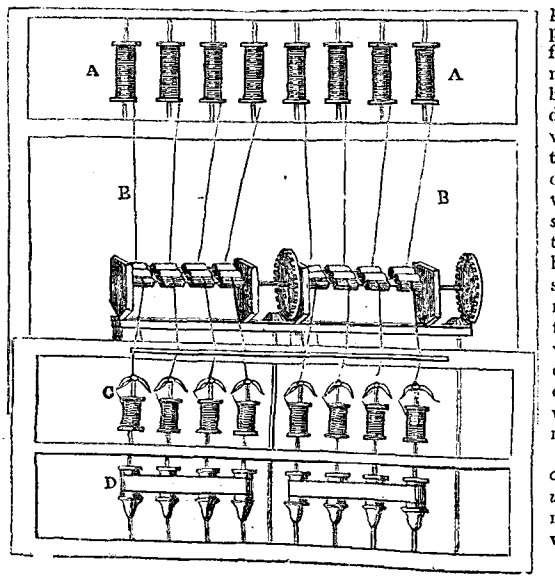

Fig. 420. is a diagram of Arkwright's original *water-frame* spinning machine, called afterwards the *water-twist*

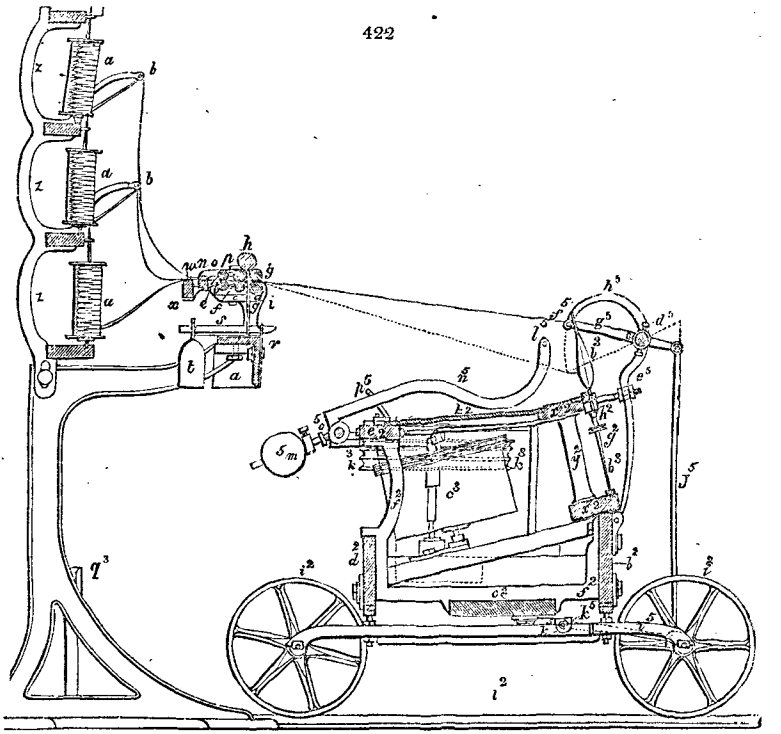
421

frame. The rovings mounted upon bobbins in the creel A A, have their ends led through between the three sets of twin rollers below B B, thence down through the eyelet hooks upon the end of the flyers of the spindles c, and finally attached to their bobbins. The spindles being driven by the band D D upon their lower part, continuously twist and wind the finished yarn upon the bobbins; constituting the first unremitting automatic machine for spinning which the world ever saw.

Contrast with the above admirable system, the primitive cotton wheel of India, as represented in the annexed figure 421. By the aid of mechanical fingers, one Englishman at his mule can turn off daily more yarn and of far finer quality than 200 of the most diligent spinsters of Hindostan.

Fig. 422., is a transverse section of the mule, in which its principal parts are shown.

422



The machine consists of two main parts; a fixed one corresponding in some measure to the water-frame or throstle, and a moveable one corresponding to the jenny. The first contains in a suitable frame the drawing roller-beam and the chief moving machinery: the second, is called the carriage, in which the remainder of the moving mechanism and the spindles are mounted.

The frame of the fixed part consists of two upright sides, and two or more intermediate parallel bearings, upon which the horizontal roller beam *a*, the basis of the drawing rollers is supported. *b*, *c*, *d*, are the three ranges of fluted iron rollers; *e*, *f*, *g*, are the upper iron rollers covered with leather; *h*, the wooden wiper-rollers covered with flannel, which being occasionally rubbed with chalk, imparts some of it to the pressure rollers beneath, so as to prevent the cotton filaments adhering to them. The rollers are made through-

out the whole length of the mule in portions containing six flutings, which are coupled together by squared ends fitted into square holes.

The skewers upon which the bobbins containing the rovings from the bobbin and fly or stretching frame, are set up, are seen at a^1, a^1, a^1, arranged in three rows in the creel z. The soft threads unwound from these bobbins, in their way to the drawing rollers, pass first through eyelets in the ends of the wire arms b^1, then through the rings or eyes of the guide bar w, and enter between the back pair of rollers. The number of these bobbins is equal to the number of spindles in the mule, and twice as great as the number of fluted portions of the rollers; for two threads are assigned to each portion.

The carriage consists of two cast-iron side pieces, and several cast-iron intermediate similar pieces, such as f^2, which all together are made fast to the planks b^2, c^2, d^2. The top is covered in with the plank k^2. The carriage runs by means of its cast-iron grooved wheels, upon the cast-iron railway l^2, which is fixed level on the floor.

The spindles stand upon the carriage in a frame, which consists of two slant rails x^2, x^2, connected by two slender rods y^2, and which frame may be set more or less obliquely. The lower rail carries the brass steps for the points of the spindles b^3; upon the upper rail brass slips are fixed pierced with holes through which the tops of the spindles play. The spindles are as usual made of steel, perfectly straight, turned truly round, and are all arranged in one plane. To each of them a small wooden or cast-iron whorl g^2 is made fast. They are distributed into groups of 24, and the whorls are arranged at such different heights, that only two of them in each group are upon a level with each other. A small brass head h^2, which every spindle has beneath the upper slant rail of the frame x^2, prevents their sitting down into the step, during their rotation, or sliding off their cop of yarn.

c^3 are drums, mounted in the carriage in a plane at right angles to the plane in which the spindles are placed. At top they have a double groove for a cord to run in, and the motion which they receive from the great fly wheel, or rim of the mule (not visible in this view) they impart to the spindles. Such a drum is assigned to every 24 spindles; and therefore a mule of 480 spindles contains 20 drums. In the middle of the carriage is seen the horizontal pulley k^3, furnished with three grooves, which stands in a line with the drums c^3.

The motion is given to the drums c^3, upon the right hand half of the carriage by a single endless band or cord which proceeds from the middle groove of the pulley k^3. The rotation of the spindles is produced by a slender cord, of which there are 12 upon each drum c^3; because every such cord goes round the drum, and also every two wharves which stand at the same level upon the spindles. It is obvious that the drums, and consequently the spindles, must continue to revolve as long as the main rim of the mule is turned, whether the carriage be at rest or in motion upon its railway.

If we suppose the carriage to be run in to its standing point, or to be pushed home to the spot from which it starts in spinning, its back plank d^2 will strike the post q^3 upon the fixed frame, and the points of the spindles will be close in front of the roller beam. The rollers now begin to turn and to deliver threads, which receive immediately a portion of their twist from the spindles; the carriage retires from the roller beam with somewhat greater speed than the surface speed of the front rollers, whereby the threads receive a certain degree of stretching, which affects most their thicker and less twisted portions, and thereby contributes greatly to the levelness of the yarn. When the carriage has run out to the end of its course, or has completed a stretch, the fluted rollers suddenly cease to revolve (and sometimes even beforehand, when a second stretch is to be made), but the spindles continue to whirl till the fully extended threads have received the proper second or after-twist. Then the carriage must be put up, or run back towards the rollers, and the threads must be wound upon the spindles.

This is the order of movements which belong to the mule. It has been shown how the rotation of the spindles is produced.

For winding-on the yarn the carriage has a peculiar apparatus, which we shall now describe. In front of it, through the whole extent to the right hand as well as the left, a slender iron rod, d^5, runs horizontally along, in a line somewhat higher than the middle of the copping portion of the spindles, and is supported by several props, such as e^5. Upon each end of the two rods, d^5, there is an arm, g^5; and betwixt these arms an iron wire, called the copping wire, f^5, is stretched, parallel with the rod d^5. For the support of this wire, there are several slender bent arms h^5 extended from the rod d^5 at several points betwixt the straight arms g^5. The rod d^5 has, besides a wooden handle at the place opposite to where the spinner stands, by which it can be readily grasped. This movement is applied at the left division of the machine, and it is communicated to the right by an apparatus which resembles a crane's bill. The two arms, g^5, in the middle of the machine, project over the rods d^5, and are connected by hinges with two vertical rods j^5, which hang together downwards in like manner with two arms i^5, proceeding from a horixontal axis k^5.

By means of that apparatus the yarn is wound upon the spindles in the following manner. As long as the stretching and twisting go on, the threads form an obtuse angle with the spindles, and thereby slide continually over their smooth rounded tips during their revolution, without the possibility of coiling upon them. When, however, the spinning process is completed, the spinner seizes the carriage with his left hand and pushes it back towards the roller beam, while with his right hand he turns round the handle of the rim or fly wheel, and consequently the spindles. At the same time, by means of the handle upon the rod d^5, he moves the copping-wire f^5, so that it presses down all the threads at once, and places them in a direction nearly perpendicular to the spindles; as shown by the dotted line y^5. That this movement of the copping wire, however, may take place without injury to the yarn, it is necessary to turn the rim beforehand a little in the opposite direction, so that the threads may get uncoiled from the upper part of the spindles, and become slack; an operation called in technical language, the *backing off*. The range upon which the threads should be wound, in order to form a conical cop upon the spindle, is hit by depressing the copping wire to various angles, nicely graduated by an experienced eye. This faller wire alone is not, however, sufficient for the purpose of winding-on a seemly cop, as there are always some loose threads which it cannot reach without breaking others.

Another wire called the *counter-faller*, l^5, must be applied under the threads. It may be raised to an elevation limited by the angular piece p^5; and is counterpoised by a very light weight m^5, applied through the bent lever n^5, which turns upon the fulcrum o^5. This wire, which applies but a gentle pressure, gives tension to all the threads, and brings them regularly into the height and range of the faller f^5. This wire must be raised once more, whenever the carriage approaches the roller beam. At this instant a new stretch commences; the rollers begin again to revolve, and the carriage resumes its former course. These motions are performed by the automatic machinery.

There is a little eccentric pulley mechanism for moving the guide beam to and fro with the soft yarns, as they enter between the back rollers. On the right hand end of the back roller shaft, a worm screw is formed which works into the oblique teeth of a pinion attached to the end of the guide beam, in which there is a series of holes for the passage of the threads, two threads being assigned to each fluted roller. In the flat disc of the pinion, an eccentric pin stands up which takes into the jointed lever upon the end of the guide beam, and as it revolves, pushes that beam alternately to the left and the right by a space equal to its eccentricity. This motion is exceedingly slow, since for each revolution of the back roller, the pinion advances only by one tooth out of the 33 which are cut in its circumference.

After counting the number of teeth in the different wheels and pinions of the mule, or measuring their relative diameters, it is easy to compute the extension and twist of the yarns; and when the last fineness is given to ascertain their marketable value. Let the ratio of speed between the three drawing rollers be $1 : 1\frac{3}{22} : 7\frac{1}{2}$; and the diameter of the back and middle roller three quarters of an inch: that of the front roller one inch; in which case the drawing is thereby increased $1\frac{1}{3}$ times, and $7\frac{1}{2} \times 1\frac{1}{3} = 10$. If the rovings in the creel bobbins have been No. 4. the yarn, after passing through the rollers, will be No. 40. By altering the change pinion (not visible in this view) the fineness may be changed within certain limits, by altering the relative speed of the rollers. For one revolution of the great rim or fly wheel of the mule, the front roller makes about 6-tenths of a turn, and delivers therefore 22·6 lines or 12ths of an inch of yarn, which, in consequence of the tenfold draught through the rollers, corresponds to 2·26 lines of roving fed in at the back rollers. The spindles or their whorls make about 66 revolutions for one turn of the rim. The pulleys or grooved wheels on which the carriage runs, perform 0·107 part of a turn while the rim makes one revolution, and move the carriage 24·1 lines upon its rails, the wheels being 6 inches in diameter.

The 22·6 lines of soft yarn delivered by the front rollers, will be stretched $1\frac{1}{2}$ lines by the carriage advancing 24·1 lines in the same time. Let the length of the railway, or of each stretch be 5 feet, the carriage will complete its course after 30 revolutions of the rim wheel, and the 5 feet length of yarn (of which $56\frac{1}{2}$ inches issue from the drawing rollers, and $3\frac{1}{2}$ inches proceed from the stretching) is, by the simultaneous whirling of the spindles, twisted 1980 times, being at the rate of 33 twists for every inch. The second twist, which the threads receive after the carriage has come to repose, is regulated according to the quality of the cotton wool, and the purpose for which the yarn is spun. For warp yarn of No. 40 or 50, for example, 6 or 8 turns of the rim wheel, that is, from 396 to 528 whirls of the spindles for the whole stretch, therefore from 7 to 9 twists per inch will be sufficient. The finished yarn thus receives from 40 to 42 twists per inch.

One spinner attends to two mules, which face each other, so that he needs merely turn round in the spot where he stands, to find himself in the proper position for the other mule. For this reason the rim wheel and handle, by which he operates, are not

placed in the middle of the length of the machine, but about two fifths of the spindles are to the right hand and three fifths to the left; the rim wheel being towards his right hand. The carriage of the one mule is in the act of going out and spinning, while that of the other is finishing its twist, and being put up by the spinner.

The quantity of yarn manufactured by a mule in a given time, depends directly upon the number of the spindles, and upon the time taken to complete every stretch of the carriage. Many circumstances have an indirect influence upon that quantity, and particularly the degree of skill possessed by the spinner. The better the machine, the steadier and softer all its parts revolve, the better and more abundant is its production. When the toothed wheels do not work truly into their pinions, when the spindles shake in their bushes, or are not accurately made, many threads break, and the work is much injured and retarded. The better the staple of the cotton wool, and the more careful has been its preparation in the carding, drawing, and roving processes, the more easy and excellent the spinning will become: warmth, dryness, cold, and moisture have great influence on the ductility, so to speak, of cotton. A temperature of 65° F., with an atmosphere not too arid, is found most suitable to the operations of a spinning mill. The finer the yarn, the slower is the spinning. For numbers from 20 to 36, from 2 to 3 stretches of warp may be made in a minute, and nearly 3 stretches of weft; for numbers above 50 up to 100, about 2 stretches; and for numbers from 100 to 150, one stretch in the minute. Still finer yarns are spun more slowly, which is not wonderful, since in the fine spinning mills of England, the mules usually contain upwards of 500 spindles each, in order that one operative may manage a great number of them, and thereby earn such high wages as shall fully remunerate his assiduity and skill.

In spinning fine numbers, the second speed is given before the carriage is run out to the end of its railway; during which course of about six inches, it is made to move very slowly. This is called the second stretch, and is of use in making the yarn level by drawing down the thicker parts of it, which take on the twist less readily than the thinner, and therefore remain softer and more extensible. The stretch may therefore be divided into three stages. The carriage first moves steadily out for about 4 feet, while the drawing rollers and spindles are in full play; now the rollers stop, but the spindles go on whirling with accelerated speed, and the carriage advances slowly, about 6 inches more; then it also comes to rest, while the spindles continue to revolve for a little longer, to give the final degree of twist. The acceleration of the spindles in the second and third stages, which has no other object but to save time, is effected by a mechanism called the *counter*, which shifts the driving band, at the proper time, upon the loose pulley, and, moreover, a second band, which had, till now, lain upon its loose pulley, upon a small driving pulley of the rim-shaft. At length, both bands are shifted upon their loose pulleys, and the mule comes to a state of quiescence.

The SELF-ACTOR MULE, or the IRON MAN, as it has been called in Lancashire, is an invention to which the combinations among the operative spinners obliged the masters to have recourse. It now spins good yarn up to 40 s with great uniformity and promptitude, and requires only juvenile hands to conduct it, to piece the broken yarns, to replace the bobbins of rovings in the creel, and to remove the finished cops from the spindles.

The self-acting mules were first constructed, I believe, by Messrs. Eaton, formerly of Manchester, who mounted ten or twelve of them in that town, four at Wiln, in Derbyshire, and a few in France. From their great complexity and small productiveness, the whole were soon relinquished, except those at Wiln. M. de Jong obtained two patents for self-acting mules, and put twelve of them in operation in a mill at Warrington, of which he was part proprietor; but with an unsuccessful result. I saw the *debris* of one of M. de Jong's self-actors in the factory of M. Nicolas Schlumberger, at Guebwiller, in Alsace, where the machine had been worked for three months, without advantage, under the care of the inventor, who is a native of that valley.

The first approximation to a successful accomplishment of the objects in view, was an invention of a self-acting mule, by Mr. Roberts, of Manchester; one of the principal points of which was the mode of governing the winding-on of the yarn into the form of a cop; the entire novelty and great ingenuity of which invention was universally admitted, and proved the main step to the final accomplishment of what had so long been a desideratum. For that invention a patent was obtained in 1825, and several headstocks upon the principle were made, which are still working successfully.

In 1830, Mr. Roberts obtained a patent for the invention of certain improvements; and by a combination of both his inventions, he produced a self-acting mule, which is generally admitted to have exceeded the most sanguine expectations, and which has been extensively adopted. There are, probably, at present, upwards of half a million of spindles of Messrs. Sharp, Roberts, and Co.'s construction, at work in the United Kingdom, and giving great satisfaction to their possessors. The advantages of these self-actors are the following: —

The saving of a spinner's wages to each pair of mules, piecers only being required, as one overlooker is sufficient to manage six or eight pairs of mules. The production of a greater quantity of yarn, in the ratio of from 15 to 20 per cent. The yarn possesses a more uniform degree of twist, and is not liable to be strained during the spinning, or in winding-on, to form the cop; consequently fewer threads are broken in these processes, and the yarn, from having fewer piecings is more regular.

The cops are made firmer, of better shape, and with undeviating uniformity; and, from being more regularly and firmly wound, contain from one third to one half more yarn than cops of equal bulk wound by hand; they are consequently less liable to injury in packing or in carriage, and the expense of packages and freight (when charged by measurement) is considerably reduced.

From the cops being more regularly and firmly wound, combined with their superior formation, the yarn intended for warps less frequently breaks in winding or reeling, consequently there is a considerable saving of waste in those processes.

Secondly, the advantages connected with weaving.

The cops being more regularly and firmly wound, the yarn, when used as weft, seldom breaks in weaving; and as the cops also contain a greater quantity of weft, there are fewer bottoms, consequently there is a very material saving of waste in the process of weaving.

From those combined circumstances, the quality of the cloth is improved, by being more free from defects caused by the breakage of the warp or weft, as well as the selvages being more regular.

The looms can also be worked at greater speed; and, from there being fewer stoppages, a greater quantity of cloth may be produced.

That the advantages thus enumerated, as derivable from the use of self-acting mules, have not been overrated, but, in many instances, have been considerably exceeded, I have, by extensive personal inquiry and observation, had ample opportunity of ascertaining.

Statement of the quantity of yarn produced on Messrs. Sharp, Roberts, and Co.'s self-acting mules, in twelve working hours, including the usual stoppages connected with spinning, estimated on the average of upwards of twenty mills: —

No. of Yarn.	No. of Twist.	No. of Weft.
16	4½ hanks	4⅞ hanks per spindle.
24	4¼ —	4⅝ —
32	4 —	4⅜ —
40	3¾ —	4⅛ —

Of the intermediate numbers the quantities are proportionate.

Results of trials made by Messrs. Sharp, Roberts, and Co., at various mills, to ascertain the comparative power required to work self-acting mules, in reference to hand-mules, during the spinning, up to the period of backing off.

Particulars of the trials referred to, and their results: —

At what Mill, and the Description of Mule.	No. and kind of Yarn.	Diameter of Pulley or Rim Wheel.	Revolutions of Pulley or Rim Wheel.	Required Force for Motion.	Total Force Employed in Spinning.
Messrs. Birley and Kirk.	*Weft.*	*Ins.*		*lbs.*	*lbs.*
Self-acting mule, 360 sps.	30 to 34	12	58	30	5463
* Hand mule, 180 sps.	ditto	15	36	26	3669 × 2 = 7338
Messrs Leech and Vandrey.	*Twist.*				
† Self-acting mule, 324 sps.	36	12	70	36	7912
Hand mules, 324 sps.	36	29	58	16½	7273
Messrs. Duckworth & Co.	*Twist.*				
Self-acting mule, 324 sps.	40	12	62	33	6421
Hand mule, 324 sps.	40	47	36	15½	6646

The mode adopted to make the trials was as follows, viz.:

A force, indicated by weight in pounds, was applied to the strap working upon the

* The trial was disadvantageous for the hand-mules, being two for 360 spindles.

† The trial was disadvantageous for the self-acting mules, being driven by a very short and light vertical strap, the hand-mule having a long horizontal strap.

driving-pulley of the respective mules, sufficient to maintain the motion of the mule whilst spinning, which weight, being multiplied by the length of strap delivered by each revolution of the pulley, and again by the number of revolutions made by the pulley whilst spinning, gave the total force in pounds, applied to the respective mules whilst spinning; for instance, suppose a mule to be driven by a pulley 12 inches diameter (3·14 ft. in circumference), such pulley making 58 revolutions during the spinning as above, and that it required a force equal to 30 lbs. weight to maintain the motion of the mule, then 33 lbs. × 3·14 feet circumference of pulley × 58 revolutions in spinning = 5·463 lbs. of force employed during the spinning, to the period of backing-off.

Mr. James Smith, of Deanstone cotton works in Scotland, obtained a patent for the invention of a *self-actor*, in February, 1834. He does not perform the backing-off by reversing the rotation of the spindle, as in common mules, or as in Mr. Roberts', but by elevating the counterfaller wire, which, being below the ends of the yarn or thread, along the whole extent of the carriage, thereby pulls off or strips the spiral coils at the point of the spindle, instead of unwinding them, as of old. This movement he considers to be of great importance towards simplifying the machinery for rendering the mule self-acting; and the particular way in which he brings the stripper into action is no doubt ingenious, but it has been supposed by many to strain the yarn. He claims as his invention the application and adaptation of a mangle wheel or mangle rack to the mule, for effecting certain successive movements, either separately or in conjunction; he claims that arrangement of the carriages of a pair of mules, by which the stretch is caused to take place over part of the same ground by both carriages, and thereby the space required for the working of the pair of mules is greatly diminished; and he claims the application of a weight, spring, or friction, for balancing the tension of the ends of the threads.

A patent was granted, in April, 1835, to Mr. Joseph Whitworth, engineer in Manchester, for some ingenious modifications of the mechanism of the mule, subservient to automatic purposes. His machinery is designed, first, to traverse the carriage in and out, by means of screws or worm-shafts, which are placed so as to keep the carriage parallel to the drawing rollers, and prevent the necessity of squaring bands, hitherto universally employed; secondly, his invention consists in an improved manner of working the drums of a self-acting mule by geer; thirdly, in the means of effecting the backing-off; fourthly, in the mechanism for working the faller-wire in building the cops; and fifthly, in the apparatus for effecting the winding of the yarns upon the spindles. As regards the throstles and doubling frames, his improvements apply, first, to the peculiar method of constructing and adapting the flyers and spindles, and producing the drag; and, secondly, to the arrangement of the other parts of the doubling machinery.

See LACE-MAKING, SINGEING, TEXTILE FABRIC, THREAD MANUFACTURE, and WEAVING.

We extract the following from the Circular of Hermann Cox and Co., dated 19th July, 1852.

Export from 1st January to 5th May, as follows:

	1852.	1851.
Exportations of Yarn - - -	50,399,189 lbs.	42,630,812 lbs.
„ Manufactured Goods -	509,350,295 yds.	493,915,720 yds.

consequently a considerable surplus on both over last year; the official return till 5th June, just out, again shows an increase, viz.

	1852.	1851.
Exportation of Yarn - - -	63,418,111 lbs.	54,634,370 lbs.
Manufactured Goods -	649,341,927 yds.	630,581,674 yds.

The following is a return of exports from Hull, from 1st January till 30th June:

	Twist.	Other Yarn.	Manufactured Cotton Goods.	Raw Cotton.
1852 -	33,182 bales	12,115 bales	11,536 bales	65,186 bales
1851 -	31,601 „	9,634 „	11,347 „	33,054 „

AMERICA.

	1851.	1852.
Stock 1st September in the Ports - -	148,000 bales	128,000 bales
Receipts till 22nd June - - -	2,250,000 „	2,936,000 „
	2,398,000 „	3,064,000 „
Shipments to Europe till 22nd June -	1,758,000 „	2,263,000 „
	640,000 „	801,000 „
Deduct Stock 22nd June - - -	304,000 „	201,000 „
American Consumption for 1851 - -	336,000 bales	600,000 bales

Last year the American spinners took from the above-named last date till 1st Sept., 137,000 bales.

FRANCE.

Notwithstanding 96,348 bales larger supply, the stock is still 12,293 bales smaller than last year.

	Stock, 1st January.	Imports to 1st July.	Total.	Deduct Stock, 1st July.	Leaves for Consumption.
1851.					
Havre -	39,825	210,140	249,965	78,377	171,588 bales
Marseilles -	15,095	26,124	41,219	17,479	23,740 „
	54,920	236,264		95,856	195,328 bales
or 7,512 bales per week.					
1852.					
Havre -	22,767	297,514	320,281	75,271	245,010 bales
Marseilles -	7,661	35,098	42,759	8,292	34,467 „
	30,428	332,612		83,563	279,477 bales

or 10,749 bales per week this year against 7,512 bales in the same period last year, or 7,326 bales average of 1851.

REMAINING CONTINENT.

We find the consumption of the first six months of 1851 and 1852 to be as follows:

	Stock, 1st January.	Direct Imports.	Total.	Deduct Stock, 1st July.	Leaves for Consumption.
1851.					
Hamburg - - -	6,300	33,730	40,030	6,730	33,300 bales
Bremen - - - -	89	21,191	21,280	12,133	9,147 „
Petersburg and Sweden - -	5,575	7,000	12,575	4,000	8,575 „
Amsterdam - - -	1,362	4,888	6,250	2,698	3,552 „
Rotterdam - - -	467	1,912	2,379	1,333	1,046 „
Antwerp - - - -	4,578	25,173	29,751	8,500	21,251 „
Trieste - - - -	22,596	79,582	102,178	49,004	53,174 „
Spain, Portugal, and Italy -	6,000	68,000	74,000	8,000	66,000 „
		241,476		99,398	196,045 bales
			Add Export from England -		95,300 „
			Total - - - -		291,345 bales

or 11,205 bales per week.

1852.	Stock, 1st January.	Direct Imports.	Total.	Deduct Stock, 1st July.	Leaves for Consumption.
Hamburg - - -	5,900	65,929	71,829	17,590	53,839 bales
Bremen - - -	1,664	16,303	17,967	3,304	14,663 „
Petersburg and Sweden -	2,000	23,000	25,000	5,000	20,000 „
Amsterdam - - -	2,101	6,890	8,991	4,157	4,834 „
Rotterdam - - -	928	11,581	12,509	8,350	4,159 „
Antwerp - - -	1,196	54,282	55,478	22,000	33,478 „
Trieste - - - -	25,914	72,392	98,306	29,857	68,449 „
Spain, Portugal, and Italy -	4,219	97,000	101,219	9,000	92,219 „
		347,377		99,658	291,641 bales
			Export from England -		147,000 „
			Total - - -		438,641 bales

or 16,870 bales per week, against 11,205 bales in the first half of last year, or against 11,664 bales average of the whole period of 1851.

The total consumption of all countries according to the preceding statements is as follows:

England - - - -	39,683 bales,	against 29,851 bales,	1851
America - - - -	11,538 „	6,461 „	
France - - - -	10,749 „	7,512 „	
Remaining Continent - -	16,870 „	11,205 „	
	78,840	55,029 bales per week.	

To which we, however, consider it advisable to add, that this increase in the consumption for the first half year (viz. 23,811 bales per week) should not be taken as any criterion against the consumption of the same period last year, when it was so much restricted through the drooping state of prices, and when spinners were induced to use up their whole stocks. We affirm therefore that this increase of consumption should only be considered in comparison with the average consumption of the whole of last year, viz.

In England - - - - - -	31,973 bales	in 1851.
America - - - - - -	9,479 „	
France - - - - - -	7,326 „	
Remaining Continent - - - -	11,664 „	
	60,442 bales per week	
Against - -	78,840 „	this year.

We have thus far represented the consumption—the extraordinary increase of the same in all countries, without exception, proves how cheap food, with peace, tends to enlarge consumption; and it remains therefore only to be hoped that the favourable prospects for the ensuing crop be not blighted. It is clearly evident that present prices do not affect the consumption: for the planters they are sufficiently remunerative to induce an extension of the culture, and so provide for the world such stocks as would prevent any ill effect arising from a future small or bad crop.

It shall now be our endeavour to point out the position of stocks in all Europe on the 31st December this year, supposing the consumption to continue at its present rate:

The American crop - - - - -	3,000,000 bales	
Of which were received by the last list of 22nd June -	2,936,329 „	
Remain to receive - - - - - -	63,671 „	
Stocks in the ports and on shipboard 22nd June - -	201,773 „	
	265,444	
The average stock left in the ports during the last six years was about 150,000 bales, but we will take for this year only - - - - - - - -	100,000 „	
Would leave for all Europe - - - -	165,444 „	

Suppose American spinners take nothing more from 22nd June till 1st September.

Brought forward - -		165,444 bales
From America, floating to England - -		150,000 „
„ „ „ to other countries - -		100,000 „
„ India „ to England - -		100,000 „
to receive from other countries till 31st December, equal to last year.		
England - from Egypt, Brazils, and Sundries -	83,000	
France - „ Egypt, Brazils, and Smyrna -	26,000	
Trieste, and other Ports „ Egypt, Brazils, and Smyrna -	40,000	
		149,000 „
Total supply for Europe - - - - -		664,444 „
Add stocks in all European ports on 1st July - -		900,421 „
Total -		1,564,865 „
Quantity of American, next crop, to be received in England		150,000 „
Ditto in Continental ports - - - -		75,000 „
		1,789,685 bales.

Therefore, if the present consumption of Europe were to continue to the end of the year, the stock would be only 39,984 in all European ports, not enough for one week.

Table of Imaginary Stocks in Great Britain on 31st December, 1852.

The American crop - - - - - - -	3,000,000 bales
Of which were received by the last list of 22nd June - -	2,936,329 „
Remain to receive - - - - - - -	63,671 „
Stocks in the ports and on shipboard 22nd June - -	201,773 „
	265,444 „
The average stock left in the ports during the last six years was about 150,000 bales, but we will take for this year only -	100,000 „
	165,444 „
We will suppose American spinners to take nothing more till 1st September, and supposing the 32 ships loading for France, and 125 for other ports take only - -	65,444 „
Would leave for Great Britain - - - -	100,000 „
As the stocks in the interior markets are only one-third of those of last year, shipments after August must fall very short; but supposing England to receive from 1st September till 31st December - - - - - - -	150,000 „
Now floating to England - - - - - -	150,000 „
From India we will suppose - - - - -	100,000 „
From Brazils, Egypt, &c., like last year in the same period -	83,000 „
Total to receive -	583,000 bales
Add stock 1st July in Great Britain - - -	717,200 „
	1,300,200 bales.

Export

until 1st July last year was 95,300 bales, for the same period this year 147,000 bales. We have shown that the Continental stocks, notwithstanding so much larger receipts, are only near on a par with those of last year; this leads us to suppose that our market must later assist those by large exports, but we will take such only equal to last year, viz. - - - - - - - *121,000 bales*

Leaves - - - - - -	1,179,200 „
Whereas the present rate of consumption requires till 31st Dec. -	1,031,758 bales.

This would leave us a stock at this year's end of all descriptions of 147,442 bales only, not sufficient for the consumption of four weeks; supposing, however, the consumption to fall to only 33,000 bales per week, the remaining stock would be only 321,000 bales, against 494,000 bales at the end of last year.

COTTON SPINNING. Messrs. Tatham, Cheetham, and Duncan, obtained in 1846 a patent for sundry improvements in apparatus for cotton spinning. Their first invention applies to the scutcher, a machine by which the cotton is cleansed and lapped in a compact and even sheet or lap upon a roller preparatory to its being fed into the carding engine, and consists in a new arrangement of rollers for compressing or calendering the sheet of cotton previous to its being lapped upon the roller; and also in a new method of weighting the calendering rollers, whereby the pressure is gradually increased as the sheet of cotton approaches the lap. The second part of the invention consists in the employment of an apparatus for collecting the fibres of cotton from the dust which is blown by the fan from the scutcher.

The third part of the invention is an improvement upon machinery patented by Tatham & Cheetham in March, 1844, which caused the sliver to be twisted as it is delivered from the carding engine into the tin-can receptacle.

The fourth relates to the application of gutta percha tintawan for covering rollers used in the several machines employed in cotton spinning. These substances may be used either alone, or combined with sulphurets, &c.

The fifth invention relates to the "flyer" now usually employed in "presser frames." Here the legs or arms of the flyer (being jointed above the top or elbow) are caused to act upon the bobbin like tongs, and thus dispense with the small spur or level at the bottom of the flyer, called the presser. Through the boss or upper part of the flyer the sliver or roving of cotton passes to the hollow arm. The top part and arms are joined together, and swivel upon a central pin or stud. At this joint a coiled spring, exactly similar to the ordinary snuffers-spring, is inserted, one end of which is to be fast to the head, and the other end to the arm of the flyer; whereby the desired elasticity is imparted to the arms, to effect the pressure on the bobbin. The lower end of the arm must be smaller, to lap one or two folds of the roving around it to create the drag usually obtained by the folds around the common press or level. — *Newton's Journal*, xxxi. p. 77.

In cotton spinning machines the roving and slubbing frames move at a great velocity, and are liable to vibrations, and consequently to much wear and tear, which Mr. Edmund Hartley, of Oldham, has tried to remedy by patented contrivances, while the speed is increased. He has also sought to improve the backing-off motion in self-actor mules. For description of his invention, see *Newton's Journal*, vol. xxxvi. p. 300.

COTTON (GUN). M. Schönbein, the patentee, states that the invention consists in the manufacture of explosive compounds applicable to mining purposes and to projectiles, and as substitutes for gunpowder, by treating and combining matters of vegetable origin with nitric and sulphuric acids.

The matter of vegetable origin which he prefers, as being best suited for the purposes of the invention, is cotton, as it comes into this country, freed from extraneous matters; and it is stated to be desirable to operate on the clean fibres of the cotton in a dry state. The acids are nitric acid of from 1·45 to 1·50 specific gravity, and sulphuric acid of 1·85 specific gravity.

The acids are mixed together in the proportions of 1 measure of nitric to 3 measures of sulphuric acid, in any suitable or convenient vessel not liable to be affected by the acids. A great degree of heat being generated by the mixture, it is left to cool until its temperature falls to 60° or 50° Fahr. The cotton is then immersed in it, and in order that it may become thoroughly impregnated or saturated with the acids, it is stirred with a rod of glass or other material not affected by the acids. The cotton should be introduced in as open a state as practicable. The acids are then poured or drawn off, and the cotton gently pressed by a presser of glazed earthenware, to press out the acids, after which it is covered up in the vessel, and allowed to stand for about an hour. It is subsequently washed in a continuous flow of water until the presence of the acids is not indicated by the ordinary test of litmus paper. To remove any uncombined portions of the acids which may remain after the cleansing process, the patentee dips the cotton in a weak solution of carbonate of potash, composed of 1 oz. of carbonate of potash to 1 gallon of water, and partially dries it by pressing, as before. The cotton is then highly explosive, and may be used in that state; but, to increase its explosive power, it is dipped in a weak solution of nitrate of potash, and, lastly, dried in a room heated by hot air or steam to about 150° Fahr.

It is considered probable that the use of the solutions of carbonate of potash and nitrate of potash may be dispensed with, although actual experience does not warrant such an omission. The patentee remarks, that nitric acid may be employed alone in the manufacture of explosive compounds, but that, as far as his experience goes, the article when so manufactured is not so good, and far more costly.

When used, care should be taken to employ a much less quantity by weight, to produce the same result, than of gunpowder; and it has been found that three parts by weight of the cotton produce the same effect as eight parts by weight of the Tower proof gunpowder.

The cotton, when prepared in the manner before mentioned, may be rammed into a piece of ordnance, a fowling piece, or musket; or may be made up into the shape of cartridges; or may be pressed, when damp, into moulds of the form of the bore of the piece of ordnance for which it is intended, so that, when dried, it shall retain the required figure; and it may also be placed in caps, like percussion caps, and made to explode by impact. Lastly, the patentee states, that although he prefers the use of cotton, other matters of vegetable origin may be similarly treated with acids to form an explosive compound, and that acids of an inferior specific gravity may be employed.

COTTON (GUN), *spontaneous combustion of, (by Dr. Gladstone)*.—"Gun-cotton, as commonly produced, especially for preparation of *collodion*, is a mixture of two distinct though analogous substances. The one is designated pyroxyline, and has the formula,

$$C_{24}\left\{\begin{matrix}H_{15}\\5NO\end{matrix}\right\}O_{20}$$

It leaves no residuum on explosion; is insoluble in ether, &c. The other has received the appellation Cotton-xyloidine, and the formula

$$C_{24}\left\{\begin{matrix}H_{17}\\3NO_4\end{matrix}\right\}O_{20}$$

It leaves a residue on explosion; is soluble in ether, &c.

"*Pyroxyline.*—This substance is produced only when cotton or cotton-xyloidine is immersed in a mixture of nitric acid, of sp. gr. 1·5, with strong oil of vitrol. Although it contains so large an amount of oxide of nitrogen, I am acquainted with no clear instance in which it has undergone spontaneous decomposition. Specimens obtained by the action of the mixed acids on cotton-xyloidine have shown no indications of change; and pyroxyline obtained in a compact translucent form, from solution in acetic ether, has also remained unaltered.

"*Cotton-Xyloidine.*—This may be prepared in a state of purity, and in a pulverulent condition, by dissolving cotton or pyroxyline in nitric acid of about sp. gr. 1·45, and precipitating the substance by water.

"Several specimens of this compound made from both sources have hitherto suffered no decompositions, but they have been generally kept in the dark. One sample of precipitated cotton-xyloidine placed in a stoppered bottle remained in a cupboard, the door of which was sometimes opened and sometimes closed. After the lapse of about three years it suddenly began to evolve nitric oxide and water: the action continued for a few weeks, and then nothing remained but a small quantity of a transparent gummy mass of a light brown colour, and possessed of a very peculiar odour. Several months produced no further alteration.

"This product of decomposition, which had about the tenacity and consistency of ordinary gum, was not explosive: when heated in a closed tube, *per se*, it gave off red fumes, and afterwards swelled up, being carbonized, and evolving empyreumatic oils. It was found to be insoluble in cold water, but when boiled in that liquid, it swelled up as a gelatinous mass, and became disintegrated. There resulted a solution which reddened litmus paper slightly, containing, however, no oxalic acid, but a small quantity of another acid, which gave a flocculent white-lead salt, insoluble in excess of acetic acid; the substance in question, though insoluble in cold water, dissolved readily in aqueous solution of potash: yet it appeared to be altered in combining with the alkali, for it was not re-precipitated when the potash was supersaturated by an acid.

"*Starch-Xyloidine.*—This is the well known substance produced when starch is treated with strong nitric acid, and water is added to the viscid mass. Its composition varies; but it is in general analogous to, if not identical with, that ascribed above to cotton-xyloidine.

"A large specimen, freely exposed to the light during more than four years, remained unaltered.

"*Higher Starch Compound.*—When ordinary starch-xyloidine is treated with a mixture of fuming nitric and sulphuric acids, and subsequently washed, it is found to have greatly increased in weight. The resulting substance is more combustible than the original xyloidine, and differs from it in several respects, but is not identical with the pyroxyline obtained from woody fibre.

"A sample of this product, which had been left eight or nine months in a room where light freely entered, was found wholly decomposed; nitrous fumes and vapour of water had been evolved, leaving a dark sticky residue. This new substance was soluble in water and in alcohol; crystallizing from the latter in tufts, which under the microscope had a beautiful arborescent appearance. It remained a couple of years or more dissolved in a very small quantity of water. What changes may have taken place in it during that period is unknown, since no proper examination had been previously made, but after the lapse of that time, the solution was found to be almost black and strongly acid.

When neutralized with an alkali it gave a copious precipitate on the addition of nitrate of silver, and a flocculent salt, or rather mixture of salts, with chloride of calcium, which, when dried and heated with hydrate of potash, evolved ammonia. At the bottom of the vessel containing the aqueous solution there had grown a compound crystal, transparent and colourless, with the exception of a few brown specks. It had the rhomboidal form which oxalic acid usually assumes, and upon further examination and analysis proved to be that substance.

"A small sample of this same starch compound, which had been washed repeatedly with glacial acetic acid for complete purification, and which had been kept constantly in the dark, was found to have suffered decomposition, nothing remaining but a viscous acid liquid. When examining these decomposed explosive compounds, I found in my laboratory a bottle filled with a brown sticky mass; the label having been destroyed by evolved acid, it could not be positively identified, but I have good reason to believe it had originally been this higher starch compound: the substance had a strong odour of hydrocyanic acid. Its solution, either in water or alcohol, had a strong acid reaction. It gave no precipitate with chloride of calcium. Flocculent salts containing metallic oxides or baryta, all easily soluble in nitric acid, were readily produced. Its combinations with the alkalis gave dark-brown aqueous solutions, from which they separated in an amorphous form on evaporation, but though exceedingly soluble in water, they were precipitated on the addition of alcohol. The mass was probably a mixture of different acids, principally non-azotized, for little nitrogen was discoverable; and although oxalic acid itself was absent, it is by no means improbable that some higher members of the series, $Cn\ Hn_1\ O_4$ were present.

"*Nitro-Mannite.*—This substance, first described by MM. Flores Domonte and Menard, is formed when mannite is dissolved in fuming nitric acid, and precipitated by sulphuric acid. Its formula, according to Strecker, is $C_{12}\ H_8\ (NO_4)\ O_{12}$. It is the only known crystallizable body belonging to this group.

"My sample of nitro-mannite kept in a glass tube, generally in the dark, has suffered some decomposition; acid fumes have been given off, but the action has not proceeded far.

"*Sugar Compound.*—It is well known that cane-sugar submitted to the action of mixed nitric and sulphuric acids is converted into a pasty explosive substance, readily soluble in alcohol, but insoluble in water, to which, however, it communicates an intensely bitter flavour. According to the observations of H. Vohl, several different compounds are produced simultaneously in this reaction. Diabetic sugar similarly treated gives a similar substance.

"I have kept samples of this product, some of which had been merely kneaded with water until the acid was removed, others regained from solution in alcohol. They have shown little signs of decomposition.

"*Milk-Sugar Compound.*—By the same treatment a substance is obtained from milk-sugar closely resembling that just described. Like the previous compound, it can be purified by solution in alcohol, but does not present itself in a crystalline form.

"A sample kept in paper was found to be much decomposed.

"*Caramel Compound.*—I procured a similar compound from pure caramel, prepared by means of absolute alcohol. The caramel having been dried and pounded, was placed in fuming nitric acid: it dissolved; upon the addition of sulphuric acid, a dark coloured oil separated, which became hard and yellow when washed with water. It was soluble in alcohol, but came out from solution without crystallizing, and always of the same colour. The compound bore a close resemblance in its various properties to those obtained from sugar.

"The sample kept by me has suffered little or no alteration.

"*Gum Compound.*—At least two different subtances of this explosive character may be produced by the action of nitric acid on gum. If the gum be treated with the fuming acid, it dissolves into a mucilaginous solution, from which water precipitates a white body, slightly soluble in that liquid, and very soluble in alcohol. A sample of this substance has not yet suffered any decomposition.

"If sulphuric acid be added to the solution of gum in fuming acid, it precipitates a white substance resembling that from sugar, but not nearly so soluble in alcohol, and very slightly in ether. Moreover, it is only softened, not melted, by a temperature of 212° Fahr. No specimen of this compound was preserved.

"Whilst treating upon this subject, it may not be amiss to append a few observations upon another decomposition of pyroxyline. When good gun-cotton is heated at a temperature a little exceeding that of boiling water, it becomes brown in colour, and is disintegrated. The odour of nitrous fumes, along with that of some cyanogen compound, is very perceptible. It thus becomes explosive at a lower temperature than formerly, a fact which may account for some of those hitherto unexplained accidents which have arisen from this article, for it is evident that gun-cotton exposed for some time to a

degree of heat quite insufficient under ordinary circumstances to cause explosion, may yet be eventually dissipated from the formation of this product.

"The brown substance thus obtained underwent no visible alteration in the space of four years. When examined lately it was found to be very soluble in water, but insoluble in alcohol or ether. Its aqueous solution tasted somewhat bitter, it reacted slightly acid, no crystals were obtained on evaporation. When boiled with a solution of potash, it evolved ammonia. When mixed with a salt of lead or copper it formed brown flocculent precipitates, but none appeared with a silver or lime salt. The organic substance which fell in combination with oxide of lead, contained a large amount of nitrogen. That portion of the fibre which had not become brown with heat was found to be no longer pyroxyline; when freed from the brown matter by washing with water, and dried, it left little residue on explosion; but on the other hand, it dissolved very readily in ether, alcohol, or cold sulphuric acid; properties of cotton-xyloidine, but not of the original substance. When, however, the manner of its production is considered, we can hardly conceive it identical with a body which would require the introduction of two atoms of hydrogen if formed from pyroxyline. Whether this change which gun-cotton undergoes at a high temperature is at all analogous to the spontaneous decomposition mentioned above, can scarcely be determined, but the presence of azotized compounds in considerable quantity, and of ammonia, rather indicates the reverse.

"The *rationale* of these decompositions is far from being elucidated by the observations here recorded, but as the substances themselves are not now in existence, nor are capable of being procured without long delay, I cannot pursue the investigation further. The only general conclusion which can be drawn appears to be, that several substances of the character above described have a tendency to suffer spontaneous decomposition from being oxidized into non-azotized acids at the expense of the peroxide of nitrogen, NO_4, they contain, which is reduced to the condition of nitric oxide, NO_2, and evolved as such, a portion of water being always given off at the same time."

COURT PLASTER is a considerable object of manufacture. It is made as follows:

Black silk is strained and brushed over ten or twelve times with the following preparation:—Dissolve ½ an ounce of balsam of benzoin in 6 ounces of rectified spirits of wine; and in a separate vessel dissolve 1 ounce of isinglass in as little water as may be. Strain each solution, mix them, and let the mixture rest, so that any undissolved parts may subside; when the clear liquid is cold it will form a jelly, which must be warmed before it is applied to the silk. When the silk coated with it is quite dry it must be finished off with a coat of a solution of 4 ounces of Chian turpentine in 6 ounces of tincture of benzoin, to prevent its cracking.*

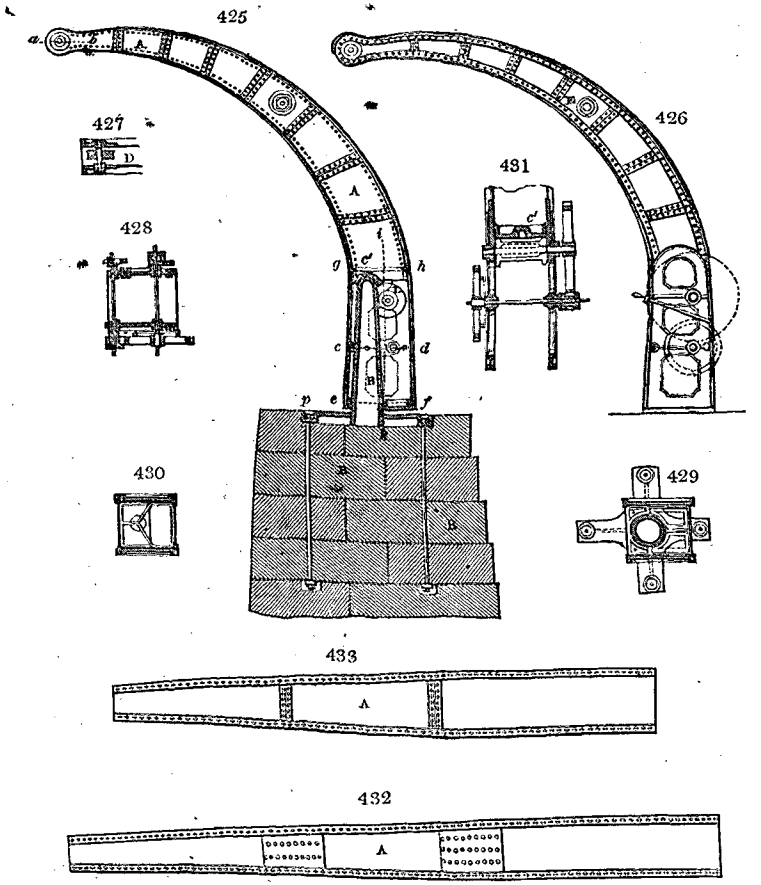
COW DUNG SUBSTITUTE, in calico printing. Sulphate, carbonate and phosphate of lime and soda.

CRANES, *Tubular, of Mr. W. Fairbairn.*—Among the many happy applications of the hollow-girder system of our great engineer, this is one of the most ingenious.

"*Fig.* 425. is a vertical section of a crane, constructed according to my said invention, and calculated for lifting or hoisting weights up to about 8 tons. *Fig.* 426. is an elevation of the same; *figs.* 427, 428, 429, and 430., are cross-sections, on the lines *a b*, *c d*, *e f*, *g h*; and *fig.* 431. a transverse vertical section on the line *i k*. A A is the jib, which, in its general outline, is of a crane-neck form, but rectangular in its cross-section, as particularly shown in *figs.* 428, 429, and 430. The four sides are formed of metal plates, firmly riveted together. Along the edges the connection of the plates is effected by means of pieces of angle iron. The connections of the plates at the cross-joints on the convex or upper side of the jib, are made by the riveting on of a plate, which covers or overlaps the ends of the two plates to be joined; the rivets at this part are disposed as represented in *fig.* 432. (a plan of the top plates), and known as 'chain riveting;' B B is the pillar, which is firmly secured by a base plate *p*, to a stone foundation B; and fits at top into a cup-shaped bearing *c*, which is so firmly secured to the side plates of the jib, at or near to the point where the curvature commences, and on which bearing the jib is free to revolve. *Fig.* 431. is a transverse vertical section of the lower part of the jib, showing the manner of fitting the bearings for the chain-barrel (which is placed in the interior), and the spindles and shafts of the wheel geering, by which the power is applied there to D, is the chain pulley, which is inserted in an aperture formed in the top of the jib. The chain passing over this pulley, enters the interior of the crane, and is continued down to the chain barrel. E is a pulley or roller, which is interposed about half-way between the chain-pulley and the chain-barrel, for the purpose of preventing the chain rubbing against the plates. *Fig.* 433. is a plan of the lower plates.

* Paris's Pharmacologia.

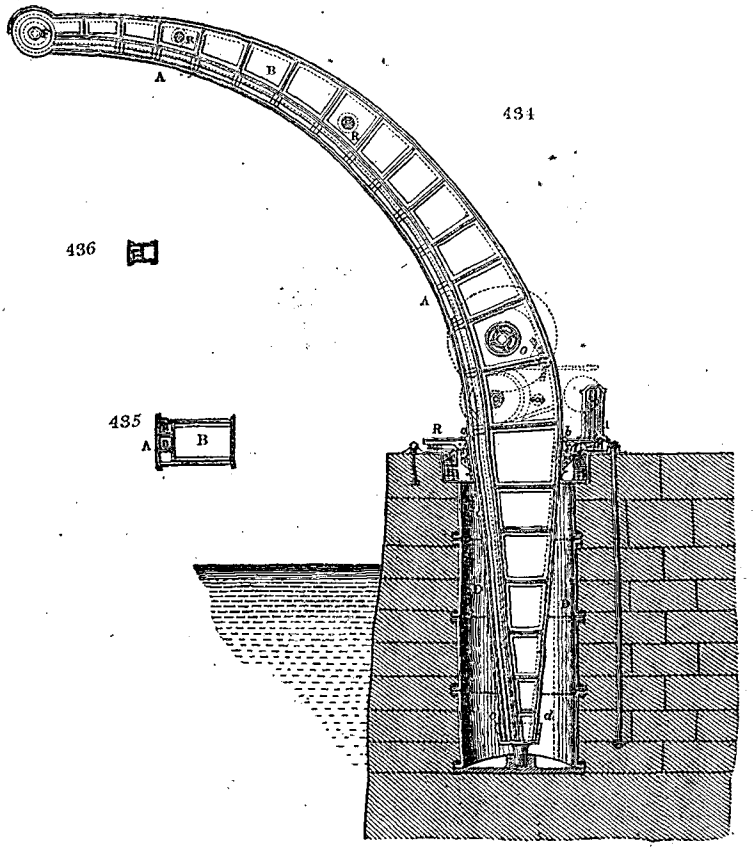
Fig. 434. is a vertical section of another crane constructed upon the same principle as that just described, but calculated for lifting much greater weights (say 20 tons); it differs in having the lower or concave side A A, of the jib strengthened by means of three additional plates B B B, whereby the interior is divided into one large and three smaller cells, as shown in *figs.* 435. and 436., which are cross sections upon the lines *a b*,



and *c d* of *fig.* 434. This arrangement of the cells to strengthen the lower or concave side is advisable, in order to obtain sufficient resistance to the compression exerted by the load lifted, without unnecessarily increasing the weight of the other parts. The tension exerted upon the upper or convex plates does not require so much materials to withstand it; *c*, is the toe of the jib, which rests in a step formed in the bottom of the cylindrical castings D, which is built into the masonry forming the basis of the machine. E E are two of a set of pulleys, which are mounted between two rings F F, and serve as anti-friction rollers for the upper bearing of the jib. The lowermost of the rings F F, rests upon a set of rollers G G, which are fitted into the top of the casting D, so that as the jib is turned round, the rings F F, and the anti-friction rollers which they carry, have perfect freedom to move along with it; H is a platform, upon which the persons working the machine may stand, and which supports a column I, within which there is mounted a spindle K, the lower end of which has keyed to it a pinion L, which gears into a circular rack M M, bolted to the top of the cylindrical casing D. N is a worm-wheel keyed to the top of the spindle K, into which an endless screw, worked by

a hand-wheel, is geered, so that, by turning the hand-wheel, the jib of the crane is made to move round in any required direction. o is the chain-barrel; p the chain-wheel; R R pulleys or rollers which support the chain, and prevent its rubbing against the plates of the jib.

"In the cranes and hoisting machines which I have described, the chain-barrels are inclosed within the jib, and the spindles of the wheel-gearing are also inside; and this



is the disposition of these parts, which I prefer; but it will be obvious that they may be also placed outside of the jib, in a manner similar to that generally followed in the construction of ordinary cranes. And having now described my said invention, and in what manner the same is to be performed, I declare that what I claim is the construction of cranes and other light lifting or hoisting machines, with jibs composed of a series of metal plates, arranged and combined so as to form a connected series of tubular or cellular compartments, as before exemplified and described."

CRAPE. (*Crêpe*, Fr.; *Krepp*, Germ.) A transparent textile fabric, somewhat like gauze, made of raw silk, gummed and twisted at the mill. It is woven with any crossing or tweel. When dyed black, it is much worn by ladies as a mourning dress. Crapes are crisped (*crepés*) or smooth; the former being double, are used in close mourning, the latter in less deep. White crape is appropriate to young unmarried females, and to virgins on taking the veil in nunneries. The silk destined for the first is spun harder than for the second; since the degree of twist, particularly for the warp, determines the degree of crisping which it assumes after being taken from the loom. It is for this purpose steeped in clear water, and rubbed with prepared wax.

Crapes are all woven and dyed with the silk in the raw state. They are finished with a stiffening of gum water.

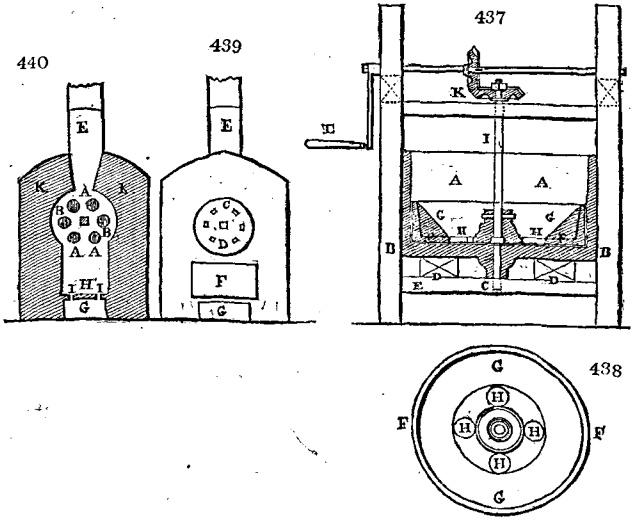
Crape is a Bolognese invention, but has been long manufactured with superior excellence at Lyons in France, and Norwich in England. There is now a magnificent fabric of it at Yarmouth, by power-loom machinery.

There is another kind of stuff, called *crépon*, made either of fine wool, or of wool and silk, of which the warp is twisted much harder than the weft. The *crépons* of Naples consist altogether of silk.

CRAYONS. (Eng. and Fr.; *Pastelstifte*, Germ.) Slender, soft, and somewhat friable cylinders, variously coloured for delineating figures upon paper, usually called chalk drawings. Red, green, brown, and other coloured crayons, are made with fine pipe or china clay paste, intimately mixed with earthy or metallic pigments, or in general with body or surface colours, then moulded and dried. The brothers Joel, in Paris, employ as crayon cement the following composition: 6 parts of shellac, 4 parts of spirit of wine, 2 parts of turpentine, 12 parts of a colouring powder, such as Prussian-blue, orpiment, whitelead, vermillion, &c., and 12 parts of blue clay. The clay being elutriated, passed through a hair sieve, and dried, is to be well incorporated by trituration with the solution of the shellac in the spirit of wine, the turpentine, and the pigment; and the doughy mass is to be pressed in proper moulds, so as to acquire the desired shape. They are then dried by a stove heat.

In order to make cylindrical crayons, a copper cylinder is employed, about 2 inches in diameter, and 1½ inches long, open at one end, and closed at the other with a perforated plate, containing holes corresponding to the sizes of the crayons. The paste is introduced into the open end, and forced through the holes of the bottom by a piston moved by a strong press. The vermicular pieces that pass through are cut to the proper lengths, and dried. As the quality of the crayons depends entirely upon the fineness of the paste, mechanical means must be resorted to for effecting this object in the best menner. The following machine has been found to answer the purpose exceedingly well.

Fig. 437. is a vertical section through the centre of the crayon mill. *Fig.* 438. is a



view of the mill from above. A, the mill tub, whose bottom B must be a hard flat plate of cast iron; the sides A being of wood or iron at pleasure. In the centre of the bottom there is a pivot C, screwed into a socket cast upon the bottom, and which may be strengthened by two cross bars D, made fast to the frame E. F, the millstone of cast-iron, concave, whose diameter is considerably smaller than that of the vessel A; it is furnished within with a circular basin of wood G, which receives the materials to be ground, and directs them to the holes H, which allow them to pass down between the under part of the muller, and the bottom of the tub, to undergo trituration.

By the centrifugal motion, the paste is driven towards the sides of the vessel, rises

over the sides of the muller, and comes again through the holes H, so as to be repeatedly subjected to the grinding operation. This millstone is mounted upon an upright shaft I, which receives rotatory motion from the bevel-wheel work K, driven by the winch L.

The furnace in which some kinds of crayons, and especially the factitious black-lead pencils, are baked, is represented in *fig.* 439. in a front elevation; and in *fig.* 440., which is a vertical section through the middle of the chimney.

A A, six tubes of greater or less size, according as the substance of the crayons is a better or worse conductor of heat. These tubes, into which the crayons intended for baking are to be put, traverse horizontally the laboratory B of the furnace, and are supported by two plates C, pierced with six square holes for covering the axes of the tubes A. These two plates are hung upon a common axis D; one of them, with a ledge, shuts the cylindrical part of the furnace, as is shown in the figure. At the extremity of the bottom, the axis D is supported by an iron fork fixed in the brickwork; at the front it crosses the plate C, and lets through an end about 4 inches square to receive a key, by means of which the axis D may be turned round at pleasure, and thereby the two plates C, and the six tubes A, are thus exposed in succession to the action of the fire in an equal manner upon each of their sides. At the two extremities of the furnace are two chimneys E, for the purpose of diffusing the heat more equably over the body of the crayons. F, *fig.* 439., is the door of the fire-place, by which the fuel is introduced; G, *fig.* 440., the ash-pit; H, the fire-place; I, holes of the grate which separate the fire-place from the ash-pit; K, brickwork exterior to the furnace.

General Lomet proposes the following composition for red crayons. He takes the softest hematite, grinds it upon a porphyry slab; and then carefully elutriates it. He makes it into a plastic paste with gum arabic and a little white soap, which he forms by moulding, as above, through a syringe, and drying, into crayons. The proportions of the ingredients require to be carefully studied.

Crayons, *lithographic.* Various formulæ have been given for the formation of these crayons. One of these prescribes, white wax, 4 parts; hard tallow-soap, shellac, of each 2 parts; lamp black, 1 part. Another is, dried tallow soap and white wax, each 6 parts; lamp black, 1 part. This mixture being fused with a gentle heat, is to be cast into moulds for forming crayons of a proper size.

CREOSOTE, or the *flesh-preserver*, from κρεας and σωζω, is the most important of the five new chemical products obtained from wood tar by Dr. Reichenbach. The other four, *paraffine, eupione, picamar,* and *pittacal,* have hitherto been applied to no use in the arts, and may be regarded at present as mere analytical curiosities.

Creosote may be prepared either from tar or from crude pyroligneous acid. The tar must be distilled till it acquires the consistence of pitch, and at the utmost till it begins to exhale the white vapours of paraffine. The liquor which passes into the receiver divides itself into three strata, a watery one in the middle, placed between a heavy and a light oil. The lower stratum alone is adapted to the preparation of creosote.

1. The liquor being saturated with carbonate of potash, is to be allowed to settle, and the oily matter which floats at top is to be decanted off. When this oil is distilled, it affords at first products lighter than water, which are to be rejected, but the heavier oil which follows is to be separated, washed repeatedly by agitation, with fresh portions of dilute phosphoric acid, to free it from ammonia, then left some time at rest, after which it must be washed by water from all traces of acidity, and finally distilled along with a new portion of dilute phosphoric acid, taking care to *cohobate,* or pour back the distilled product repeatedly into the retort.

2. The oily liquid thus rectified is colourless; it contains much *creosote,* but at the same time some *eupione,* &c. It must therefore be mixed with potash lye at 1·12 sp. grav., which dissolves the creosote. The eupione floats upon the surface of that solution, and may be decanted off. The alkaline solution is to be exposed to the air, till it blackens by decomposition of some foreign matter. The potash being then saturated with dilute sulphuric acid, the creosote becomes free, when it may be decanted or syphoned off and distilled.

3. The treatment by potash, sulphuric acid, &c., is to be repeated upon the brownish creosote till it remains colourless, or nearly so, even upon exposure to air. It must be now dissolved in the strongest potash lye, subjected to distillation anew, and lastly, re-distilled with the rejection of the first products which contain much water, retaining only the following, but taking care not to push the process too far.

In operating upon pyroligneous acid, if we dissolve effloresced sulphate of soda in it to saturation, at the temperature of 267° F., the creosote oil will separate, and float upon the surface. It is to be decanted, left in repose for some days, during which it will part with a fresh portion of the vinegar and salt. Being now saturated while hot with carbonate of potash and distilled with water, an oily liquor is obtained, of a pale yellow colour. This is to be rectified by phosphoric acid, &c., like the crude product of creosote from tar.

Creosote is apparently composed of 76·2 carbon, 7·8 hydrogen, and 16·0 oxygen, in 100 parts. It is an oily looking liquid, slightly greasy to the touch, void of colour, having an acrid burning taste, and capable of corroding the epidermis in a short time. It possesses a penetrating disagreeable smell, like that of highly smoked hams, and when inhaled up the nostrils causes a flow of tears. Its specific gravity is 1·037, at 58° F. Its consistence is similar to that of oil of almonds. It has no action upon the colours of litmus or turmeric, but communicates to white paper a stain which disappears spontaneously in a few hours, and rapidly by the application of heat.

It boils without decomposition at 398° F., under the average barometric pressure, remains fluid at 16° F., is a non-conductor of electricity, refracts light powerfully, and burns in a lamp with a ruddy smoky flame.

When mixed with water at 58° F. it forms two different combinations, the first being a solution of 1 part of creosote in 400 of water; the second, a combination of 1 part of water with 10 parts of creosote. It unites in all proportions with alcohol, hydric ether, acetic ether, naphtha, eupione, carburet of sulphur, &c.

Creosote dissolves a large quantity of iodine and phosphorus, as also of sulphur with the aid of heat, but it deposits the greater part of them in crystals on cooling. It combines with potash, soda, ammonia, lime, baryta, and oxide of copper. Oxide of mercury converts creosote into a resinous matter, while itself is reduced to the metallic state. Strong sulphuric and nitric acids decompose it.

Creosote dissolves several salts, particularly the acetates, and the chlorides of calcium and tin; it reduces the nitrate and acetate of silver. It also dissolves indigo blue; a remarkable circumstance. Its action upon animal matters is very interesting. It coagulates albumen, and prevents the putrefaction of butcher's meat and fish. For this purpose these substances must be steeped a quarter of an hour in a weak watery solution of creosote, then drained and hung up in the air to dry. Hence Reichenbach has inferred that it is owing to the presence of creosote that meat is cured by smoking; but he is not correct in ascribing the effect to the mere coagulation of the albumen, since *fibrine* alone, without creosote, will putrefy in the course of 24 hours, during the heats of summer. It kills plants and small animals. It preserves flour paste unchanged for a long time.

Creosote exists in the tar of beech-wood, to the amount of from 20 to 35 per cent., and in crude pyrolignous acid to that of $1\frac{1}{2}$.

It ought to be kept in well-stoppered bottles, because when left open it becomes progressively yellow, brown, and thick.

Creosote has considerable power upon the nervous system, and has been applied to the teeth with advantage in odontalgia, as well as to the skin in recent scalds. But its medicinal and surgical virtues have been much exaggerated. Its flesh-preserving quality is rendered of little use, from the difficulty of removing the rank flavour which it imparts.

Having been employed by a chemical manufacturer to examine his creosote, and compare it with others with a view to the improvement of his process, I found that the article, as made by eminent houses, differed considerably in its properties.

The specific gravities varied in the several specimens as follows: — 1. a specimen given me by Messrs. Zimmer and Sell, at their factory in Sachsenhausen, by Frankfurt on the Maine, had a specific gravity of 1·0524; 2. a sample made in the north of England, sp. gr. 1·057, and its boiling point varied from 370° to 380° F. Mr. Morson's creosote, which is much esteemed, has a sp. gr. of 1·070, and boils first at 280°, but progressively rises in temperature up to 420°, when it remains stationary. The German creosote was distilled from the tar of the pyrolignous acid manufacture. Creosote, I believe, is often made from Stockholm tar. Berzelius gives the sp. gr. of creosote at 1·037, and its boiling point at 203° C. = 397·4° F. I deemed it useless to subject to ultimate analysis products differing so considerably in their physical properties. They were all very soluble in potash lye.

CROSS-FLUCKANS or FLOOKANS. The name given by the Cornish miners to clay veins of more ancient formation.

CRUCIBLES (*Creusets*, Fr.; *Schmelztiegel*, Germ.) are small conical vessels, narrower at the bottom than the mouth, for reducing ores in docimasy by the dry analysis, for fusing mixtures of earthy and other substances, for melting metals, and compounding metallic alloys. They ought to be refractory in the strongest heats, not readily acted upon by the substances ignited in them, not porous to liquids, and capable of bearing considerable alternations of temperature without cracking; on which account they should not be made too thick. The best crucibles are formed from a pure fire-clay, mixed with finely ground *cement* of old crucibles, and a portion of black-lead or graphite. Some pounded coke may be mixed with the plumbago. The clay should be prepared in a similar way as for making pottery ware; the vessels after being formed must be slowly dried, and then properly baked in the kiln. Crucibles formed of a mixture of 8 parts in bulk of Stourbridge clay and cement, 5 of coke, and 4 of graphite,

have been found to stand 23 meltings of 76 pounds of iron each, in the Royal Berlin foundry. Such crucibles resisted the greatest possible heat that could be produced, in which even wrought iron was melted, equal to 150° or 155° Wedgewood; and bore sudden cooling without cracking. Another composition for brass-founding crucibles is the following;—½ Stourbridge clay; ¼ burned clay cement; ⅛ coke powder; ⅛ pipe clay. The pasty mass must be compressed in moulds. The Hessian crucibles from Great Almerode and Epterode are made from a fire-clay which contains a little iron, but no lime; it is incorporated with siliceous sand. The dough is compressed in a mould, dried, and strongly kilned. They stand saline and leaden fluxes in docimastic operations very well; are rather porous on account of the coarseness of the sand, but are thereby less apt to crack from sudden heating or cooling. They melt under the fusing point of bar iron. Beaufoy in Paris has lately succeeded in making a tolerable imitation of the Hessian crucibles with a fire-clay found near Namur in the Ardennes.

Berthier has published the following elaborate analyses of several kinds of crucibles; —

	Hessian.	Beaufoy.	English for Cast Steel.	St. Etienne for Cast Steel.	Glass Pots at Nemours.	Bohemian Glass Pots.	Glass Pots of Creusot.
Silica - -	70·9	64·6	63·7	65·2	67·4	68·0	68·0
Alumina -	24·8	33·4	20·7	25·0	32·0	29·0	28·0
Oxide of Iron - -	3·8	1·0	4·0	7·2	0·8	2·2	2·0
Magnesia -	trace	- -	- -	trace	trace	0·5	trace
Water - -	- -	- -	10·3*	- -	- -	- -	1·0

Wurzur states the composition of the sand and clay in the Hessian crucibles as follows: —

Clay; silica 10·1; alumina 65·4; oxides of iron and manganese 1·2; lime 0·3; water 23

Sand; 95·6 2·1 1·5 0·8

Black-lead crucibles are made of two parts of graphite and one of fire-clay; mixed with water into a paste, pressed in moulds, and well dried; but not baked hard in the kiln. They bear a higher heat than the Hessian crucibles, as well as sudden changes of temperature; have a smooth surface, and are therefore preferred by the melters of gold and silver. This compound forms excellent small or portable furnaces.

Mr. Anstey describes his patent process for making crucibles, as follows. Take two parts of fine ground raw Stourbridge clay, and one part of the hardest gas coke, previously pulverised, and sifted through a sieve of one-eighth of an inch mesh (if the coke is ground too fine, the pots are very apt to crack). Mix the ingredients together with the proper quantity of water, and tread the mass well. The pot is moulded by hand upon a wooden block, supported on a spindle which turns in a hole in the bench; there is a gauge to regulate the thickness of the melting pot, and a cap of linen or cotton placed wet upon the core before the clay is applied, to prevent the clay from sticking partially to the core, in the taking off; the cap adheres to the pot only while wet, and may be removed without trouble or hazard when dry. He employs a wooden bat to assist in moulding the pot; when moulded, it is carefully dried at a gentle heat. A pot dried as above, when wanted for use, is first warmed by the fire-side, and is then laid in the furnace with the mouth downwards (the red cokes being previously damped with cold ones in order to lessen the heat); more coke is then thrown in till the pot is covered, and it is now brought gradually to a red heat. The pot is next turned and fixed in a proper position in the furnace, without being allowed to cool, and is then charged with cold iron, so that the metal, when melted, shall have its surface a little below the mouth of the pot. The iron is melted in about an hour and a half, and no flux or addition of any kind is made use of. A pot will last for fourteen or even eighteen successive meltings, provided it is not allowed to cool in the intervals; but if it cool, it will probably crack. These pots it is said can bear a greater heat than others without softening, and will, consequently, deliver the metal in a more fluid state than the best Birmingham pots will. See a figure of the crucible mould under STEEL.

CRYSTAL is the geometrical form possessed by a vast number of mineral and saline substances; as also by many vegetable and animal products. The integrant particles of matter have undoubtedly determinate forms, and combine with one another by the attraction of cohesion, according to certain laws, and points of polarity, whereby they assume a vast variety of secondary crystalline forms. The investigation of these laws belongs to crystallography, and is foreign to the practical purpose of this volume.

* This crucible had been analyzed before being baked in the kiln.

Instructions are given under each object of manufacture which requires crystallization, how to conduct this process; see BORAX, SALT, &c.

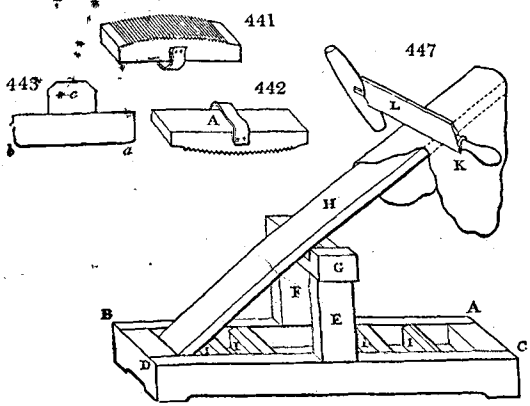
CUDBEAR was first made an article of trade in this country, by Dr. Cuthbert Gordon, from whom it derived its name, and was originally manufactured on a great scale by Mr. G. Mackintosh at Glasgow, nearly 80 years ago. Cudbear or persio is a powder of a violet red colour, difficult to moisten with water, and of a peculiar but not disagreeable odour. It is partially soluble in boiling water, becomes red with acids, and violet blue with alkalis. It is prepared in the same way as archil, only towards the end the substance is dried in the air, and is then ground to a fine powder, taking care to avoid decomposition, which renders it glutinous. In Scotland they use the lichen tartareus, more rarely the lichen calcareus, and omphalodes; most of which lichens are imported from Sweden and Norway, under the name of rock moss. The lichen is suffered to ferment for a month, and is then stirred about to allow any stones which may be present to fall to the bottom. The red mass is next poured into a flat vessel, and left to evaporate till its urinous smell has disappeared, and till it has assumed an agreeable colour verging upon violet. It is then ground to fine powder. During the fermentation of the lichen, it is watered with stale urine, or with an equivalent ammoniacal liquor of any kind, as in making archil.

CUPELLATION is a mode of analyzing gold, silver, palladium, and platinum, by adding to small portions of alloys, containing these metals, a bit of lead, fusing the mixture in a little *cup* of bone earth called a *cupel*, then by the joint action of heat and air oxidizing the copper, tin, &c., present in the precious metals. The oxides thus produced are dissolved and carried down into the porous *cupel* in a liquid state, by the vitrified oxide of lead. See ASSAY, GOLD, and SILVER.

CURRYING OF LEATHER (*Corroyer*, Fr.; *Zurichten*, Germ.) is the art of dressing skins after they are tanned, for the purposes of the shoe-maker, coach and harness maker, &c., or of giving them the necessary smoothness, lustre, colour, and suppleness. The currier's shop has no resemblance to the tanner's premises, having quite a different set of tools and manipulations.

The currier employs a strong hurdle about a yard square, made either of basket twigs, or of wooden spars, fixed rectangularly like trellis work, with holes 3 inches square, upon which he treads the leather, or beats it with a mallet or hammer, in order to soften it, and render it flexible.

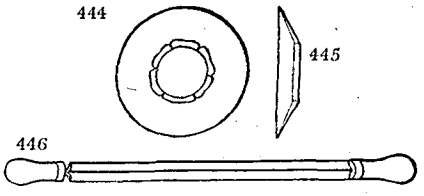
The *head knife*, called in French *couteau a revers*, on account of the form of its edge, which is much turned over, is a tool 5 or 6 inches broad, and 15 or 16 long; with two handles, one in the direction of the blade, and the other perpendicular to it, for the purpose of guiding the edge more truly upon the skin. The pommel (*paumelle*) is so called because it clothes the palm of the hand, and performs its functions. It is made of hard wood, and of a rectangular shape, 1 foot long, 5 inches broad, flat above and rounded below. It is furrowed over the rounded surface with transverse parallel straight grooves. These grooves are in section sharp-edged isosceles triangles. *Figs.* 441. and 442., represent the pommel in an upper and under view. The flat surface is provided with a leather strap for securing it to the hand of the workman. Pommels are made of different sizes, and with grooves of various degrees of fineness. Cork pommels are also used, but they are not grooved. Pommels serve to give grain and pliancy to the skins.



The *stretching iron*, *fig.* 443., is a flat plate of iron or copper, fully a fourth of an inch thick at top, and thinning off at bottom in a blunt edge, shaped like the arc of a circle of large diameter, having the angles *a* and *b* rounded, lest in working they should penetrate the leather. The top *c* is mounted with leather to prevent it from hurting the hands. A copper stretching knife is used for delicate skins. The workman holds this tool nearly perpendicular, and scrapes the thick places powerfully with his two hands, especially those where some tan or flesh remains. He thus equalizes the thickness of

the skin, and renders it at the same time more dense and uniform in texture. This tool is of very general use in currying.

The round knife, *figs.* 444. and 445. (*lunette* in French), is a circular knife from 10 to 12 inches in diameter, with a round 4 or 5 inch hole in its centre, for introducing the hands and working it. It is concave, as shown in the section *fig.* 445., presenting the form of a spherical zone. The concave part is that applied to the skin. Its edge is not perfectly straight; but is a little turned over on the side opposite to the skin, to prevent it from entering too far into the leather. The currier first slopes off with the head knife from the edges, a portion equal to what he afterwards removes with the round one. By this division the work is done sooner and more exactly. All the oiled or greased skins are dressed with the round knife.



The *cleaner* is a straight two-handled knife two inches broad, of which there are two kinds, a sharp-edged and a blunt one. *Fig.* 446.

The *mace* is made of wood, having a handle 30 inches long, with a cubical head or mallet; upon the two faces of which, parallel to the line of the handle, there are 4 pegs of hard wood turned of an egg-shape, and well polished, so as not to tear the moistened leather when it is strongly beat and softened with the mace.

The horse or trestle, *fig.* 447., consists of a strong wooden frame, A B C D, which serves as a leg or foot. Upon the middle of this frame there are two uprights, E F, and a strong cross beam, G, for supporting the thick plank H, upon which the skins are worked. This plank may be set at a greater or less slope, according as its lower end is engaged in one or other of the cross bars, I I I I, of the frame. In the figure, a skin K is represented upon the plank with head knife upon it, in the act of being pared.

A cylindrical bar fixed horizontally at its ends to two buttresses projecting from the wall, serves by means of a parallel stretched cord, to fix a skin by a coil or two in order to dress it. This is accordingly called the *dresser*. The tallow cloth is merely a mop made of stout rags, without the long handle; of which there are several, one for wax, another for oil, &c. Strong-toothed pincers with hook-end handles, drawn together by an endless cord, are employed to stretch the leather in any direction, while it is being dressed. The currier uses clamps like the letter U, to fix the edges of the leather to his table. His polisher is a round piece of hard wood, slightly convex below, with a handle standing upright in its upper surface, for seizing it firmly. He first rubs with sour beer, and finishes with barberry juice.

Every kind of tanned leather not intended for soles or such coarse purposes, is generally curried before being delivered to the workmen who fashion it, such as shoemakers, coachmakers, saddlers, &c. The chief operations of the currier are four: —

1. Dipping the leather, which consists in moistening it with water, and beating it with the *mace*, or a mallet upon the hurdle. He next applies the *cleaners*, both blunt and sharp, as well as the head knife, to remove or thin down all inequalities. After the leather is shaved, it is thrown once more into water, and well scoured by rubbing the grain side with pumice stone, or a piece of slaty grit, whereby it parts with the bloom, a whitish matter, derived from the oak bark in the tan pit.

2. Applying the pommel to give the leather a granular appearance, and a correspondent flexibility. The leather is first folded with its grain sides in contact, and rubbed strongly with the pommel, then rubbed simply upon its grain side; whereby it becomes extremely flexible.

3. Scraping the leather. This makes it of uniform thickness. The workman holds the tool nearly perpendicular upon the leather, and forcibly scrapes the thick places with both his hands.

4. Dressing it by the round knife. For this purpose he stretches the leather upon the wooden cylinder, lays hold of the pendent under edge with the pincers attached to his girdle, and then with both hands applies the edge of the knife to the surface of the leather, slantingly from above downwards, and thus pares off the coarser fleshy parts of the skin. This operation requires great experience and dexterity; and when well performed improves greatly the look of the leather.

The hide or skin being rendered flexible and uniform, is conveyed to the shed or drying house, where the greasy substances are applied, which is called dubbing (daubing), or stuffing. The oil used for this purpose is prepared by boiling sheep-skins or doe-skins, in cod oil. This application of grease is often made before the graining board or pommel is employed.

Before waxing, the leather is commonly coloured by rubbing it with a brush dipped into a composition of oil and lamp-black on the flesh side, till it be thoroughly black; it

is then black-sized with a brush or sponge, dried, tallowed with the proper cloth, and slicked upon the flesh with a broad smooth lump of glass; sized again with a sponge; and when dry, again curried as above described.

Currying leather on the hair or grain side, termed black on the grain, is the same in the first operation with that drest on the flesh, till it is scoured. Then the first black is applied to it while wet, by a solution of copperas put upon the grain, after this has been rubbed with a stone; a brush dipped in stale urine is next rubbed on, then an iron slicker is used to make the grain come out as fine as possible. It is now stuffed with oil. When dry, it is seasoned; that is, rubbed over with a brush dipped in copperas water, on the grain, till it be perfectly black. It is next slicked with a good grit-stone, to take out the wrinkles, and smooth the coarse grain. The grain is finally raised with the pommel or graining board, by applying it to the leather in different directions. When thoroughly dry, it is grained again in two or three ways.

Hides intended for covering coaches are shaved nearly as thin as shoe hides, and blacked upon the grain.

CUTLERY. (*Coutellerie* Fr.; *Messerschmidwaare*, Germ.) Three kinds of steel are made use of in the manufacture of different articles of cutlery, viz. common steel, shear steel, and cast steel. Shear steel is exceedingly plastic and tough. All the edge tools which require great tenacity without great hardness are made of it, such as table knives, scythes, plane-irons, &c.

Cast steel is formed by melting blistered steel in covered crucibles, with bottle glass, and pouring it into cast-iron moulds, so as to form it into ingots: these ingots are then taken to the tilt, and drawn into rods of suitable dimensions. No other than cast steel can assume a very fine polish, and hence all the finer articles of cutlery are made of it, such as the best scissors, penknives, razors, &c.

Formerly cast steel could be worked only at a very low heat; it can now be made so as to be welded to iron with the greatest ease. Its use is consequently extended to making very superior kinds of chisels, plane-irons, table-knives, &c.

Forging of table knives. — Two men are generally employed in the forging of table knives; one called the foreman or maker, and the other the striker.

The steel called common steel is employed in making the very common articles; but for the greatest part of table knives which require a surface free from flaws, shear steel and cast steel are generally preferred. That part of the knife termed the blade is first rudely formed and cut off. It is next welded to a rod of iron about $\frac{1}{2}$ inch square, in such a manner as to leave as little of the iron part of the blade exposed as possible. A sufficient quantity of the iron now attached to the blade, is taken off from the rod to form the bolster or shoulder, and the tang.

In order to make the bolster of a given size, and to give it at the same time shape and neatness, it is introduced into a die, and a swage placed upon it; the swage has a few smart blows given it by the striker. This die and swage are, by the workman, called prints.

After the tangs and bolster are finished, the blade is heated a second time, and the foreman gives it its proper anvil finish; this operation is termed smithing. The blade is now heated red hot, and plunged perpendicularly into cold water. By this means it becomes hardened. It requires to be tempered regularly down to a blue colour: in which state it is ready for the grinder.

Mr. Brownill's method of securing the handles upon table knives and forks, is, by lengthening the tangs, so as to pass them completely through the handle, the ends of which are to be tinned after the ordinary mode of tinning iron; and, when passed through the handle, the end of the tang is to be spread by beating, or a small hole drilled through it, and a pin passed to hold it upon the handle. After this, caps of metal, either copper plated, or silver, are to be soldered on the projecting end of the tang, and while the solder is in a fluid state, the cap is to be pressed upon the end of the handle and held there until the solder is fixed, when the whole is to be cooled by being immersed in cold water.

Mr. Thomason's patent improvements consist in the adaptation of steel edges to the blades of gold and silver knives. These steel edges are to be attached to the other metal of whatever quality it may be, of which the knife, &c., is made, by means of solder, in the ordinary mode of effecting that process. After the edge of steel is thus attached to the gold, silver, &c., it is to be ground, polished, and tempered by immersion in cold water, or oil, after being heated. This process being finished, the other parts of the knife are then wrought and ornamented by the engraver or chaser, as usual.

A patent was obtained in 1827, by Mr. Smith of Sheffield, for rolling out knives at one operation.

In the ordinary mode of making knives, a sheet of steel being provided, the blades are cut out of the sheet, and the backs, shoulders, and tangs, of wrought iron, are

attached to the steel blades, by welding at the forge. The knife is then ground to the proper shape, and the blade polished and hardened.

Instead of this welding process, the patentee proposes to make the knives entirely of steel, and to form them by rolling in a heated state between massive rollers; the shoulders or bolsters, and the tangs for the handles being produced by suitable recesses in the peripheries of the rollers; just as railway rails are formed. When the knife is to be made with what is called a scale tang, that is, a broad flat tang, to which the handle is to be attached in two pieces, riveted on the sides of the tang, the rollers are then only to have recesses cut in them, in a direction parallel to the axis for forming the bolster.

The plate of steel having been heated, is to be pressed between the two rollers, by which the blades and the parts for the scale tangs will be pressed out flat and thin, and those parts which pass between the grooves or recess will be left thick or protuberant, forming the bolster for the shoulder of the blade. But if the tangs are to be round in order to be fixed into single handles, then it will be necessary also to form transverse grooves in the rollers, that is, at right angles to those which give shape to the bolsters, the transverse grooves corresponding in length to the length of the intended tang. When the plates of steel have been thus rolled, forming three or more knives in a breadth, the several knives are to be cut out by the ordinary mode of what is called slitting, and the blades and shoulders ground, hardened, and polished in the usual way.

Forks are generally a distinct branch of manufacture from that of knives, and are purchased of the fork makers by the manufacturers of table knives, in a state fit for receiving the handles.

The rods of steel from which the forks are made, are about $\frac{3}{8}$ths of an inch square. The tang and shank of the fork are first roughly formed. The fork is then cut off, leaving at one end about 1 inch of the square part of the steel. This part is afterwards drawn out flat to about the length of the prongs. The shank and tang are now heated, and a proper form given to them by means of a die and swage. The prongs are afterwards formed at one blow by means of the stamp; this machine is very similar to that used in driving piles, but it is worked by one man. It consists of a large anvil fixed in a block of stone nearly on a level with the ground. To this anvil are attached two rods of iron of considerable thickness, fixed 12 inches asunder, perpendicularly to the anvil, and diagonally to each other. These are fastened to the ceiling. The hammer or stamp, about 100 lbs. in weight, having a groove upon either side corresponding to the angles of the upright rods, is made to slide freely through its limited range, being conducted by its two iron supporters. A rope is attached to the hammer, which goes over a pulley on the floor of the room above, and comes down to the person who works the stamp: two corresponding dies are attached, one to the hammer, and the other to the anvil. That part of the fork intended to form the prongs, is heated to a pretty white heat and placed in the lower die, and the hammer containing the other die is made to fall upon it from a height of about 7 or 8 feet. This forms the prongs and the middle part of the fork, leaving a very thin substance of steel between each prong, which is afterwards cut out with an appropriate instrument called a flie-press. The forks are now annealed by surrounding a large mass of them with hot coals, so that the whole shall become red hot. The fire is suffered gradually to die out, and the forks to cool without being disturbed. This process is intended to soften, and by that means to prepare them for filing. The inside of the prongs are then filed, after which they are bent into their proper form and hardened. When hardened, which is effected by heating them red-hot and plunging them into cold water, they are tempered by exposing them to the degree of heat at which grease inflames. See STAMPS.

Penknives are generally forged by a single hand, with the hammer and the anvil simply. The hammer in this trade is generally light, not exceeding $3\frac{1}{2}$ lbs. The breadth of the face, or the striking part, is about one inch; if broader, it would not be convenient for striking so small an object. The principal anvil is about 5 inches, and 10 upon the face, and is provided with a groove into which a smaller anvil is wedged. The smaller anvil is about 2 inches square upon the face. The blade of the knife is first drawn out at the end of the rod of steel, and as much more is cut off along with it as is thought necessary to form the joint. The blade is then taken in a pair of tongs, and heated a second time to finish the joint part, and at the same time to form a temporary tang for the purpose of driving into a small haft used by the grinder. Another heat is taken to give the blade a proper finish. The small recess called the nail hole, used in opening the knife, is made while it is still hot by means of a chisel, which is round on one side, and flat upon the other.

Penknives are hardened by heating the blade red hot, and dipping them into water up to the shoulder. They are tempered by setting them side by side, with the back downwards upon a flat iron plate laid upon the fire, where they are allowed to remain till they are of a brown or purple colour.

The blades of pocket knives, and all that come under the denomination of spring knives, are made in the same way.

The forging of razors is performed by a foreman and striker, as in making table knives.

They are generally made of cast steel. The rods, as they come from the tilt, are about ½ inch broad, and of a thickness sufficient for the back of a razor.

There is nothing peculiar in the tools made use of in forging razors: the anvil is a little rounded at the sides, which affords the opportunity of making the edge thinner, and saves an immense labour to the grinder.

Razors are hardened and tempered in a similar manner to penknives. They are, however, left harder, being only let down to yellow or brown colour.

The forging of scissors is wholly performed by the hammer, and all the sizes are made by a single hand. The anvil of the scissor-maker weighs about 1½ cwt.; it measures, on the face, about 4 by 11 inches. It is provided with two gates or grooves for the reception of various little indented tools termed by the workman bosses: one of these bosses is employed to give proper figure to the shank of the scissors; another for forming that part which has to make the joint; and a third is made use of for giving a proper figure to the upper side of the blade. There is also another anvil placed on the same block, containing two or three tools called beak-irons, each consisting of an upright stem about 6 inches high, at the top of which a horizontal beak projects; one of these beaks is conical, and is used for extending the bow of the scissors; the other is a segment of a cylinder with the round side upwards, containing a recess for giving a proper shape and smoothness to the inside of the bow.

The shank of the scissors is first formed by means of one of the bosses, above described, leaving as much steel at the end as will form the blade. A hole is then punched about ¼ inch in width, a little above the shank. The blade is drawn out and finished, and the scissors separated from the rod a little above the hole. It is heated a third time, and the small hole above mentioned is extended upon the beak-irons so as to form the bow. This finishes the forging of scissors. They are promiscuously made in this way, without any other guide than the eye, having no regard to their being in pairs. They are next annealed for the purpose of filling such parts of them as cannot be ground, and afterwards paired.

The very large scissors are made partly of iron, the blades being of steel.

After the forging, the bow and joints, and such shanks as cannot be ground, are filed. The rivet hole is then bored, through which they are to be screwed or riveted together. This common kind of scissors is only hardened up to the joint. They are tempered down to a purple or blue colour. In this state they are taken to the grinder.

Grinding and polishing of cutlery. — The various processes which come under this denomination are performed by machinery, moving in general by the power of the steam-engine or water-wheel.

Grinding wheels or grinding mills are divided into a number of separate rooms; every room contains six places called troughs; each trough consists of a convenience for running a grindstone and a polisher at the same time, which is generally occupied by a man and a boy.

The business of the grinder is generally divided into three stages, viz. grinding, glazing, and polishing.

The grinding is performed upon stones of various qualities and sizes, depending on the articles to be ground. Those exposing much flat surface, such as saws, fenders, &c., require stones of great diameter, while razors, whose surface is concave, require to be ground upon stones of very small dimensions. Those articles which require a certain temper, which is the case with most cutting instruments, are mostly ground on a wet stone; for which purpose the stone hangs within the iron trough, filled with water to such a height that its surface may just touch the face of the stone.

Glazing is a process following that of grinding; it consists in giving that degree of lustre and smoothness to an article which can be effected by means of emery of various degrees of fineness. The tool on which the glazing is performed, is termed a glazer. It consists of a circular piece of wood, formed of a number of pieces in such a manner that its edge or face may always present the endway of the wood. Were it made otherwise, the contraction of the parts would destroy its circular figure. It is fixed upon an iron axis similar to that of the stone. Some glazers are covered on the face with leather, others with metal, consisting of an alloy of lead and tin; the latter are termed caps. In others, the wooden surface above is made use of. Some of the leather-faced glazers, such as are used for forks, table knives, edge tools, and all the coarser polished articles, are first coated with a solution of glue, and then covered with emery. The surfaces of the others are prepared for use by first turning the face very

true, then filling it with small notches by means of a sharp-ended hammer, and lastly filling up the interstices with a compound of tallow and emery.

The pulley of the glazer is so much less than that of the stone, that its velocity is more than double, having in general a surface-speed of 1,500 feet in a second.

The process of polishing consists in giving the most perfect polish to the different articles. Nothing is subjected to this operation but what is made of cast steel, and has been previously hardened and tempered.

The polisher consists of a circular piece of wood covered with buff leather, the surface of which is covered from time to time, while in use, with the crocus of iron, called also colcothar of vitriol.

The polisher requires to run at a speed much short of that of the stone, or the glazer. Whatever may be its diameter, the surface must not move at a rate exceeding 70 or 80 feet in a second.

CYANATES; saline compounds of cyanic acid with the bases potash, soda, ammonia, baryta, &c. The first is prepared by calcining at a dull red heat, a mixture of ferro-cyanide of potassium (prussiate of potash) and black oxide of manganese. The cyanates have not hitherto been applied to any use in the arts.

CYANHYDRIC ACID; another name for the hydrocyanic or prussic acid. See Prussian Blue and Prussic Acid.

CYANIDES; compounds of cyanogen with the metals; as cyanide of potassium, sodium, barium, calcium, iron, mercury. The last is the only one of importance in a manufacturing point of view, since from it prussic acid is often made.

CYANIDES, FERRO. Double compounds of cyanogen with iron, and of cyanogen with another metal, such as potassium, sodium, barium, &c. The ordinary yellow prussiate of potash has this constitution, and is called the ferro-cyanide.

CYANIDE OF POTASSIUM. This salt, so much used now in the electrotype processes, is prepared, according to Liebig's formula, by mixing 8 parts of pounded prussiate of potash, sharply dried, with 3 parts of pure carbonate of potash, fusing the mixture in an iron crucible, by a moderate red heat, and keeping it so, till the glass or iron rod with which the fluid mass should be occasionally stirred, comes out covered with a white crust. The crucible is then to be removed from the fire; and after the disengaged iron has fallen to the bottom, the supernatant fluid, still obscurely red hot, is to be poured off upon a clean surface of iron or platinum. After concretion and cooling, the white saline mass is to be pounded while hot, and then kept in a well-stopped bottle. It consists of about only 60 per cent. of cyanide of potassium, and 1 of cyanate of potash. For most purposes, and the analysis of ores, the latter ingredient is no ways detrimental. It contains much of other potash salts.

CYANOGEN. A gaseous compound of two prime equivalents of charcoal = 12, and one of azote = 14 = 26; hydrogen being the radix, or 1. It consists of two volumes of vapour of carbon, and one volume of azote, condensed into one volume; and has therefore a density equal to the sum of the weights of these 3 gaseous volumes = 1·815. Cyanogen is readily procured by exposing the cyanide of mercury to a dull red heat in a retort; the gas is evolved and may be collected over mercury. Its smell is very sharp and penetrating; it perceptibly reddens tincture of litmus; it is condensable by pressure at a low temperature into a liquid; and by a still greater degree of cold, it is solidified. When a lighted taper is applied to a mixture of cyanogen and oxygen, an explosion takes place; carbonic acid is formed, and the azote is set at liberty.

For a connected view of the various compounds of cyanogen employed in the arts, see Prussian Blue.

CYDER (*Cidre*, Fr.; *Apfelwein*, Germ.); the vinous fermented juice of the apple. The ancients were acquainted with cyder and perry, as we learn from the following passage of Pliny the naturalist: "Wine is made from the Syrian pod, from pears and apples of every kind." Book xiv. chap. 19. The term cyder or *cidre* in French, at first written *sidre*, is derived from the latin word *sicera*, which denoted all other fermented liquors except grape wine. Cyder seems to have been brought into Normandy by the Moors of Biscay, who had preserved the use of it after coming into that country from Africa. It was afterwards spread through some other provinces of France, whence it was introduced into England, Germany, and Russia. It is supposed that the first growths of Normandy afford still the best specimens of cyder. Devonshire and Herefordshire are the counties of England most famous for this beverage.

Strong and somewhat elevated ground, rather dry, and not exposed to the air of the sea, or to high winds, are the best situations for the growth of the cyder apple. The fruit should be gathered in dry weather. The juice of apples is composed of a great deal of water; a little sugar analogous to that of the grape; a matter capable of causing fermentation with contact of air; a pretty large proportion of mucilage, with malic acid, acetic acid, and an azotized matter in a very small quantity. The seeds contain a bitter substance and a little essential oil; the pure parenchyma or cellular membrane

constitutes not more than two per cent. of the whole. After the apples are gathered, they are left in the barn-loft for fifteen days or upwards to mellow; some of them in this case, however, become soft and brown. This degree of maturation diminishes their mucilage, and developes alcohol and carbonic acid; in consequence of which the cyder suffers no injury. There is always, however, a little loss; and if this ripening goes a little further it is very apt to do harm, notwithstanding the vulgar prejudice of the country people to the contrary. Too much care, indeed, cannot be taken to separate the sound from the spoiled apples; for the latter merely furnish an acid leaven, give a disagreeable taste to the juice, and hinder the cyder from fining, by leaving in it a certain portion of the parenchyma, which the gelatinous matter or the fermentation has diffused through it. Unripe apples should be separated from the ripe also, for they possess too little saccharum to be properly susceptible of the vinous fermentation.

In France, where cyder-making is most scientifically practised, it is prepared by crushing the apples in a mill with revolving edge-stones, turned in a circular stone cistern by one or two horses. When the fruit is half mashed, about one-fifth of its weight of river water is added, or the water of lakes. The latter have been found by experience to be preferable to other water.

In some places a mill composed of two cast-iron fluted cylinders placed parallel to each other under the bottom of a hopper, is employed for crushing the apples. One of the cylinders is turned by a winch, and communicates its motion in the opposite direction by means of the flutings working into each other. Each portion of the fruit must be passed thrice through this rude mill in order to be sufficiently mashed; and the same quantity of water must be added as in the edge stone mill.

After the apples are crushed they are usually put into a large tub or tun for 12 or 24 hours. This steeping aids the separation of the juice, because the fermentative motion which takes place in the mass breaks down the cellular membranes; but there is always a loss of alcohol carried off by the carbonic acid disengaged, while the skins and seeds develope a disagreeable taste in the liquid. The vatting might be suppressed if the apples were so comminuted as to give out their juice more readily. With slight modifications, the process employed in rasping and squeezing the beet-roots might in my opinion be applied with great advantage to the cyder manufacture. See Sugar.

After the vatting, the mashed fruit is carried to the press and put upon a square wicker frame or into a hair bag, sometimes between layers of straw, and exposed stratum super stratum to strong pressure till what is called a cheese or cake is formed. The mass is to be allowed to drain for some time before applying pressure, which ought to be very gradually increased. The juice which exudes with the least pressure affords the best cyder; that which flows towards the end acquires a disagreeable taste from the seeds and the skins. The must is put into casks with large bungholes, where it soon begins to exhibit a tumultuous fermentation. The cask must be completely filled, in order that all the light bodies suspended in the liquid when floated to the top by the carbonic acid may flow over with the froth; this means of clearing cyder is particularly necessary with the weak kinds, because it cannot be expected that these matters in suspension will fall to the bottom of the casks after the motion has ceased. In almost every circumstance besides, when no saccharine matter has been added to the must, that kind of yeast which rises to the top must be separated, lest by precipitation it may excite an acid fermentation in the cyder. The casks are raised upon gawntrees or stillions, in order to place flat tubs below them to receive the liquor which flows over with the froth. At the end of 2 or 3 days for weak cyders, which are to be drunk somewhat sweet, of 6 or 10 days or more for stronger cyders, with variations for the state of the weather, the fermentation will be sufficiently advanced, and the cyder may be racked off into other casks. Spirit puncheons preserve cyder better than any other, but in all cases the casks should be well seasoned and washed. Sometimes a sulphur match is burned in them before introducing the cyder, a precaution to be generally recommended, as it suspends the activity of the fermentation, and prevents the formation of vinegar.

The cyder procured by the first expression is called cyder without water. The cake remaining in the press is taken out, divided into small pieces, and mashed anew, adding about half the weight of water, when the whole is carried back to the press and treated as above described. The liquor thus obtained furnishes a weaker cyder which will not keep, and therefore must be drunk soon.

The cake is once more mashed up with water, and squeezed, when it yields a liquor which may be used instead of water for moistening fresh ground apples.

The processes above described, although they have been long practised, and have therefore the stamp of ancestral wisdom, are extremely defective. Were the apples ground with a proper rotatory rasp which would tear all their cells asunder, and the mash put through the hydraulic press in bags between hurdles of wicker-work, the juice would be obtained in a state of perfection fit to make a cyder superior to many

wines. An experimental process of this kind has been actually executed in France upon a considerable scale, with the best results. The juice had the fine flavour of the apple, was fermented by itself without any previous fermentation in the mash, and afforded an excellent strong cyder which kept well.

When the must of the apples is weak or sour, good cyder cannot be made from it without the addition of some saccharine matter. The syrup into which potato farina is convertible by *diastase* (saccharine ferment), see STARCH and SUGAR, would answer well for enriching poor apple juice.

The value of apples to produce this beverage of good quality is proportionate to the specific gravity of their juice. M. Couverchel has given the following table, illustrative of that proposition: —

Juice of the green renette, queen apple (*reinette verte*)	1094
English renette	1080
Red renette	1072
Musk renette	1069
Fouillet rayé	1064
Orange apple	1063
Renette of Caux	1060
Water	1000

Cyder apples may be distributed into three classes, the sweet, the bitter, and the sour. The second are the best; they afford a denser juice, richer in sugar, which clarifies well, and when fermented keeps a long time; the juice of sweet apples is difficult to clarify; but that of the sour ones makes bad cyder. Late apples are in general to be preferred. With regard to the proper soil for raising apple trees, the reader may consult with advantage an able essay upon "The Cultivation of Orchards and the making of Cyder and Perry," by Frederick Falkner, Esq., in the fourth volume of the Royal Agricultural Journal. He adverts judiciously to the necessity of the presence of alkaline and earthy bases, in the soils of all deciduous trees, and especially of such as produce acid fruits.

In November, 2340 kilogrammes of apples (2½ tons English, nearly) are supposed to afford 1000 litres (220⅓ gallons) of pure cyder; and 600 litres of a small cyder made with the marc mixed with water and pressed. But many persons mix all together, and thus manufacture 1600 litres out of the above weight of fruit. In France, the fermented liquor, as soon as it is clear, is often racked off into casks containing the fumes of burning sulphur, whereby it ceases to ferment, and preserves much of its sugar undecomposed. It is soon afterwards bottled. Average cyder should yield 6 per cent. of alcohol on distillation.

D.

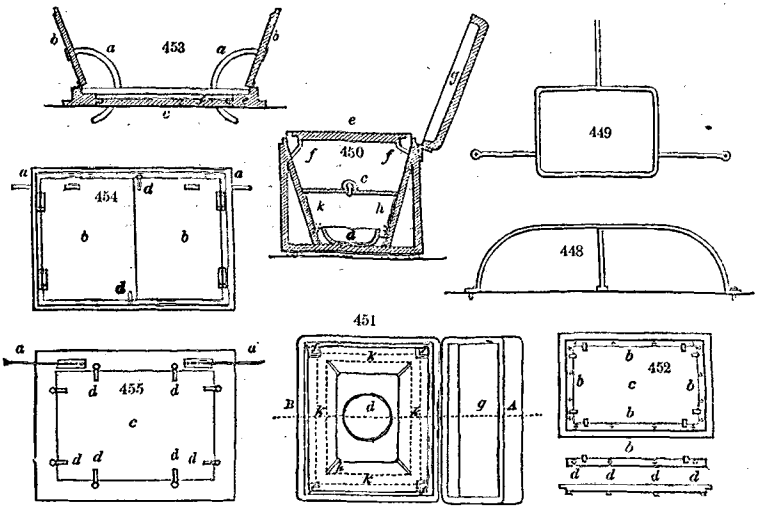
DAGUERREOTYPE. This new and most ingenious invention, for producing pictures by the action of light, is due to M. Daguerre and M. Niepce, two Frenchmen. It was purchased from them by the French government for the benefit of the nation at large; but was made the subject of an exclusive patent in this country by M. Daguerre, as our government never purchases any scientific invention.

The fixation of the images, formed in the focus of the camera obscura, is made on very smooth surfaces of pure silver plated on copper. The process is divided into five operations. 1. The first consists in polishing and cleaning the silver surface, by friction with cotton fleece imbued with olive oil, upon the plate, previously dusted over with very finely-ground dry pumice-stone out of a muslin bag. The hand of the operator should be moved round in circles of various dimensions. The plates should be laid upon a sheet of paper solidly supported. The pumice must be ground to an impalpable powder upon a porphyry slab with water, and then dried. The surface is next to be rubbed with a dossil of cotton, slightly moistened with nitric acid, diluted with sixteen parts of water, by applying the tuft to the mouth of the phial of acid, and inverting it for a moment. Two or three such dossils should be used in succession. The plate is lastly to be sprinkled with pumice powder or Venetian tripoli, and rubbed clean with cotton.

The next step is to heat the plate by placing it in a wire frame (*fig.* 449.), with the silver surface uppermost, over a spirit lamp, meanwhile moving it so as to act equally on every part of the plate. In about five minutes a whitish coating will indicate that this operation is completed. The plate must now be laid upon a flat metal or marble slab to cool it quickly. The white surface is to be brightened by rubbing it with cotton and pumice powder. It must be once more rubbed with the cotton imbued with acid, and afterwards dried by friction with cotton and pumice; avoiding to touch

the plate with the fingers, or with the part of the cotton held in them, or to breathe upon the plate, since spots would thereby be produced. After cleaning with cotton alone, the plate is ready for the next operation.

2. Here the foHowing implements are required: 1. the box represented in *figs.* 450. and 451.; 2. the thin board or frame, *fig.* 452.; four small metallic bands of the same



metals as the plates, also shown in *fig.* 452., a small handle and a box of small nails or tacks, and a phial of iodine.

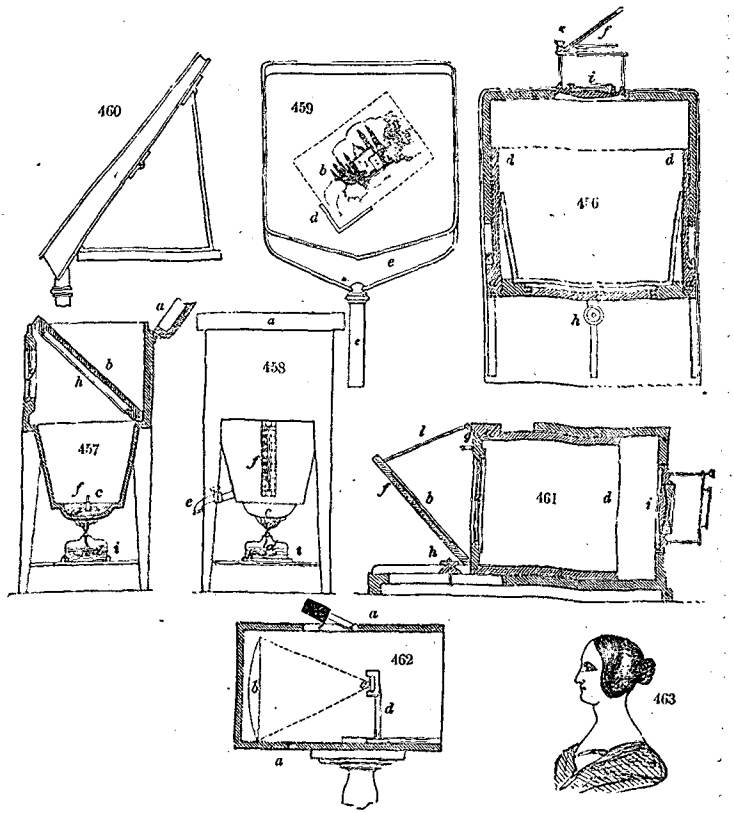
After fixing, by the metallic bands and the small nails, the plate upon the thin board, with the silver uppermost, several particles of iodine are then to be spread in the dish *d*, at the bottom of the box, *figs.* 450. and 451. The thin board with the plate is next placed, with the silver *beneath*, upon small supports at the four corners of the box, and its cover is applied. The plate must be left in this position till the surface of the silver acquires a fine golden hue, caused by the vapours of the iodine rising through the gauze cover of the dish, and condensing upon it; but it should not be allowed to assume a violet tint. The room should be darkened, and no heat should be employed. When the box is in constant use it gets impregnated with iodine, and acts more uniformly and rapidly; but in general states of the atmospheric temperature this operation will be effected in about twenty minutes. If the purple colour be produced, the plate must be repolished, and the whole process repeated.

The plate with its golden hue is to be introduced with its board into the frame, *figs.* 453, 454, 455., which is adapted to the camera obscura. During this transfer the light must not be suffered to strike upon the surface of the plate; on which account, the camera obscura may be lighted briefly with a small wax taper.

3. The plate is now submitted to the third operation, that of the camera obscura, *figs.* 456. and 448.; and with the least possible delay. The action of this machine is obviously quicker the brighter the light which acts upon it; and more correct, according as the focus is previously accurately adjusted to the place of the plate, by moving backwards and forwards a roughened pane of glass, till the focal point be found; and the plate is to be inserted precisely there, see *figs.* 453, 454, 455. This apparatus exactly replaces the ground glass. While the prepared plate is being fastened, the camera must be closed. The darkening shutters, *b b*, of the apparatus are opened by means of the two semicircles *a*, *a*. The plate is now in a proper position to receive and retain the impression of the image of the objects presented the moment that the camera is opened. Experience alone can teach the proper length of time for submitting the plate to the concentrated rays of light; because that time varies with the climate, the seasons, and the time of day. More time should not be allowed to pass than what is necessary for fixing a distinct impression, because the parts meant to be clear would be apt to become clouded.

4. The fourth is the operation with quicksilver, which must follow as soon as possible the completion of the third. Here a phial of quicksilver, a spirit lamp (the apparatus represented in *figs.* 457. and 458.), and a glass funnel with a long neck, are required. The funnel is used for pouring the mercury into the cup *c*, placed in the

bottom of the apparatus, so as to cover the bulb of the thermometer *f*. No day-light must now be admitted, but that of a small taper only should be used by the operator in conducting the process. The board with the plate is to be withdrawn from the



camera, and inserted into the grooves of the blackened board, *b*, *fig.* 457. This black board is laid back into the box at an angle of 45° with the horizon; the prepared metal surface *h* being placed undermost, so that it may be viewed through the side glass, *g*; and the cover, *a*, of the box must be put down gently to prevent any particles of mercury from being thrown about by the agitation of the air. The whole being thus prepared, the spirit-lamp is lighted, and placed under the cup containing the mercury, and left there until the thermometer indicates a temperature of 140° Fahr., when the lamp is to be removed. The heat should in no case be permitted to exceed 167° F.

The impression of the image of nature is now actually made upon the plate; but it is as yet invisible; and it is only after a lapse of several minutes that faint tracings of the objects begin to be seen through the peep-glass by the momentary gleam of a taper. The plate should be left in the box till the thermometer has cooled to 113° F., when it is to be taken out.

After each operation, the interior of the apparatus, and the black board or frame, should be carefully wiped, in order to remove every particle of mercury.

The picture may now be inspected in a feeble light, to see how far the process has succeeded. The plate, freed from the metallic bands, is to be placed in a box, provided with a cover and grooves, to exclude the light, till it is made to undergo the fifth and last operation, which may be done after any convenient interval of time without detriment, provided the plate be kept in the dark. The following articles are now required:—1. strong brine, or a weak solution of hyposulphite of soda; 2. the apparatus represented in *figs.* 459. and 460.; 3. two troughs of tin-plate; 4. a jug of distilled water. The object of this process is to fix the photogenic picture. One of the

troughs is to be filled with brine to the depth of an inch, and the other with pure water, both liquids being heated somewhat under the boiling pitch. The solution of hyposulphite of soda is preferable, and does not need to be warm. The plate is to be first immersed in the pure water for a moment, and transferred immediately to the saline solution, and moved to and fro in it to equalize the action of the liquor. Whenever the yellow tint of the iodine is removed, the plate is to be lifted out by the edges, and dipped straightway in the water-trough. The apparatus of *figs.* 459. and 460. is then brought into use, with a vessel filled with distilled water, hot, but not boiling. The plate, when lifted out of the water-trough, is to be placed immediately on the inclined plane *e*; and without allowing it time to dry, is to be floated over with the hot distilled water from the top, so as to carry off all the saline matter. As the quicksilver which traces the images will not bear touching, the silvered plate should be secured by a cover of glass, made tight at the edges by pasting paper round them.

In *fig.* 451., which is a plan view of the iodine-box apparatus, *c* is an interior cover; *d* is the iodine-dish; *e* is the thin board to which the silvered plate is fixed, as shown at *fig.* 450.; *g* is the cover of the box; *h h* are small rods, at the four corners of the inclined lining, *k*, of the box, to support the lid *c*; *j* is a gauze of wire cloth cover, to diffuse the iodine vapour; *k* is the wooden lining, sloping like a hopper; *d d*, in *fig.* 454., are buttons to fasten the board on the doors; *e* shows the thickness of the frame; *f* is the silvered plate. In *fig.* 461., *a* is the ground glass of the camera; *b* is a mirror inclined about 45° to the horizon, by means of the rod *l*. The image of the object is easily brought into focus by moving forward or backward the sliding-box *d*, in laying hold of it with both hands by the projections *a*, *fig.* 454. When the focus is adjusted, the thumb-screw, *h*, fixes the whole. The mirror is kept closed by two hooks at *f*, which take into small eyes at *g*. The frame and ground glass plate are withdrawn and replaced by the frame carrying the prepared plate, as represented in *fig.* 448., with the shading doors, *b*, open in the camera. These doors and the sliding-box *d* are lined with black velvet. The object glass is achromatic and periscopic, the concave being outside in the camera; its diameter is about 3½ inches, and focus about 13 inches. A diaphragm is placed before the object glass, at 3½ inches from it, and its aperture may be closed by a plate moving in a pivot. This camera reverses the objects from left to right; but this may be obviated by placing a plane mirror on the outside beyond the aperture of the diaphragm, as at *f*, *fig.* 456., where it is fixed by means of a screw, *k*. Loss of light is thereby occasioned.

Fig. 457. is an upright section, and *fig.* 458. a front elevation of the mercurial apparatus. *a*, the cover; *b*, the black board, with grooves to receive the board *h*; *c*, the cup of quicksilver; *d*, the spirit-lamp; *e*, a small cock, through which the quicksilver may be run off, if the apparatus be laid to one side; *f*, the thermometer; *g*, a glass window; *h*, the board bearing the metallic plate; *l*, a stand for the spirit lamp, which is held by the ring *k*, so that its flame may strike the bottom of the cup. The whole of the inside of the apparatus should be blackened and varnished.

Fig. 459. is a front view of the washing apparatus made of tin plate, varnished. The plates, to be washed, are laid on the angular ledge, *d*; *e* is a ledge to conduct the water to the receptacle *c*. *Fig.* 460. is a side view of the washing apparatus. The patent was enrolled in February, 1840. (See *Newton's Journal*, C. S. xvi. 1.)

Mr. Richard Beard having purchased from M. Daguerre a licence to practise his invention above described, received from a foreigner a communication of certain improvements, for which he obtained a patent in June, 1840. The first of these is the substitution of a concave reflecting mirror for the lens in the camera obscura. *Fig.* 462. represents in section a slight wooden box, *a a*, open at the front, opposite to the person sitting for the portrait. In the back part of the box a concave mirror, *b*, is placed, to reflect the rays coming from the person. A small frame, *c*, is fixed to an adjustable pedestal, *d*, which slides in grooves in the bottom of the box, for the purpose of being set at the focal point of the mirror. In this frame, *c*, a polished surface is first to be placed for trial, to receive the image correctly, as observed by the operator, by looking through the opening, *e*, in the top of the box. The prepared silvered plate is now substituted in the exact place for the trial one. The luminous impression being made, the slide, *d*, is withdrawn, and the plate removed; carefully shut up in a box from the light.

The second object of this patent is making the prepared surface more uniform, by passing two plates, with their silvered faces in contact, several times between hardened rollers, annealing them at a low red heat after each passage.

His third object is to use a compound of bromine and iodine, instead of the latter alone, for coating the silver; which increases its sensibility to light, thereby shortening and improving the operation of taking likenesses. He also recommends to use a combination of iodine with nitric acid. Finally, Mr. Beard finds that by placing a screen of any desired colour behind the sitter, the appearance of his Daguerreotype portrait is improved. (*Newton's Journal*, xxiii. 112.)

M. A. F. J. Claudet, who had also purchased a licence from M. Daguerre, obtained a patent in December, 1841, for certain improvements upon the original process. His first object is to give the front of the camera-obscura such an aperture as to admit the largest object glass intended to be used; and of such he provides a series of different dimensions, each attached to its board, that may be fitted by a slide to the front of the camera.

One of the greatest difficulties in the Daguerreotype process was the impossibility of ascertaining the precise moment at which the light had produced, on the prepared plate, the effect requisite for the vapour of mercury to bring out the image. By applying the vapour to the plate while the silver surface is being acted upon by the light, the operator is enabled to see when his picture is complete. Another advantage of this joint operation is, that the effect of the mercury upon those parts of the plate which have been acted upon by the light, are more perfect when caused to take place immediately under the luminous influence. Hence, instead of using the distinct box with the cup of quicksilver, he places a cup containing that metal in the camera obscura, with its spirit-lamp, and exhales the vapours there. When the mercury has risen to the proper temperature, the aperture of the object-glass is thrown open, and the light, reflected from the object to be delineated, is allowed to operate.

He watches the effect through an opening in the side of the camera, where he views the prepared plate by the light of a lantern passing through a piece of red or orange-coloured glass in the (other) side of the camera. Whenever the light and mercury, by their simultaneous action, have produced a good image, the object-glass is covered, and the silver plate, with its picture, removed, in order to be washed, and finished. M. Claudet embellishes his Daguerreotype portraits by placing behind the sitter screens of painted scenery, which furnish pleasing back grounds. He specifies also various kinds of artificial illuminations, to be used in the absence of solar light. (*Newton's Journal*, C. S. xx. 430.)

According to M. Barnard, Daguerre's iodized plate should be exposed for half a minute to the action of chlorine, mixed with a large proportion of common air; whereby it becomes so sensitive, that the pictorial impression is produced in the short space of time necessary for removing and replacing the screen of the camera. The mercury is afterwards employed; as also the hyposulphite wash. Daguerreotype pictures are coloured by dusting over them powders of proper hues, which are immediately washed by passing the plate through water. What remains of the colour after this ablution does not seem in the least to injure the appearance or alter the form of the image. It would seem that those parts of the picture which were at first black, retain, after being washed, a larger proportion of colouring matter than the lighter parts.

Several valuable improvements seem to have been made in Vienna upon the Daguerreotype process; and among others, the mode of using *chloriodine*.

The best form of box for applying the chloriodic vapour is square, with its bottom of plate glass, supported a little above the table by feet, a thumb-screw being one of them, in order to give a certain inclination to the glass plate for spreading the chloriodine over it uniformly. A sheet of white paper being laid beneath the box, enables the operator to see whether the liquid chloriodine is properly distributed. There is a groove round the top of the box, into which the ledge of the lid fits tight. A thermometer is placed in the box.

Voigtland's lenses consist of two achromatic object glasses placed apart; the first nearest the object, having an aperture of 18 lines; the second one of 19 lines; the solar focus of the two is $5\frac{1}{2}$ inches. A system of lenses of so short a focus with so large apertures affords from 11 to 12 times more illumination than Daguerre's original apparatus did. The finest portraits can be produced in the course of from 10 to 30 seconds with this arrangement. Such an apparatus, elegantly made in brass, costs only 120 gulden, or about 10 guineas.

Voigtland has recently made a camera with two object glasses, as above arranged, each having an aperture of 37 lines, and a combined focus of 12 inches. By means of this instrument, portraits $5\frac{1}{2}$ inches in size can be made. The landscapes produced in them are very beautiful. Its price is 144 gulden, about 12 guineas. Along with the above apparatus, a box with a bottom of amalgamated copper is used for applying the vapour of mercury.

By peculiar methods of polishing the silvered copper plate peculiar tones and tints may be given to the picture. The olive oil and pumice powder are indispensable for removing the scratches from the plate and to render its surface uniform. If a delicate blue tone be desired, the plate should be a second time polished with sulphuric ether and washed tripoli; and a third time with dilute nitric acid and Paris red, rubbing the plate lastly with a piece of wash-leather and crocus. But if a brownish black tone be wished for, a like series of operations is to be gone through, only instead of the ether and tripoli, spirit of ammonia and Vienna lime is to be used.

To give the plate the utmost sensibility to light, a film of iodine should be given in the first place. If with dry iodine, this should be strewed, then covered with cotton, and lastly with a sheet of paper, and the plate above the last, but not so as to touch it. This may be done also with a solution of 1 part of iodine in 6 of spirits of wine, put into a saucer, which is laid on the bottom of the box and covered with gauze. The plate is to be removed whenever it has acquired a faint brazen tint. By this means the plate receives the impressions of light so well as to produce good contrasts between the white and the dark places. The application of bromine afterwards causes a rapid reception of the image, and occasions the deep black shades of an object. The best form is *brome* water, made by dissolving the bromine in a little distilled water, and then adding more, when it is wanted, till the solution acquires a straw yellow colour. A delicate thermometer being put into the box, the solution is to be spread uniformly on the glass bottom, the plate being laid on above and covered up, while the time of exposure must be counted by seconds, with a clock or watch. If the temperature be

41°. F.	the time should be	258 seconds.
50°	———	230 —
59°	———	201 —
68°	———	158 —
77°	———	113 —

By attending to these instructions exact results may always be obtained.

A second mode of experimenting is with bromiodine; prepared by dissolving 1 part of bromine in an alcoholic solution of 5 parts of iodine; and diluting this mixture with water, till it acquires the colour of Bavarian beer. The action of this application upon the plate is so rapid as hardly to leave time for consideration. It must be watched every instant till the dark gold yellow tint appears; when it is ready for the camera.

The best time of day for Daguerreotype operations is from an hour after the sun rises till he comes within 45° of the meridian, and not again till he has passed the meridian by 45°. When the sitting is too long, the parts which should be pure white become of a dirty blue tint, and the dark parts become brown. The picture is burnt, so to speak.

Chloride of gold applied to the picture has the effect of fixing and enlivening the tints. A small grate being fixed by a clamp to the edge of a table, the plate is laid upon it with the image uppermost, and overspread evenly with solution of chloride of gold, by means of a fine broad camel hair brush, without letting any drop over the edge. A spirit lamp is now brought under the plate, and moved to and fro till a number of small steam bubbles appear upon the image. The spirit lamp must be immediately withdrawn. The remainder of the chloride solution must be poured back into the phial, to be used on another occasion. It is lastly to be washed and examined. This operation has been repeated three or four times with the happiest effect, of giving fixity and force to the picture. It may then be wiped with cotton without injury.

By dusting various pigment powders from small cotton wool dossils upon the picture, previously coated with an alcoholic solution of copal, and nearly dry, the appearance of a coloured miniature has been very successfully imitated. The varnish must be applied delicately with one stroke of a broad brush of badger hair.*

Daguerreotype Engraving. This new art, patented by M. A. F. J. Claudet on the 21st November, 1843, is established on the following facts. A mixed acid, consisting of water, nitric acid, nitrate of potash, and common salt in certain proportions, being poured upon a Daguerreotype picture, attacks the pure silver, forming a chloride of that metal, but does not affect the white parts, which are produced by the mercury of the picture. This action does not last long. Water of ammonia, containing a little chloride of silver in solution, dissolves the rest of that chloride, which is then washed away, leaving the naked metal to be again attacked, especially with the aid of heat. The metallic surface should have been perfectly purified by means of alcohol and caustic potass. For the rest of the ingenious but complex details, see *Newton's Journal*, C. S. vol. xxv. p. 112.

DAHLINE, the same as Inuline, the fecula obtained from elecampane, analogous in many respects to starch. It is not employed in the arts.

DAMASCUS BLADES, are swords or scymitars, presenting upon their surface a variegated appearance of *watering*, as white, silvery, or black veins, in fine lines, or fillets; fibrous, crossed, interlaced or parallel, &c. They are brought from the East, being fabricated chiefly at Damascus, whence their name. Their excellent quality has become proverbial; for which reason these blades are much sought after by military men, and are high priced. The oriental processes have never been satisfactorily described; but of late years methods have been devised in Europe to imitate the fabric very well.

* See Praktische Anweisung zum Daguerrotypiren, Leipzig. &c. 1843.

Clouet and Hachette pointed out the three following processes for producing Damascus blades: 1., that of *parallel fillets*; 2., that by *torsion*; 3., the *mosaic*. The first, which is still pursued by some French cutlers, consists in scooping out with a graving tool the faces of a piece of stuff composed of thin plates of different kinds of steel. These hollows are by a subsequent operation filled up, and brought to a level with the external faces, upon which they subsequently form tress-like figures. 2. The method of torsion, which is more generally employed at present, consists in forming a bundle of rods or slips of steel, which are welded together into a well-wrought bar, twisted several times round its axis. It is repeatedly forged, and twisted alternately; after which it is slit in the line of its axis, and the two halves are welded with their outsides in contact; by which means their faces will exhibit very various configurations. 3. The mosaic method consists in preparing a bar, as by the torsion plan, and cutting this bar into short pieces of nearly equal length, with which a faggot is formed and welded together; taking care to preserve the sections of each piece at the surface of the blade. In this way, all the variety of the design is displayed, corresponding to each fragment of the cut bar.

The blades of Clouet, independently of their excellent quality, their flexibility, and extreme elasticity, have this advantage over the oriental blades, that they exhibit in the very substance of the metal, designs, letters, inscriptions, and, generally speaking, all kinds of figures which had been delineated beforehand.

Notwithstanding these successful results of Clouet, it was pretty clear that the watered designs of the true Damascus scymitar were essentially different. M. Bréant has at last completely solved this problem. He has demonstrated that the substance of the oriental blades is a cast-steel more highly charged with carbon than our European steels, and in which, by means of a cooling suitably conducted, a crystallization takes place of two distinct combinations of carbon and iron. This separation is the essential condition; for if the melted steel be suddenly cooled in a small crucible or ingot, there is no damascene appearance.

If an excess of carbon be mixed with iron, the whole of the metal will be converted into steel; and the residuary carbon will combine in a new proportion with a portion of the steel so formed. There will be two distinct compounds; namely, pure steel, and carburetted steel or cast-iron. These at first being imperfectly mixed will tend to separate, if while still fluid they be left in a state of repose; and form a crystallization in which the particles of the two compounds will place themselves in the crucible in an order determined by their affinity and density conjoined. If a blade forged out of steel so prepared be immersed in acidulous water, it will display a very distinct damascus appearance; the portions of pure steel becoming black, and those of carburetted steel remaining white, because the acids with difficulty disengage its carbon. The slower such a compound is cooled, the larger the damascus veins will be. Tavernier relates that the steel crucible ingots, like those of wootz, for making the true oriental damascus, come from Golconda, that they are of the size of a halfpenny roll, and when cut in two, form two swords.

Steel combined with manganese forges easily, but it is brittle when cold; it displays however the damascus appearance very strongly.

A mixture of 100 parts of soft iron, and 2 of lamp black, melts as readily as ordinary steel. Several of the best blades which M. Bréant presented to the Société d'Encouragement are the product of this combination. This is an easy way of making cast-steel without previous cementation of the iron. 100 parts of filings of very gray cast-iron, and 100 parts of like filings previously oxidized, produced, by their fusion together, a beautiful damascene steel, fit for forging into white arms, sabres, swords, &c. This compound is remarkable for its elasticity, an essential quality, not possessed by the old Indian steel. The greater the proportion of the oxidized cast-iron, the tougher is the steel. Care should be taken to stir the materials during their fusion, before it is allowed to cool; otherwise they will not afford a homogeneous damasc. If the steel contains much carbon it is difficult to forge, and cannot be drawn out except within a narrow range of temperature. When heated to a red-white it crumbles under the hammer; at a cherry-red it becomes hard and brittle; and as it progressively cools it becomes still more unmalleable. It resembles completely Indian steel, which European blacksmiths cannot forge, because they are ignorant of the suitable temperature for working it. M. Bréant, by studying this point, succeeded in forging fine blades.

Experience has proved that the orbicular veins, called by the workmen *knots* or *thorns* (*ronces*), which are seen upon the finest Eastern scymitars, are the result of the manner of forging them, as well as the method of twisting the Damascus bars. If these be drawn in length, the veins will be longitudinal; if they be spread equally in all directions, the stuff will have a crystalline aspect; if they be made wavy in the two directions, undulated veins will be produced like those in the oriental damascus.

DAMASK is a variegated textile fabric, richly ornamented with figures of flowers,

fruits, landscapes, animals, &c., woven in the loom. and is by far the most rich, elegant, and expensive species of ornamental weaving, tapestry alone excepted. The name is said to be derived from Damascus, where it was anciently made.

Damask belongs to that species of texture which is distinguished by practical men by the name of tweeling, of which it is the richest pattern. The tweel of damask is usually half that of full *satin*, and consequently consists of eight leaves moved either in regular succession or by regular intervals, eight leaves being the smallest number which will admit of alternate tweeling at equal intervals.

In the article CARPET, two representations have been given of the damask draw-loom.

The generic difference of tweeling, when compared with common cloth, consists in the intersections, although uniform and equidistant, being at determinate intervals, and not between the alternate threads. Hence we have specimens of tweeled cloth, where the intersections take place at the third, fourth, fifth, sixth, seventh, eighth, or sixteenth interval only. The threads thus deflecting only from a straight line at intervals, preserve more of their original direction, and a much greater quantity of materials can be combined in an equal space, than in the alternate intersection, where the tortuous deflection, at every interval, keeps them more asunder. On this principle tweeled cloths of three and four leaves are woven for facility of combination alone. The coarser species of ornamented cloths, known by the names of dornock and diaper, usually intersect at the fifth, or half satin interval. The sixth and seventh are rarely used, and the intersection at the eighth is distinguished by the name of satin in common, and of damask in ornamental tweeling. It will further be very obvious, that where the warp and woof cross only at every eighth interval, the two sides of the cloth will present a diversity of appearance; for on one side the longitudinal or warp threads will run parallel from one end of a web to the other, and, on the other, the threads of woof will run also parallel, but in a transverse direction across the cloth, or at right angles to the former. The points of intersection being only at every eighth interval, appear only like points; and in regular tweeling these form the appearance of diagonal lines, inclined at an angle of 45° (or nearly so) to each of the former.

The appearance, therefore, of a piece of common tweeled cloth is very similar to that of two thin boards glued together, with the grain of the upper piece at right angles to that of the under one. That of an ornamental piece of damask may, in the same manner, be very properly assimilated to a piece of veneering, where all the wood is of the same substance and colour, and where the figures assume a diversity of appearance from the ground, merely by the grain of the one being disposed perpendicularly to that of the other. See TEXTILE FABRIC.

From this statement of the principle, it results that the most unlimited variety of figures will be produced, by constructing a loom by which every individual thread of warp may be placed either above or below the woof at every intersection; and to effect this, in boundless variety, is the object of the Jacquard mounting, which see.

The chief seat of this manufacture is probably the town and neighbourhood of Dunfermline, in Fifeshire, and Lisburn and Ardoyne, near Belfast, where it is considered as the staple, having proved a very profitable branch of traffic to the manufacturer, and given employment to many industrious people.

The material used there is chiefly linen; but many have been recently woven of cotton, since the introduction of that article into the manufacture of cloth has become so prevalent. The cotton damasks are considerably cheaper than those of linen, but are not considered either so elegant or durable. The cotton, also, unless frequently bleached, does not preserve the purity of the white colour nearly so well as the linen.

DAMASKEENING; the art of ornamenting iron, steel, &c., by making incisions upon its surface, and filling them up with gold or silver wire; chiefly used in enriching sword blades, guards, and gripes, locks of pistols, &c.

Its name shows the place of its origin, or, at least, the place where it has been practised in the greatest perfection, viz. the city of Damascus, in Syria; though M. Felibien attributes the perfection of the art to his countryman, Cursinet, who wrought under the reign of Henry IV.

Damaskeening is partly mosaic work, partly engraving, and partly carving. As mosaic work, it consists of pieces inlaid; as engraving, the metal is indented, or cut in intaglio; and as carving, gold and silver are wrought into it in *relievo*.

There are two ways of damaskeening; in the first, which is the most beautiful, the artists cut into the metal with a graver, and other tools proper for engraving upon steel, and afterwards fill up the incisions, or notches, with a pretty thick silver or gold wire. In the other, which is only superficial, they content themselves to make hatches, or strokes across the iron, &c., with a cutting knife, such as is used in making small files. As to the first, it is necessary for the gravings or incisions to be made in the

dove-tail form, that the gold or silver wire, which is thrust forcibly into them, may adhere the more strongly. As to the second, which is the more usual, the method is this: — Having heated the steel till it changes to a violet, or blue colour, they hatch it over and across with the knife; then draw the ensign or ornament intended, upon this hatching, with a fine brass point or bodkin. This done, they take fine gold wire, and conducting or chasing it according to the figures already designed, they sink it carefully into the hatches of the metal with a copper tool.

DAMASSIN is a kind of damask, with gold and silver flowers, woven in the warp and woof; or occasionally with silk organzine.

DAMPS, *in mining*, are noxious exhalations, or rather gases, so called from the German *dampf*, vapour. There are two principal kinds of mine gases, the *fire-damp*, or carburetted hydrogen, and the *choke-damp*, or carbonic acid gas. See MINES.

DAPHNINE; the bitter principle of the *Daphne alpina*.

DATOLITE. A mineral composed of silica, lime and boracic acid.

DECANTATION, (Eng. and Fr.; *Abgiessen*, Germ.) is the act of pouring off the clear supernatant fluid from any sediment or deposit. It is much employed in the chemical arts, and is most conveniently effected by a syphon.

DECOCTION, (Eng. and Fr.; *Abkochung*, Germ.) means either the act of boiling a liquid along with some organic substance, or the liquid compound resulting from that act.

DECOMPOSITION, (Eng. and Fr.; *Zersetzung*, Germ.) is the separation of the constituent principles of any compound body. The following table, the results of important researches recently made by M. Persoz, professor of chemistry at Strasburg, shows the order in which decompositions take place among the successive substances.

Nitric Acid.	Muriatic Acid.
Oxide of Magnesium	Oxide of Manganesium
— Silver	— Cobalt
— Cobalt	— Nickel
— Nickel	Protox. of Mercury
Protox. of Cerium	— Cerium
Oxide of Zinc	Oxide of Zinc
Protox. of Manganese	Protox. of Manganese
Oxide of Lead	— Iron
— Cadmium	— Uranium
— Copper	— Copper
— Glucinum	— Tin
— Aluminum	Oxide of Glucinum
— Uranium	— Aluminum
— Chromium	— Uranium
Protox. of Mercury	— Chromium
Oxide of Mercury	— Iron
— Iron	— Tin
— Bismuth	— Bismuth
	— Antimony

By means of the cupric oxide we may separate, 1., the ferric oxide from the manganous oxide; 2., the cobaltic, nickelic, zincic and cerous oxides from the uranic, ferric, chromic, and aluminic oxides; 3., the ferrous oxide from the chromic oxide, when dissolved in the muriatic acid.

In boiling a muriatic solution of the cobaltic, nickelic, and manganous oxides, with the mercuric oxide, the first two oxides alone are precipitated. Alumina separates the cadmic oxide from the bismuthic oxide, the stannous oxide from the stannic oxide, and the stannous oxide from the antimonic acid. The cupric oxide separates also by precipitation, the aluminic, uranic, chromic, titanic, and vanadic oxides from all the oxides which are precipitable in the state of sulphuret by hydrosulphuret of ammonia.

As an example of this mode of analysis —

Dissolve pech-blende in aqua regia, precipitate its copper by sulphuretted hydrogen, boil the liquid along with nitric acid, in order to transform all the uranium into uranic acid. Next boil it along with cupric oxide, which precipitates only the uranic and ferric oxides. Redissolve the precipitate in nitric acid, and boil the solution with mercuric oxide, which does not precipitate the ferric oxide. Finally, separate the copper and the mercury from the uranium, by means of sulphuretted hydrogen. In this process we may substitute plumbic oxide for the cupric oxide, and succeed equally well.

Knowledge, like the above, of the elective affinities and habitudes of chemical bodies, simple and compound, imparts to its possessor an irresistible power over the unions and

disunions of the elements, which he can exercise with certainty in effecting innumerable transformations in the arts.

DECREPITATION, (Eng. and Fr.; *Verknistern*, Germ.) is the crackling noise, attended with the flying asunder of their parts, made by several salts and minerals, when heated. It is caused by the unequal sudden expansion of their substance by the heat. Sulphate of baryta, chloride of sodium, calcareous spar, nitrate of baryta, and many more bodies which contain no water, decrepitate most violently, separating at the natural joints of their crystalline structure. Some chemists have preposterously enough ascribed the phenomenon to the expansion of the combined water into steam. What a specimen of inductive philosophy!

DEFECATION (Eng. and Fr.; *Klaren*, Germ.); the freeing from dregs or impurities.

DEFLAGRATION (Eng. and Fr.; *Verpuffung*, Germ.); the sudden blazing up of a combustible; as of charcoal or sulphur when thrown into melted nitre.

DELPHINIA. The vegeto-alkaline principle of the *Delphinium staphysagria*, or stavesacre. It is poisonous.

DELIQUESCENT (*Zerfliessen*, Germ.) is said of a solid which attracts so much moisture from the air as to become spontaneously soft or liquid; such as potash and muriate of lime.

DEPHLEGMATION is the process by which liquids are deprived of their watery particles. It is applied chiefly to spirituous liquors, and is now nearly obsolete, as involving the alchemistical notion of a peculiar principle called phlegm.

DEPHLOGISTICATED; deprived of phlogiston,—formerly supposed to be the common combustible principle. It is nearly synonymous with oxygenated. The idea originally attached to the word having proceeded from false logic, the word itself should never be used either in science or manufactures.

DEPILATORY. (*Depilatoire*, Fr.; *Enthaarensmittel*, Germ.) Is the name of any substance capable of removing hairs from the human skin without injuring its texture. They act either mechanically or chemically. The first are commonly glutinous plasters formed of pitch and resin, which stick so closely to the part of the skin where they are applied, that when removed, they tear away the hairs with them. This method is more painful, but less dangerous than the other, which consists in the solvent action of a menstruum, so energetic as to penetrate the pores of the skin, and destroy the bulbous roots of the hairs. This is composed either of caustic alkalis, sulphuret of baryta, or arsenical preparations. Certain vegetable juices have also been recommended for the same purpose; as spurge and acacia. The bruised eggs of ants have likewise been prescribed. But the *oriental rusma* yields to nothing in depilatory power. Gadet de Gassincourt has published in the *Dictionnaire des Sciences Medicales* the following recipe for preparing it.

Mix two ounces of quicklime, with half an ounce of orpiment or realgar, (sulphuret of arsenic); boil that mixture in one pound of strong alkaline lye, then try its strength by dipping a feather into it, and when the flue falls off, the *rusma* is quite strong enough. It is applied to the human skin by a momentary friction, followed by washing with warm water. Such a caustic liquid should be used with the greatest circumspection, beginning with it somewhat diluted. A soap is sometimes made with lard and the above ingredients; or soft soap is combined with them; in either case to form a depilatory pommade. Occasionally one ounce of orpiment is taken to eight ounces of quicklime, or two to twelve, or three to fifteen; the last mixture being of course the most active. Its causticity may be tempered by the addition of one-eighth of starch or rye flour, so as to form a soft paste, which being laid upon the hairy spot for a few minutes, usually carries away the hairs with it.

The *rusma* should never be applied but to a small surface at a time, for independently of the risk of corroding the skin, dangerous consequences might ensue from absorption of the arsenic.

DEPOSITION OF METALS. Felted fabrics have been coated with metals of various kinds, by means of electricity, in the following way:—A plate of copper, for example, as a dye or matrix, is coated on one side with a resinous non-conducting varnish, and on the other with graphite or plumbago, and the cloth is strained over it, and cemented to it. The matrix being immersed in a solution of sulphate of copper, and connected with a zinc pole of a galvanic battery; while another plate of copper is immersed in the solution and connected with the copper pole of the battery, the deposition of the metal upon the matrix commences. When the surface of the matrix is covered with a thin film of copper, the depositing metal begins to penetrate the interstices of the cloth, and if the operation is continued sufficiently long, will appear in small globules at the other side. As soon as the required thickness of metal has been deposited, the matrix is removed from the solution, and the cloth separated therefrom. The surface of the metallic coating will be either plain or ornamented, according as the

surface of the matrix is prepared, whether with a raised or sunk pattern. And the metallic deposit may be afterwards gilt or otherwise ornamented. Other details are given in the specification of M. Julius Schatlaender.—*Newton's Journal*, C. S. xxv. 96.

DESICCATING APPARATUS. The useful problem of depriving timber of its moisture has received a complete solution by Messrs. Davison & Symington, who in November, 1843, patented a method of transmitting currents of air highly heated (by an arrangement similar to those employed in the hot blast of iron-smelting), through casks made of green wood, or through chambers in which the deals or planks are piled up. The same means have since been found effective for cleansing old tainted beer tuns, or wine hogsheads, of their fermentative qualities; and hence they are now very generally had recourse to in breweries. A fan or other blowing machine is used for propelling the heated air. Mechanical friction with chains or otherwise is used in conjunction with the ventilating process.

Desiccating System. "When we first noticed this system we instanced its application to the seasoning of beer casks, as the most striking exemplification of its efficacy which then offered itself to our observation; but though we have been fully borne out in our views of the importance of that application, by the subsequent adoption of Messrs. Davison & Symington's plans in some of the largest breweries in the kingdom, this turns out to be, after all, but one of the least of the triumphs which the system has achieved. From the seasoning of casks the patentees have gone on, step by step, till they now undertake seasoning of wood and wooden articles of every description; and give fair promise of benefiting largely, not only every art and manufacture of which wood is an element, but the public at large. We have been obligingly permitted by them to inspect and make extracts from their 'Dry Seasoning Book,' and some of these extracts afford the best possible proofs of the advantages derivable from this desiccating system. They are records of work actually done—not by way of experiment merely, but in the ordinary course of an established and fast increasing trade. Each extract shows, first, the weight of the wood when sent in to be seasoned; next, the daily diminution in weight produced by the desiccating process; and lastly, the total quantity of moisture expelled—moisture which if allowed to remain in the wood could tend only to produce rot and decay. The extracts give also, in the case of planks, the degree of shrinkage in width produced. Some of the results are exceedingly startling. Mahogany is reduced in weight by desiccation 24·4 per cent., and pine planks 34·5. The woods least affected are fir and white deal, which lose 12·50 per cent. The degree of shrinkage produced is still more remarkable; amounting, in both the cases noticed, to not less than three-fourths. It will be observed, moreover, that all these effects are produced in the course of a few days, some ten or twelve at most, while by the ordinary mode of drying they could hardly be accomplished in as many months."—*Mr. Robertson, in his Mechanics' Magazine.*

We need scarcely add that the less moisture there is left in wood, the greater its strength—the more complete its fitness for every purpose to which it can be applied.

DETONATION. See FULMINATING, for the mode of preparing detonating powder for the percussion caps of fire-arms.

DEUTOXIDE literally means the second oxide, but is usually employed to denote a compound containing two atoms or two prime equivalents of oxygen to one or more of a metal. Thus we say deutoxide of copper, and deutoxide of mercury. Berzelius has abbreviated this expression by adopting the principles of the French nomenclature of 1787; according to which the higher stage of oxidizement is characterized by the termination *ic*, and the lower by *ous*, and he writes accordingly cupric and mercuric, to designate the deutoxides of these two metals; cuprous and mercurous to designate their protoxides. I have adopted this nomenclature in the article DECOMPOSITION, and in some other parts of this Dictionary, as being short and sufficiently precise.

DEXTRINE is a matter of a gummy appearance into which the interior substance of the molecules of starch are converted, through the influence of diastase or acids. It derives its name from the circumstance that it turns, more than any other body, the plane of polarization to the right hand. It is white, insipid, without smell, transparent, in thin plates, friable, with a glassy fracture when well dried. It is not altered by the heat of boiling water, but at 280° F. it becomes brown, and acquires the flavour of toasted bread. It is not coloured by iodine, like starch, it does not form mucic acid with the nitric, as common gum does, and it is transformed into grape sugar, when heated along with dilute sulphuric acid or diastase.

Dextrine is much employed by the French pastrycooks and confectioners; it is a good substitute for gum arabic in medicine. For the conversion of potato or other starch into dextrine, by the action of diastase, see BREWING.

This substance has exactly the same chemical composition as starch, consisting of 24 atoms of carbon, 20 of hydrogen, and 10 of oxygen (Dumas); but it is distinguished

from starch by its solubility in cold water, like gum, and not being affected by iodine. British gum, as it is called, or roasted starch, is merely dextrine somewhat discoloured; a substance apparently used for the paste on the Queen's head post office letter stamps. A process discovered by M. Payen, and patented in France by M. Henzé, for making dextrine, consists in moistening one ton of dry starch with water containing 4½ lbs. of strong nitric acid. The starch thus uniformly wetted, is made up into small bricks or loaves, and dried in a stove. It is then rubbed down into a coarse powder, and exposed in a stove-room to a stream of air heated to about 160° F. Being now triturated, sifted, and heated in a stove to about 228° F., it forms a perfect dextrine of a fair colour, because the acid acts as a substitute for the higher heat, used in making the British gum. Such an article makes a fine dressing for muslin and silk goods, and is much employed in French surgery, for making a stiff paste support to the bandages of fractured limbs.

DIAMOND. Since this body is merely a condensed form of carbon, it cannot in a chemical classification be ranked among stones; but as it forms in commerce the most precious of the gems, it claims our first attention in a practical treatise on the arts. Diamonds are distinguishable by a great many peculiar properties, very remarkable and easily recognized, both in their rough state, and when cut and polished. Their most absolute and constant character is a degree of hardness superior to that of every mineral, whence diamonds scratch all other bodies, and are scratched by none. Their peculiar adamantine lustre, not easy to define, but readily distinguishable by the eye from that of every other gem, is their most obvious feature. Their specific gravity is 3·55. Whether rough or polished, diamonds acquire by friction positive electricity, but do not retain it for more than half an hour. The natural form of diamonds is derivable from an octahedron, and they never present crystals having one axis longer than the other. Their structure is very perceptibly lamellar, and therefore, notwithstanding their great hardness, they are brittle, and give way in the line of their cleavage, affording a direct means of arriving at their primitive form,—the regular octahedron.

The diamond possesses either single or double refraction, according to its different crystalline forms; its refractive power on light is far greater than it ought to be in the ratio of its density; the index of refraction being 2·44, whence Newton long ago supposed it to consist of inflammable matter. Its various forms in nature present a circumstance peculiar to this body; its faces are rarely terminated by planes, like most other native crystals, but they are often rounded off, and the edges between them are curved. When these secondary faces are attentively examined with a lens, we remark that they are marked with striæ, sometimes very fine and almost imperceptible, but at others well defined; and that these striæ are parallel to the edges of the octahedron, and consequently to those of the plates that are applied on the primitive faces of this figure.

Diamonds are usually colourless and transparent; when coloured, their ordinary tint verges upon yellow, or smoke yellow, approaching sometimes to blackish-brown. Green diamonds are next to yellow the most common; the blue possess rarely a lively hue, but they are much esteemed in Scotland. The rose or pink diamonds are the most valued of the coloured kind, and exceed sometimes in price the most limpid; though, generally speaking, the latter are the most highly prized.

The geological locality of the diamond seems to be in diluvial gravel, and among conglomerate rocks; consisting principally of fragments of quartz, or rolled pebbles of quartz mixed with ferruginous sand, which compose sometimes hard aggregated masses. This kind of formation is called *cascalho* in Brazil. Its accompanying minerals are few in number, being merely black oxide of iron, micaceous iron ore, pisiform iron ore, fragments of slaty jasper, several varieties of quartz, principally amethyst. In Mr. Heuland's splendid collection there was a Brazilian diamond imbedded in brown iron ore; another in the same, belonging to M. Schuch, librarian to the Crown Princess of Portugal; and in the cabinet of M. Eschwege there is a mass of brown iron ore, containing a diamond in the drusy cavity of a green mineral, conjectured to be arseniate of iron. From these facts it may be inferred with much probability that the matrix or original repository of the diamond of Brazil is brown iron ore, which occurs in beds of slaty quartzose micaceous iron ore, or in beds composed of iron-glance and magnetic iron ore, both of which are apparently subordinate in that country to primitive clay slate.

The loose earth containing diamonds lies always a little way beneath the surface of the soil, towards the lower outlet of broad valleys, rather than upon the ridges of the adjoining hills.

Only two *places* on the earth can be adduced with certainty as diamond mines or rather districts; a portion of the Indian peninsula, and of Brazil.

India has been celebrated from the most remote antiquity as the country of diamonds. Its principal mines are in the kingdoms of Golconda and Visapour, extending from

Cape Comorin to Bengal, at the foot of a chain of mountains called the *Orixa*, which appear to belong to the trap rock formation. In all the Indian diamond soils, these gems are so dispersed, that they are rarely found directly, even in searching the richest spots, because they are enveloped in an earthy crust, which must be removed before they can be seen. The stony matter is therefore broken into pieces, and is then, as well as the looser earth, washed in basins scooped out on purpose. The gravel thus washed is collected, spread out on a smooth piece of ground, and left to dry. The diamonds are now recognized by their sparkling in the sun, and are picked out from the stone.

The diamond mines of Brazil were discovered in 1728, in the district of Serro-do-Frio. The ground in which they are imbedded has the most perfect resemblance to that of the East Indies, where the diamonds occur. It is a solid or friable conglomerate, consisting chiefly of a ferruginous sand, which encloses fragments of various magnitude of yellow and bluish quartz, of schistose jasper, and grains of gold disseminated with oligist iron ore,—all mineral matters different from those that constitute the neighbouring mountains; this conglomerate, or species of pudding-stone, almost always superficial, occurs sometimes at a considerable height on the mountainous table-land. The most celebrated diamond mine is that of Mandarga, on the Jigitonhonha, in the district of Serro-do-Frio to the north of Rio-Janeiro. The river Jigitonhonha, three times broader than the Seine at Paris, and from 3 to 9 feet deep, is made nearly dry, by drawing the waters off with sluices at a certain season; and the *cascalho*, or diamond gravel, is removed from the channel by various mechanical means, to be washed elsewhere at leisure. This cascalho, the same as the matrix of the gold mines, is collected in the dry season, to be searched into during the rainy; for which purpose it is formed into little mounds of 15 or 16 tons weight each. The washing is carried on beneath an oblong shed, by means of a stream of water admitted in determinate quantities into boxes containing the cascalho. A negro washer is attached to each box; inspectors are placed at regular distances on elevated stools, and whenever a negro has found a diamond, he rises up and exhibits it. If it weighs 17½ carats, he receives his liberty. Many precautions are taken to prevent the negroes from secreting the diamonds. Each squad of workmen consists of 200 negroes, with a surgeon and an almoner or priest.

The flat lands on either side of the river are equally rich in diamonds over their whole surface, so that it becomes very easy to estimate what a piece of ground not yet washed may produce.

It is said that the diamonds surrounded with a greenish crust are of the *first* water, or are the most limpid when cut. The diamonds received in the different mines of the district, are deposited once a month in the treasury of Tejuco; and the amount of what was thus delivered from 1801 to 1806, may be estimated at about 18 or 19 thousand carats *per annum*.

On the banks of the torrent called Rio-Pardo, there is another mine of diamonds. The ground presents a great many friable rocks of pudding-stone, distributed in irregular strata. It is chiefly in the bed of this stream, that masses of cascalho occur, peculiarly rich in diamonds. They are much esteemed, particularly those of a greenish-blue colour. The ores that accompany the diamond at Rio-Pardo differ somewhat from those of the washing grounds of Mandanga, for they contain no pisiform iron ore; but a great many pebbles of slaty jasper. This table land seems to be very high, probably not less than 5,500 feet above the level of the sea.

Tocaya, a principal village of Minas-Novas, is 34 leagues to the north-east of Tejuco, in an acute angle of the confluence of the Jigitonhonha and the Rio-Grande. In the bed of the streamlets which fall westward into the Jigitonhonha, those rolled white topazes are found which are known under the name of *minas-novas* with *blue topazes*, and aquamarine beryls. In the same country are found the beautiful cymophanes or chrysoberyls so much prized in Brazil. And it is from the cantons of Indaia and Abaite that the largest diamonds of Brazil come; yet they have not so pure a water as those of the district of Serro-do-Frio, but incline a little to the lemon yellow.

Diamonds are said to come also from the interior of the island of Borneo, on the banks of the river Succadan, and from the peninsula of Malacca.

It is known that many minerals become phosphorescent by heat, or exposure to the sun's light. Diamonds possess this property, but all not in equal degree, and certain precautions must be observed to make it manifest. Diamonds need to be exposed to the sunbeam for a certain time, in order to become self-luminous; or to the blue rays of the prismatic spectrum, which augment still more the faculty of shining in the dark. Diamonds susceptible of phosphorescence exhibit it either after a heat not raised to redness, or the electric discharge. They possess not only a great refractive power in the mean ray of light, but a high dispersive agency, which enables them to throw out the most varied and vivid colours in multiplied directions.

Louis de Berquem discovered in 1476, the art of cutting diamonds by rubbing them

against one another, and of polishing them with their own powder. These operations may be abridged by two methods: 1. by availing ourselves of the direction of the laminæ of the diamond to split them in that direction, and thus to produce several facets. This process is called cleaving the diamond. Some, which appear to be *macle* crystals, resist this mechanical division, and are called *diamonds of nature*. 2. by sawing the diamonds by means of a very delicate wire, coated with diamond powder.

Diamonds take precedence of every gem for the purpose of dress and decoration; and hence the price attached to those of a pure water increases in so rapid a proportion, that, beyond a certain term, there is no rule of commercial valuation. The largest diamond that is known seems to be that of the Rajah of Mattan, in the East Indies. It was of the purest water, and weighs 367 carats, or at the rate of 4 grains to a carat, upwards of 3 ounces troy. It is shaped like an egg, with an indented hollow near the smaller end; it was discovered at Landak about 100 years ago; and though the possession of it has cost several wars, it remained in the Mattan family for 90 years. A governor of Batavia, after ascertaining the qualities of the gem, wished to be the purchaser, and offered 150,000 dollars for it, besides two war brigs with their guns and ammunition, together with a certain number of great guns, and a quantity of powder and shot. But this diamond possessed such celebrity in India, being regarded as a talisman involving the fortunes of the Rajah and his family, that he refused to part with it at any price.

The Mogul diamond passed into the possession of the ruling family of Kabul, as has been invariably affirmed by the members of that family, and by the jewellers of Delhi and Kabul. It has been by both parties identified with the great diamond, now known under the name of the Koh-i-Noor, or *mountain of light*, — which was displayed by its present proprietor, her Majesty the Queen, at the recent Great Exhibition. It is now being properly cut by skilful Dutch artists, under the charge of Messrs. Garrard, jewellers in London, in order to bring out all its lustre, and remove some superficial specks or clouds. The weight of it has been of old variously stated.

The diamond possessed in the time of the traveller Tavernier, by the emperor of Mogul, a kingdom now no more, weighed 279 carats, and was reckoned worth upwards of 400,000*l.* sterling. It was said to have lost the half of its original weight in the cutting. After these prodigious gems, the next are: — 1. That of the emperor of Russia, bought by the late empress Catherine, which weighs 193 carats. It is said to be of the size of a pigeon's egg, and to have been bought for 90,000*l.*, besides an annuity to the Greek merchant of 4,000*l.* It is reported that the above diamond formed one of the eyes of the famous statue of Sherigan, in the temple of Brama, and that a French grenadier, who had deserted into the Malabar service, found the means of robbing the pagoda of this precious gem, and escaped with it to Madras, where he disposed of it to a ship captain for 2,000*l.*, who resold it to a Jew for 12,000*l.* From him it was transferred for a large sum to the Greek merchant. 2. That of the emperor of Austria, which weighs 139 carats, and has a slightly yellowish hue. It has, however, been valued at 100,000*l.* 3. That of the French State, called the Regent or Pitt diamond, remarkable for its form and its perfect limpidity. Although it weighs only 136 carats, its fine qualities have caused it to be valued at 160,000*l.* though it cost only 100,000*l.*

The largest diamond furnished by Brazil, now in possession of the Crown of Portugal, weighs, according to the highest estimates, 120 carats. It was found in the streamlet of Abaïte, in a clay-slate district.

The diamonds possessed of no extraordinary magnitude, but of a good form and a pure water, may be valued by a certain standard rule. In a brilliant, or rose-diamond of regular proportions, so much is cut away that the weight of the polished gem does not exceed one-half the weight of the diamond in the rough state; whence the value of a cut diamond is esteemed equal to that of a similar rough diamond of double weight, exclusive of the cost of workmanship. The weight and value of diamonds is reckoned by carats of 4 grains each; and the comparative value of two diamonds of equal quality but different weights, is as the squares of these weights respectively. The average price of rough diamonds that are worth working, is about 2*l.* for one of a single carat; but as a polished diamond of one carat must have taken one of two carats, its price in the rough state is double the square of 2*l.*, or 8*l.* Therefore, to estimate the value of a wrought diamond, ascertain its weight in carats, double that weight, and multiply the square of this product by 2*l.*

Hence, a wrought diamond of

1 carat	is worth	£ 8
2	—	32
3	—	72
4	—	128
5	—	200
6	—	288

			£
of	7 carats	is worth	392
	8	—	512
	9	—	612
	10	—	800
	20	—	3200,

beyond which weight the prices can no longer rise in this geometrical progression, from the small number of purchasers of such expensive toys. A very trifling spot or flaw of any kind lowers exceedingly the commercial value of a diamond.

Diamonds are used not only as decorative gems, but, for more useful purposes, as for cutting glass by the glazier, and all kinds of hard stones by the lapidary.

On the structure of the glazier's diamond we possess some very interesting observations and reflections by Dr. Wollaston. He remarks, that the hardest substances brought to a sharp point scratch glass, indeed, but do not cut it, and that diamonds alone possessed that property; which he ascribes to the peculiarity of its crystallization in rounded faces, and curvilinear edges. For glass-cutting, those rough diamonds are always selected which are sharply crystallized, hence called diamond sparks; but cut diamonds are never used. The inclination to be given to a set diamond in cutting glass is comprised within very narrow limits; and it ought, moreover, to be moved in the direction of one of its angles. The curvilinear edge adjoining the curved faces, entering as a wedge into the furrow opened up by itself, thus tends to separate the parts of the glass; and in order that the crack which causes the separation of the vitreous particles may take place, the diamond must be held almost perpendicular to the surface of the glass. The Doctor proved this theory by an experiment. If, by suitable cutting with the wheel, we make the edges of a spinel ruby, or corundum-telesie (sapphire) curvilinear, and the adjacent faces curved, these stones will cut glass as well as a glazier's diamond, but being less hard than it, they will not preserve this property so long. He found that upon giving the surface of even a fragment of flint the same shape as that of the cutting diamond, it acquired the same property; but, from its relative softness, was of little duration. The depth to which the fissure caused by the glazier's diamond penetrates does not seem to exceed the two-hundredth of an inch.

I shall here introduce Mr. Milburn's valuable observations on the choice of rough diamonds, as published in his work on *Oriental Commerce*.

The colour should be perfectly crystalline, resembling a drop of clear spring water, in the middle of which you will perceive a strong light, playing with a great deal of spirit. If the coat be smooth and bright, with a little tincture of green in it, it is not the worse, and seldom proves bad, but if there is a mixture of yellow with green, then beware of it; it is a soft greasy stone, and will prove bad.

If the stone has a rough coat, so that you can hardly see through it, and the coat be white and look as if it were rough by art, and clear of flaws or veins, and no blemish cast in the body of the stone, (which may be discovered by holding it against the light) the stone will prove good.

It often happens that a stone will appear of a reddish hue on the outward coat, not unlike the colour of rusty iron, yet by looking through it against the light, you may observe the heart of the stone to be white (and if there be any black spots, or flaws, or veins in it, they may be discovered by a true eye, although the coat of the stone be the same), and such stones are generally good and clear.

If a diamond appears of a greenish bright coat, resembling a piece of green glass, inclining to black, it generally proves hard, and seldom bad; such stones have been known to have been of the first water, and seldom worse than the second; but if any tincture of yellow seems to be mixed with it, you may depend on its being a very bad stone.

All stones of a milky cast, whether the coat be bright or dull, if ever so little inclining to a bluish cast, are naturally soft, and in danger of being flawed in the cutting; though they should have the good fortune to escape, yet they will prove dead and milky, and turn to no account.

All diamonds of cinnamon colour are dubious; but if of a bright coat mixed with a little green, then they are certainly bad, and are accounted among the worst of colours. You will meet with a great many diamonds of a rough cinnamon-coloured coat, opaque: this sort is generally very hard, and, when cut, contain a great deal of life and spirit; but the colour is very uncertain; it is sometimes white, sometimes brown, and sometimes of a fine yellow. Rough diamonds are frequently *beamy*, that is look fair to the eye, yet are so full of veins to the centre, that no art or labour can polish them. A good diamond should never contain small spots of a white or gray colour of a nebulous form; it should be free from small reddish and brownish grains, that sometimes occur on their surface, or in their interior. A good diamond should split readily in the direction of the cleavage; it sometimes happens, however, that the folia are curved, as is

the case in twin crystals. When this happens, the stone does not readily cut and polish, and is therefore of inferior value.

In the cut and polished gem, the thickness must always bear a certain proportion to the breadth. It must not be too thin nor thick; for, when too thin, it loses much of its fire, and appears not unlike glass.

The term *carat* is said to be derived from the name of a bean, the produce of a species of *erythina*, a native of the district of Shangallas, in Africa, a famous mart of gold-dust. The tree is called *kuara*, a word signifying sun in the language of the country; because it bears flowers and fruit of a flame colour. As the dry seeds of this pod are always of nearly uniform weight, the savages have used them from time immemorial to weigh gold. The beans were transported into India, at an ancient period, and have been long employed there for weighing diamonds. The carat of the civilized world is, in fact, an imaginary weight, consisting of 4 nominal grains, a little lighter than 4 grains troy (*poids de marc*); it requires 74 carat grains and $\frac{1}{16}$ to equipoise 72 of the other.

In valuing a cut diamond, we must reckon that one half of its weight has been lost in the lapidary's hands; whence its weight in this state should be doubled before we calculate its price by the general rule for estimating diamonds. The French multiply by 48 the square of this weight, and they call the product in francs the value of the diamond. Thus, for example, a cut diamond of 10 carats would be worth $(10 \times 2)^2 \times 48 = 19{,}200$ francs, or 768*l.*, allowing only 25 francs to the pound sterling.

The diamond mines of Brazil have brought to its government, from the year 1730 till 1814, 3,023,000 carats; being at the average rate annually of 36,000 carats, or a little more than 16 libs. weight. They have not been so productive in the latter years of that period; for, according to Mr. Mawe, between 1801 and 1806, only 115,675 carats were obtained, being 19,279 a year. The actual expenses incurred by the government, during this interval, was 4,419,700 francs: and deducting the production in gold from the washings of the diamond gravel, or *cascalho*, it is found that the rough diamonds cost in exploration, per carat, 38 francs 20 c., or nearly 31*s.* British money. The contraband is supposed to amount to one third of the above legitimate trade. Brazil is almost the only country where diamonds are mined at the present day; it sends annually to Europe from 25 to 30 thousand carats, or from 10 to 16¼ libs.

DIAMONDS, *cutting of.* Although the diamond is the hardest of all known substances, yet it may be split by a steel tool, provided a blow be applied; but this requires a perfect knowledge of the structure, because it will only yield to such means in certain directions. This circumstance prevents the workman from forming facettes or planes generally, by the process of splitting; he is therefore obliged to resort to the process of abrasion, which is technically called cutting. The process of cutting is effected by fixing the diamond to be cut on the end of a stick, or handle, in a small ball of cement, that part which is to be reduced being left to project. Another diamond is also fixed in a similar manner; and the two stones being rubbed against each other with considerable force, they are mutually abraded, flat surfaces, or facettes, being thereby produced. Other facettes are formed by shifting the diamonds into fresh positions in the cement, and when a sufficient number are produced, they are fit for polishing. The stones, when cut, are fixed for this purpose, by imbedding them in soft solder, contained in a small copper cup, the part, or facette, to be polished, being left to protrude.

A flat circular plate of cast-iron is then charged with the powder produced during the abrasion of the diamonds; and by this means a tool is formed which is capable of producing the exquisite lustre so much admired on a finely-polished gem. Those diamonds that are unfit for working on account of the imperfection of their lustre or colour, are sold, for various purposes, under the technical name of Bort. Stones of this kind are frequently broken in a steel mortar, by repeated blows, until they are reduced to a fine powder, which is used to charge metal plates of various kinds, for the use of jewellers, lapidaries, and others. Bort, in this state of preparation, is incapable of polishing any gems; but it is used to produce flat surfaces on rubies and other precious stones.

Fine drills are made of small splinters of bort, which are used for drilling small holes in rubies, and other hard stones, for the use of watch-jewellers, gold and silver wire-drawers, and others, who require very fine holes drilled in such substances. These drills are also used to pierce holes in china, where rivets are to be inserted; also for piercing holes in artificial enamel teeth, or any vitreous substances, however hard.

DIAMOND DUST. The demand for diamond dust within a few years has increased very materially, on account of the increased demand for all articles that are wrought by it, such as cameos, intaglios, &c. Recently there has been a discovery made of the peculiar power of diamond dust upon steel; it gives the finest edge to all

kinds of cutlery, and threatens to displace the hone of Hungary. It is well known that in cutting a diamond, (the hardest substance in nature,) the dust is placed on the teeth of the saw — to which it adheres, and thus prevents the instrument from making its way through the gem. To this dust, too, is to be attributed solely the power of man to make brilliants from rough diamonds; from the dust is obtained the perfection of the geometrical symmetry, which is one of the chief beauties of the mineral, and also that adamantine polish, which nothing can injure or affect, save a substance of its own nature.

DIAMOND MICROSCOPES were first suggested by Dr. Goring, and have been well executed by Mr. Pritchard. Previous to grinding a diamond into a spherical figure, it should be ground flat and parallel upon both sides, that by looking through it, as opticians try flint glass, we may see whether it has a double or triple refractive power, as many have, which would render it useless as a lens. Among the 14 different crystalline forms of the diamond, probably the octahedron and the cube are the only ones that will give a single vision. It will, in many cases, be advisable to grind diamond lenses plano-convex, both because this figure gives a low spherical aberration, and because it saves the trouble of grinding one side of the gem. A concave tool of cast iron, paved with diamond powder, hammered into it by a hardened steel punch, was employed by Mr. Pritchard. This ingenious artist succeeded in completing a double convex of equal radii, of about $\frac{1}{25}$ of an inch focus, bearing an aperture of $\frac{1}{30}$ of an inch with distinctness upon opaque objects, and its entire diameter upon transparent ones. This lens gives vision with a trifling chromatic aberration; in other respects, like Dr. Goring's Amician reflector, but without its darkness, its light is said to be superior to that of any compound microscope whatever, acting with the same power, and the same angle of aperture. The advantage of seeing an object without *aberration* by the interposition of only a single magnifier, instead of looking at a picture of it with an eye-glass, is evident. We thus have a simple direct view, whereby we shall see more accurately and minutely the real texture of objects.

DIAPER, is the name of a kind of cloth, used chiefly for table linen. It is known among the French by the name of *toile fourré*, and is ornamented with the most extensive figures of any kind of tweeled cloth, excepting damask. The mounting of a loom for working diaper is, in principle, much the same as a draw-loom, but the figures being less extensive, the mounting is more simple, and is wrought entirely by the weaver, without the aid of any other person. As tweeled cloths, of any number of leaves, are only interwoven at those intervals when one of the leaves is raised, the woof above, and the warp below, is kept floating or flushed, until the intersection takes place. Of consequence, the floating yarn above appears across the fabric, and that below longitudinally. This property of tweeled cloths is applied to form the ornamental figures of all kinds of tweeled goods, merely by reversing the floating yarn when necessary. In the simpler patterns, this is effected by a few additional leaves of treddles; but when the range of pattern becomes too great to render this convenient, an apparatus called a *back harness* is employed, and the cloth woven with this mounting is called diaper. Diapers are generally five-leaf tweels, that is to say, every warp floats under four threads of woof, and is raised, and of course interwoven with the fifth. This is done either successively, forming diagonals at 45° upon the cloth, or by intervals of two threads, which is called the broken tweel. The latter is generally, if not universally, adopted in the manufacture of diaper. The reason of preferring the broken to the regular tweel, where ornaments are to be formed, is very obvious. The whole depending upon reversed flushing to give the appearance of oblique or diagonal lines through either, would destroy much of the effect, and materially injure the beauty of the fabric. The broken tweel, on the contrary, restores to the tweeled cloth a great similarity of appearance to plain, or alternately interwoven fabrics, and at the same time preserves the facility of producing ornaments by reversing the flushing. The simplest kinds of reversed tweels will be found described under TEXTILE FABRICS.

DIASTASE. This curious substance, extracted by water from crushed malt, and precipitated from that infusion by alcohol, as is described under FERMENTATION, has been made the subject of new researches by M. Guerin Varry. The conclusions deducible from his interesting experiments are the following: —

1. One part of diastase, dissolved in 30 parts of cold water, put with 408 parts of potato starch out of contact of air, did not exercise the slightest action upon this substance in the course of 63 days, under a temperature varying from 68° to 79° Fahr.

2. Two parts of diastase do not in the course of an hour cause the globules of three parts of starch to burst, at a temperature approaching very nearly to that of the hot water which bursts them into a paste. It follows that diastase acts no part in the process of germination, towards eliminating the teguments of the starch, or transforming its interior portion into sugar, and a gummy matter assimilated by plants.

3. Diastase liquefies and saccharifies the paste of starch without absorption or disengagement of gas; a reaction which takes place equally in vacuo as in the open air.

4. 100 parts of starch made into a paste with 39 times their weight of water, mixed with 6·13 parts of diastase dissolved in 40 parts of water, and kept for an hour between 140° and 149° Fahr., afforded 86·91 parts of sugar.

5. A paste containing 100 parts of starch, and 1393 parts of water, put in contact with 12·25 parts of diastase dissolved in 367 parts of cold water, having been maintained at 68° Fahr. during 24 hours, produced 77·64 parts of sugar.

6. The preceding experiment, repeated at the temperature of melting ice, afforded at the end of 2 hours, 11·82 parts of sugar.

7. The most favourable proportions and circumstances for the production of a great quantity of sugar, are a slight excess of diastase or barley malt, (at least 25 per cent. of the latter), about 50 parts of water to one of starch, and a temperature between 140° and 149° Fahr. It is of the greatest consequence for the saccharification to take place as speedily as possible, so that the sugar produced may not be left in contact with much gummy matter (*dextrine*), in which case the diastase will not convert the latter into sugar. In fact, the liquefaction and saccharification should proceed simultaneously.

8. The sugar of starch prepared either with diastase, or sulphuric acid, crystallizes in cauliflowers, or in prisms with rhomboidal facets. It has the same composition as sugar of grapes.

9. Diastase even in excess does not saccharify the gummy matter dissolved in the water along with the starch-sugar, but when the gum is insulated, it is convertible almost entirely into sugar.

10. Gum arabic, cane sugar, and beer yeast, suffer no change from diastase.

11. A watery solution of diastase readily decomposes on keeping, either in contact or out of contact of air.

12. When starch-sugar, whether obtained by means of diastase or sulphuric acid, is submitted to the spirituous fermentation, the sum of the weights of the alcohol, carbonic acid, and water of crystallization of the sugar, is less than the weight of the sugar by about 3½ per cent. This difference proceeds in a great measure from the formation of some acetic acid, lactic acid, volatile oil, and probably some other unknown products in the act of fermentation.

DIDYM. A new metal, found in oxide of cerium, and so called as being associated in that ore as a *twin* brother of *lanthanum*.

DIES FOR STAMPING, (*Coins*, Fr.; *Münzstampeln*, Germ.) The first circumstance that claims particular attention in the manufacture of dies, is the selection of the best kind of steel for the purpose, and this must in some measure be left to the experience of the die-forger, who, if well skilled in his art, will be able to form a tolerably correct judgment of the fitness of the metal for the purpose, by the manner in which it works upon the anvil. It should be rather fine-grained than otherwise, and above all things perfectly even and uniform in its texture, and free from spots and patches finer or coarser than the general mass. But the very fine and uniform steel with a silky fracture, which is so much esteemed for some of the purposes of cutlery, is unfit for our present purpose, from the extreme facility with which it acquires great hardness by pressure, and its liability to cracks and flaws. The very coarse-grained, or highly crystalline steel, is also equally objectionable; it acquires fissures under the die-press, and seldom admits of being equally and properly hardened. The object, therefore, is to select a steel of a medium quality as to fineness of texture, not easily acted upon by dilute sulphuric acid, and exhibiting an uniform texture when its surface is washed over with a little aquafortis, by which its freedom from pins of iron, and other irregularities of composition, is sufficiently indicated.

The best kind of steel being thus selected, and properly forged at a high heat into the rough die, it is softened by very careful annealing, and in that state, having been smoothed externally, and brought to a table in the turning lathe, it is delivered to the engraver.

The process of annealing the die consists in heating it to a bright cherry red, and suffering it to cool gradually, which is best effected by bedding it in a crucible or iron pot of coarsely-powdered charcoal, that of animal substances being generally preferred. In this operation it is sometimes supposed that the die, or at least its superficial parts, becomes super-carbonized, or highly-converted steel, as it is sometimes called; but experience does not justify such an opinion, and I believe the composition of the die is scarcely, certainly not materially, affected by the process, for it does not remain long enough in the fire for the purpose.

The engraver usually commences his labours by working out the device with small steel tools, in intaglio; he rarely begins in relief (though this is sometimes done); and having ultimately completed his design, and satisfied himself of its general effect and

correctness, by impressions in clay, and dabs, or casts in type metal, the die is ready for the important operation of hardening, which, from various causes, a few of which I shall enumerate, is a process of much risk and difficulty; for should any accident now occur, the labour of many months may be seriously injured, or even rendered quite useless.

The process of hardening soft steel is in itself very simple, though not very easily explained upon mechanical or chemical principles. We know by experience that it is a property of this highly valuable substance to become excessively hard, if heated and suddenly cooled; if, therefore, we heat a bar of soft malleable and ductile steel red hot, and then suddenly quench it in a large quantity of cold water, it not only becomes hard, but fragile and brittle. But as a die is a mass of steel of considerable dimensions, this hardening is an operation attended by many and peculiar difficulties, more especially as we have at the same time to attend to the careful preservation of the engraving. This is effected by covering the engraved face of the die with a protecting face, composed of fixed oil of any kind, thickened with powdered charcoal: some persons add pipe-clay, others use a pulp of garlic, but pure lamp-black and linseed oil answer the purpose perfectly. This is thinly spread upon the work of the die, which, if requisite, may be further defended by an iron ring; the die is then placed with its face downwards in a crucible, and completely surrounded by powdered charcoal. It is heated to a suitable temperature, that is, about cherry red, and in that state is taken out with proper tongs, and plunged into a body of cold water, of such magnitude as not to become materially increased in temperature; here it is rapidly moved about, until all noise ceases, and then left in the water till quite cool. In this process it should produce a bubbling and hissing noise; if it pipes and sings, we may generally apprehend a crack or fissure.

No process has been found to answer better than the above simple and common mode of hardening dies, though others have had repeated and fair trials. It has been proposed to keep up currents and eddies of cold water in the hardening cistern, by means of delivery-pipes, coming from a height; and to subject the hot die, with its face uppermost, to a sudden and copious current of water, let fall upon it from a large pipe, supplied from a high reservoir; but these means have not in any way proved more successful, either in saving the die, or in giving it any good qualities. It will be recollected, from the form of the die, that it is necessarily only, as it were, case-hardened, the hardest strata being outside, and the softer ones within, which envelope a core, something in the manner of the successive coats of an onion; an arrangement which we sometimes have an opportunity of seeing displayed in dies which have been smashed by a violent blow.

The hardening having been effected, and the die being for the time safe, some further steps may be taken for its protection; one of these consists in a very mild kind of tempering, produced by putting it into water, gradually raised to the boiling point, till heated throughout, and then suffering it gradually to cool. This operation renders the die less apt to crack in very cold weather. A great safeguard is also obtained by thrusting the cold die into a red-hot iron ring, which just fits it in that state, and which, by contracting as it cools, keeps its parts together under considerable pressure, preventing the spreading of external cracks and fissures, and often enabling us to employ a split or die for obtaining punches, which would break to pieces without the protecting ring.

If the die has been successfully hardened, and the protecting paste has done its duty, by preserving the face from all injury and oxidizement, or burning, as it is usually called, it is now to be cleaned and polished, and in this state constitutes what is technically called a MATRIX; it may of course be used as a multiplier of medals, coins, or impressions, but it is not generally thus employed, for fear of accidents happening to it in the coining press, and because the artist has seldom perfected his work upon it in this state. It is, therefore, resorted to for the purpose of finishing a PUNCH, or steel impression for relief. For this purpose a proper block of steel is selected, of the same quality, and with the same precautions as before, and being carefully annealed, or softened, is turned like the matrix, perfectly true and flat at the bottom, and obtusely conical at top. In this state, its conical surface is carefully compressed by powerful and proper machinery upon the matrix, which, being very hard, soon allows it to receive the commencement of an impression; but in thus receiving the impression, it becomes itself so hard by condensation of texture as to require during the operation to be repeatedly annealed, or softened, otherwise it would split into small superficial fissures, or would injure the matrix; much practical skill is therefore required in taking this impression, and the punch, at each annealing, must be carefully protected, so that the work may not be injured.

Thus, after repeated blows in the die-press, and frequent annealing, the impression

from the matrix is at length perfected, or brought completely up, and having been retouched by the engraver, is turned, hardened, and collared, like the matrix, of which it is now a complete impression in relief, and, as we have before said, is called a punch.

This punch becomes an inexhaustible parent of dies, without further reference to the original matrix; for now by impressing upon it plugs of soft steel, and by pursuing with them an exactly similar operation to that by which the punch itself was obtained, we procure impressions from it to any amount, which of course are fac-similes of the matrix, and these dies being turned, hardened, polished, and, if necessary, tempered, are employed for the purposes of coinage.

The distinction between striking medals and common coin, is very essential, and the work upon the dies is accordingly adjusted to each. Medals are usually in very high relief, and the effect is produced by a succession of blows; and as the metal in which they are struck, be it gold, silver, or copper, acquires considerable hardness at each stroke of the press, they are repeatedly annealed during the process of bringing them up. In a beautiful medal, which Mr. Wyon some time since completed for the Royal Navy College, the obverse represents a head of the King, in very bold relief; it required thirty blows of a very powerful press to complete the impression, and it was necessary to anneal each medal after every third blow, so that they went ten times into the fire for that purpose. In striking a coin or medal, the lateral spread of the metal, which otherwise would ooze out as it were from between the dies, is prevented by the application of a steel collar, accurately turned to the dimensions of the dies, and which, when left plain, gives to the edge of the piece a finished and polished appearance; it is sometimes grooved, or milled, or otherwise ornamented, and occasionally lettered, in which case it is made in three separate and moveable pieces, confined by a ring, into which they are most accurately fitted, and so adjusted that the metal may be forced into the letters by its lateral spread, at the same time that the coin receives the blow of the screw-press.

Coins are generally completed by one blow of the coining-press. These presses are worked in the Royal Mint by machinery, so contrived that they shall strike, upon an average, sixty blows in a minute; the blank piece, previously properly prepared and annealed, being placed between the dies by part of the same mechanism.

The number of pieces which may be struck by a single die of good steel, properly hardened and duly tempered, not unfrequently amounts at the Mint to between three and four hundred thousand; but the average consumption of dies is of course much greater, owing to the variable qualities of steel, and to the casualties to which the dies are liable; thus, the upper and lower die are often violently struck together, owing to an error in the layer-on, or in that part of the machinery which ought to put the blank into its place, but which now and then fails so to do. This accident very commonly arises from the boy who superintends the press neglecting to feed the hopper of the layer-on with blank pieces. If a die is too hard, it is apt to break or split, and is especially subject to fissures, which run from letter to letter upon the edge. If too soft, it swells, and the collar will not rise and fall upon it, or it sinks in the centre, and the work becomes distorted and faulty. He, therefore, who supplies the dies for an extensive coinage, has many accidents and difficulties to encounter. There are eight presses at the Mint, frequently at work for ten hours each day, and the destruction of eight pair of dies per day (one pair for each press) may be considered a fair average result, though they much more frequently fall short of, than exceed this proportion. It must be remembered, that each press produces 3600 pieces per hour; but, making allowance for occasional stoppages, we may reckon the daily produce of each press at 30,000 pieces; the eight presses, therefore, will furnish a diurnal average of 240,000 pieces.

DIGESTER is the name of a copper kettle or pot of small dimensions, made very strong, and mounted with a safety valve in its top. Papin, the contriver of this apparatus, used it for subjecting bones, cartilages, &c. to the solvent action of high-pressure steam, or highly heated water, whereby he proposed to facilitate their digestion in the stomach. This contrivance is the origin of the French cookery pans, called *autoclaves*, because the lid is self-keyed, or becomes steam-tight by turning it round under clamps or ears at the sides, having been previously ground with emery to fit the edge of the pot exactly. In some autoclaves the lid is merely laid on with a fillet of linen as a lute, and then secured in its place by means of a screw bearing down upon its centre from an arched bar above. The safety valve is loaded either by a weight placed vertically upon it, or by a lever of the second kind pressing near its fulcrum, and acted upon by a weight which may be made to bear upon any point of its graduated arm.

Chevreul has made a useful application of the digester to vegetable analysis. His instrument consists of a strong copper cylinder, into which enters a tight cylinder of

silver, having its edge turned over at right angles to the axis of the cylinder, so as to form the rim of the digester. A segment of a copper sphere, also lined with silver, stops the aperture of the silver cylinder, being applied closely to its rim. It has a conical valve pressed with a spiral spring, of any desired force, estimated by a steelyard. This spring is enclosed within a brass box perforated with four holes; which may be screwed into a tapped orifice in the top of the digester. A tube screwed into another hole serves to conduct away the condensable vapours at pleasure into a Woulfe's apparatus.

DIMITY is a kind of cotton cloth originally imported from India, and now manufactured in great quantities in various parts of Britain, especially in Lancashire. Dr. Johnson calls it *dimmity*, and describes it as a kind of fustian. The distinction between fustian and dimity seems to be, that the former designates a common tweeled cotton cloth of a stout fabric, which receives no ornament in the loom, but is most frequently dyed after being woven. Dimity is also a stout cotton cloth, but not usually of so thick a texture; and is ornamented in the loom, either with raised stripes or fancy figures, is seldom dyed, but usually worn white, as for bed and bed-room furniture. The striped dimities are the most common, they require less labour in weaving than the others; and the mounting of the loom being more simple, and consequently less expensive, they can be sold at much lower rates. See TEXTILE FABRICS, for particular details of the plan of mounting them.

DISINFECTION OF CLOTHING, (*Messrs. Davison and Symington's patent process*). — The absorption of noxious effluvia by clothes or soft and porous articles of merchandise, has been long recognised as a fact by men who have directed special attention to this subject.

The use of the various liquid disinfectants, which have of late been proposed, is not applicable to articles of clothing; and the common practice of baking clothes in ovens is liable to lead to their destruction, owing to the impossibility of regulating the temperature to which it is necessary to expose them. The only plan which combines economy with certainty of disinfection, is that which has been patented by Messrs. Davison and Symington, and which is now extensively employed in various manufactures. This plan consists in exposing the articles of clothing in a large chamber to rapid currents of air heated to a temperature insufficient to injure them, *i. e.* varying from 200° to 250°. We have had an opportunity of witnessing this process as applied to certain branches of manufacture, and the results were of the most satisfactory kind. In the case of infected clothing, it is obvious, that while a high temperature tends to destroy the animal poisons, a rapid current of air, constantly passing through the chamber, tends to carry them off. The temperature of the current of air can be so regulated that common albumen is speedily dried into a yellow transparent solid, without coagulation, or if necessary, the heat may be increased from 400° to 500°, according to the nature of the articles which are exposed. Dr. Copland has already directed the attention of the profession to this process, and observes that, "the great advantage of this method is its easy applicability to all kinds, and to any number of objects and articles without injury to their textures or fabrics." From an inspection of one of these chambers, when the temperature of the current of air was 116°, we can state that the process of Messrs. Davison and Symington for the drying and disinfecting of the clothing of cholera and fever patients, will be far more efficacious than the common plan of washing and baking. In our opinion, an apparatus of this kind, fitted up in large hospitals, infirmaries, prisons and workhouses, as well as all quarantine stations, would be admirably adapted to prevent the diffusion of infectious diseases.

DISTILLATION, (Eng. and Fr.; *Branntweinbrennerei*, Germ.) means, in the commercial language of this country, the manufacture of intoxicating spirits; under which are comprehended the four processes, of *mashing* the vegetable materials, *cooling* the worts, exciting the vinous *fermentation*, and separating by a peculiar vessel called a *still* the alcohol combined with more or less water. This art of evoking the fiery demon of drunkenness from his attempered state in wine and beer, was unknown to the ancient Greeks and Romans. It seems to have been invented by the barbarians of the north of Europe, as a solace to their cold and humid clime; and was first made known to the southern nations in the writings of Arnoldus de Villa Nova, and his pupil, Raymond Lully of Majorca, who declares this admirable essence of wine to be an emanation of the divinity, an element newly revealed to man, but hid from antiquity, because the human race were then too young to need this beverage, destined to revive the energies of modern decrepitude. He further imagined that the discovery of this *aqua vitæ*, as it was called, indicated the approaching consummation of all things — the end of this world. However much he erred as to the value of this remarkable essence, he truly predicted its vast influence upon humanity, since to both civilized and savage nations it has realized greater ills than were threatened in the fabled box of Pandora.

I shall consider in this place the first three of these subjects, reserving for the article STILL an account of the construction and use of that apparatus.

Whiskey, from the Irish word Usquebaugh, is the British name of the spirituous liquor manufactured by our distillers, and corresponds to the *Eau de vie* of the French, and the *Branntwein* of the Germans. It is generated by that intestine change which grape juice and other glutino-saccharine liquids spontaneously undergo when exposed to the atmosphere at common temperatures; the theory of which will be expounded under the article FERMENTATION. The production of whiskey depends upon the simple fact, that when any vinous fluid is boiled, the alcohol being very volatile, evaporates first, and may thereby be separated from the aqueous vegetable infusion in which it took its birth. Sugar is the only substance which can be transformed into alcohol. Whatsoever fruits, seeds, or roots afford juices or extracts capable of conversion into vinous liquor, either contain sugar ready formed, or starch susceptible of acquiring the saccharine state by proper treatment. In common language, the intoxicating liquor obtained from the sweet juices of fruits is called wine; and that from the infusions of farinaceous seeds, beer; though there is no real difference between them in chemical constitution. A similar beverage, though probably less palatable, is procurable from the juices and infusions of many roots, by the process of fermentation. Wine, cyder, beer, and fermented wash of every kind, when distilled, yields an identical intoxicating spirit, which differs in these different cases merely in flavour, in consequence of the presence of a minute quantity of volatile oils of different odours.

I. The juices of sweet fruits contain a glutinous ingredient which acts as a ferment in causing their spontaneous change into a vinous condition; but the infusions of seeds, even in their germinated or malted state, require the addition of a glutinous substance called yeast, to excite the best fermentation. In the fabrication of wine or beer for drinking, the fermentative action should be arrested before all the fruity saccharum is decomposed; nor should it on any account be suffered to pass into the acetous stage; whereas for making distillery wash, that action should be promoted as long as the proportion of alcohol is increased, because the formation of a little acetic acid is not injurious to the quality of the distilled spirit, but rather improves its flavour by the addition of acetic ether, while all the undecomposed sugar is lost. Distillers operate upon the saccharine matter from corn of various kinds in two methods; in the first they draw off a pure watery extract from the grain, and subject this species of wort to fermentation; in the second they ferment and distil the infused mass of grains. The former is the practice of the distillers in the United Kingdom, and is preferable on many accounts; the latter, which is adopted in Germany, Holland, and the north of Europe, is less economical, more uncertain in the product, and affords a cruder spirit, in consequence of the fetid volatile oil evolved from the husks in the still. The substances employed by the distillers may be distributed into the following classes: —

1. Saccharine juices. At the head of these stands cane-juice, which fresh from the mill contains from 12 to 16 per cent. of raw sugar, and like the must of the grape enters into the vinous fermentation without the addition of yeast, affording the species of spirit called Rum, which is possessed of a peculiar aroma derived from an essential oil in the cane. An inferior sort of rum is fabricated from molasses, mixed with the skimmings and washings of the sugar pans. When molasses or treacle is diluted with twenty times its weight of warm water, and when the mixture has cooled to 78° F., if one twelfth of its weight of yeast be added, fermentation will speedily ensue, and an ardent spirit will be generated, which when distilled has none of the aroma of rum; proving this to reside in the immediate juice or substance of the cane, and to be dissipated at the high temperature employed in the production of molasses. Though the cane juice will spontaneously undergo the vinous fermentation, it does so more slowly and irregularly than the routine of business requires, and therefore is quickened by the addition of the lees of a preceding distillation. So sensible are the rum distillers of the advantage of such a plan, that they soak woollen cloths in the yeast of the fermenting vats, in order to preserve a ferment from one sugar season to another. In Jamaica and some other of our colonies, 50 gallons of spent wash or lees are mixed with 6 gallons of molasses, 36 gallons of sugar-pan skimmings (a substance rich in aroma), and 8 gallons of water; in which mixture there is about one twelfth part of solid saccharum. Those who attend more to the quality than the quantity of their rum, will use a smaller proportion of the spent wash, which is always empyreumatic, and imparts more or less of its odour to the spirit distilled from it. The fermentation is seldom complete in less than 9 days, and most commonly it requires from 12 to 15; the period being dependent upon the capacity of the fermenting tun, and the quality of its contents. The liquid now becomes clear, the froth having fallen to the bottom, and few bubbles of gas are extricated from it, while its specific gravity is reduced from 1·050 down to 0·992. The sooner it is subjected to distillation after this period the better, to prevent

the loss of alcohol by the supervention of the acetous stage of fermentation, an accident very liable to happen in the sugar colonies. The crude spirit obtained from the large single still at the first operation, is rectified in a smaller still. About 114 gallons of rum, proof strength, specific gravity 0·920, are obtained from 1200 gallons of wash. Now these 1200 gallons weigh 12,600 libs., and contain nearly one eighth of their weight of sugar = 1575 libs.; which should yield nearly its own weight of proof spirit, whose bulk is $= \frac{1575}{0{\cdot}92} = 1712$ pound measures = 171·2 gallons; whereas only 114 are obtained; proving the processes to be conducted in a manner far from economical, even with every reasonable allowance,

Mr Edwards gives the following estimate: "The total amount of sweets from an estate in Jamaica which makes 200 hogsheads of sugar, is 16,666 gallons. The wash set at the rate of 12 per cent. sweets, should return 34,720 gallons of low wines, which should give 14,412 gallons of rum, or 131 puncheons of 110 gallons each."

By my own experiments on the quantity of proof spirit obtainable from molasses by fermentation (afterwards to be detailed), one gallon of sweets should yield one gallon of spirit; and hence the above 16,666 gallons should have afforded the same bulk of rum. But here we are left somewhat in the dark, by not knowing the specific gravity of the rum spoken of by Mr. Edwards. The only light let in upon us is when he mentions rum oil-proof, that is, a spirit in which olive oil will sink; indicating a density nearly the same with our actual excise proof, for olive oil at 60° F. has the specific gravity 0·919. When a solution of sugar of the proper strength is mixed with wine lees, and fermented, it affords a spirit by distillation not of the rum, but of the brandy flavour.

The sweet juices of palm trees and cocoa nuts, as also of the maple, and ash, birch, &c., when treated like cane juice, afford vinous liquors from which ardent spirits, under various names, are obtained; as *arrack*, &c.; the quantity being about 50 pounds of alcohol of 0·825 for every 100 pounds of solid saccharine extract present. Honey similarly treated affords the metheglin so much prized by our ancestors. Good whey, freed from curd by boiling, will yield 4 per cent. of spirit of wine, when fermented with the addition of a little yeast.

2. The juices of apples, pears, currants, and such fruits, afford by fermentation quantities of alcohol proportional to the sugar they contain. But the quality of the spirit is much better when it is distilled from vinous liquids of a certain age, than from recently fermented must. Cherries are employed in Germany, and other parts of the Continent, for making a high-flavoured spirit called *Kirsch-wasser*, or cherry water. The fully ripe fruit is crushed by a roller press, or an edge-stone mill, along with the kernels; the pulp is fermented in a mass, the liquid part is then drawn off, and distilled. More or less prussic acid enters from the kernels into this spirit, which renders it very injurious, as a liquor, to many constitutions. I was once nearly poisoned by swallowing a wine glass of it in the valley of Chamouni. The ripened red fruit of the mountain ash constitutes a good material for vinous fermentation. The juice being mixed with some water and a little yeast, affords when well fermented, according to Hermstaedt, 12 pounds, or 1½ gallons, of alcohol from 2 bushels of the ripe berries.

3. Many roots contain sugar, particularly beet, from which no less than 7 per cent. of it may be extracted by judicious means. Hermstaedt recommends to mash the steam boiled clean roots, and add to the paste two-thirds of its weight of boiling water, and a thirtieth of its weight of ground malt, mixing the materials well, and then leaving them three hours in a covered vessel. The mixture must now be passed through a wire sieve, with meshes of one-third of an inch square each; the residuum is washed with a little cold water, and, when the temperature has fallen to 77° F., the proper quantity of yeast must be added, and the fermentation suffered to proceed in a covered tun. In 5 or 6 days it will be complete, and will afford by distillation, from 100 pounds of beet root, about 10 or 12 pounds of proof spirits. Carrots and parsnips, when similarly treated, yield a considerable quantity of alcohol.

II. *Ardent spirits or whiskey from fecula or starchy materials.*

I have already pointed out, in the article BEER, how the starch is transformed into a saccharine condition, by malting and mashing; and how a fermentable wort may be obtained from starchy meal. By like operations may all vegetable substances, which consist chiefly of starch, become materials for a whiskey distillery. To this class belong all the farinaceous grains, potatos, and the pods of shell fruits, as beans, vetches, horse-chesnuts, acorns, &c.

1. *Whiskey from corn.* All those species of corn which are employed in breweries answer for distilleries; as wheat, rye, barley, and oats; as well as buckwheat, and maize or Indian corn. The product of spirits which these different grains afford, depends upon the proportion of starch they contain, including the small quantity of uncrystallizable sugar present in them. Hermstaedt, who has made exact experiments upon the subject, reckons a quart (Prussian or British) of spirits, containing 30 per cent. of the absolute alcohol of Richter, for 2 pounds of starch. Hence 100 pounds of starch should yield

85 pounds of alcohol; or 4·375 gallons imperial, equal to 7·8 gallons of spirits, excise proof.

100 pounds of the following grains afford in spirits of specific gravity 0·9427, containing 45 per cent. of absolute alcohol ($= \frac{9}{11}$ of British proof,) the following quantities: —

Wheat, 40 to 45 pounds of spirits; rye, 36 to 42; barley, 40; oats, 36; buckwheat, 40; maize, 40. The mean of the whole may be taken at 40 pounds, equal to $4\frac{1}{4}$ gallons imperial, of 0·9427 specific gravity = 3·47 gallons, at excise proof. The chief difference in these several kinds of corn consists in their different bulks under the same weight; a matter of considerable importance; for since a bushel of oats weighs little more than the half of a bushel of wheat, the former becomes for some purposes less convenient in use than the latter, though it affords a good spirit.

Barley and rye are the species of grain most commonly employed in the European distilleries for making whiskey. Barley is mostly taken either partly or altogether in the malted state; while the other corns are not malted, but merely mixed with a certain proportion of barley malt to favour the saccharine fermentation in the mashing. It is deemed preferable to use a mixture of several sorts of grain, instead of a single one; for example, wheat with barley and oats; or barley with rye and wheat; for the husks of the oats diffused through the wheat flour and rye meal keep it open or porous when mashed, and thus favour the abstraction of the wort; while the gluten of the wheat tends to convert the starch of the barley and oats into sugar. When the whole of the grain, however, is malted, a much more limpid wort is obtained than from a mixture of malt with raw grain; hence the pure malt is preferable for the ale and porter brewer, while the mixture affords a larger product, at the same cost of materials, to the distiller. When barley is the only grain employed, from one-third to one-sixth of malt is usually mixed with it; but when wheat and rye are also taken, the addition of from one-eighth to one-sixteenth of barley malt is sufficient. Oats are peculiarly proper to be mixed with wheat, to keep the meal open in the mashing.

The following are the proportions used by some experienced Scotch distillers.

250 bolls, containing 6 bushels each, being used for a mashing, consist of,

25	bolls of oats, weighing	284 lbs. per boll, or	$47\frac{1}{3}$ lbs. per bushel;
42	malt	240	40
25	rye	320	$53\frac{1}{3}$
158	barley	320	$53\frac{1}{3}$
250		mean	$48\frac{1}{2}$

From each boll, weighing 291 lbs., 14 imperial gallons of proof whiskey are obtained on an average; equivalent to 11·2 gallons at 25 over proof.

The malting for the distilleries is to be conducted on the same principles as for the breweries, but the malt ought to be lightly kiln-dried, and that preferably at a steam heat, instead of a fire, which is apt to give an empyreumatic smell to the grain that passes into the spirits. For such persons, indeed, as relish the smell of burned turf, called peat-reek in Scotland, the malt should be dried by a turf fire, whereby the whiskey will acquire that peculiar odour.

But this smell, which was originally prized as a criterion of whiskey made from pure malt, moderately fermented and distilled with peculiar care, has of late years lost its value, since the artifice of impregnating bad raw grain whiskey with peet-smoke has been extensively practised.

Dr. Kolle, in his treatise on making spirits, describes a malting kiln with a copper plate heated with steam, 18 feet long, and 12 feet broad, on which a quantity of malt being spread thin, is changed every 3 or 4 hours, so that in 24 hours he turns out upwards of 28 cwt. of an excellent and well-kilned article. The malt of the distiller should be as pale as possible, because with the deepening of the colour an empyreumatic principle is generated.

When Indian corn is the subject of distillation, it must be malted in the same way as described in the article Beer. According to Hermstaedt, its flour may be advantageously mixed with the crushed malt in the mash tun. But its more complete dissolution may be accomplished by Siemen's mode of operating upon potatos, presently to be described.

1. *Mashing.* Barley and raw grain are ground to meal by millstones, but malt is merely crushed between rollers. If only one-tenth or one-eighth of malt be used with nine-tenths or seven-eighths of barley, some husks of oats are added, to render the mash mixture more drainable.

When 40 bushels of barley and 20 of malt form one mashing, from 600 to 700 gallons of water, heated to 150° F., are mixed with these 60 bushels in the mash tun,

and carefully incorporated by much manual labour with wooden oars, or in great concerns by the mechanical apparatus used in the breweries. This agitation must be continued for 2 or 3 hours, with the admission from time to time of about 400 additional gallons of water, at a temperature of 190°, to counteract the cooling of the materials. But since the discovery of *diastase*, as the best heat for saccharifying starch is shewn to be not higher than 160° F., it would be far better to mash in a tun, partially, at least, steam encased, whereby we could preserve the temperature at the appropriate degree for generating the greatest quantity of sugar.

If the wort be examined every half-hour of the mashing period, it will be found to become progressively sweeter to the taste, thinner in appearance, but denser in reality.

The wort must be drawn off from the grains whenever it has attained its maximum density, which seldom exceeds 150 lbs. per barrel; that is, $\frac{360 + 150}{360} = 1{\cdot}42$, or 42 per cent. As the corn of the distiller of raw grain has not the same porosity as the brewer's, the wort cannot be drawn off from the bottom of the tun, but through a series of holes at the level of the liquor, bored in a pipe stuck in at the corner of the vessel. About one-third only of the water of infusion can thus be drawn off from the pasty mass. More water is therefore poured on at the temperature of 190°, well mixed by agitation for half an hour, then quietly infused for an hour and a half, and finally drawn off as before. Fully 400 gallons of water are used upon this occasion, and nearly as much liquor may be drawn off. Lastly, to extract from the grains every thing soluble, about 700 gallons of boiling hot water are turned in upon them, thoroughly incorporated, then left quietly to infuse, and drawn off as above. This weak wort is commonly reserved for the first liquor of the next mashing operation upon a fresh quantity of meal and malt.

The English distiller is bound by law to make his mixed worts to be let down into the fermenting tun of a specific gravity not less than 1·050, nor more than 1·090; the Scotch and Irish distillers not less than 1·080, nor more than 1·080; which numbers are called, gravity 50, 90, 80, and 80, respectively.

With the proportion of malt, raw grain, and water, above prescribed, the infusion first drawn off may have a strength = 20 per cent. = spec. grav. 1·082, or 73 lbs. per barrel; the second of 50 lbs. per barrel, or 14 per cent.; and the two together would have a strength of 61·2 lbs. per barrel = 17 per cent., or spec. grav. 1·070. From experiments carefully made upon a considerable scale, it appears that no more than four-fifths of the soluble saccharo-starchy matter of the worts is decomposed in the best regulated fermentations of the distiller from raw grain. For every 2 lbs. so decomposed, 1 lb. of alcohol, spec. grav. 0·825 is generated; and as every gallon of spirits of the spec. grav. 0·909 contains 4·6 lbs. of such alcohol, it will take twice 4·6 or 9·2 lbs. of saccharine matter to produce the said gallon. To these 9·2 lbs., truly transmuted in the process, we must add one-fifth, or 1·84 lbs., which will raise to 11·04 the amount of solid matter employed in producing a gallon of the above spirits.

Some distillers mash a fourth time; and always use the feeble wort so obtained in mashing fresh grain.

2. As the imperfect saccharine infusion obtained from raw grain is much more accescent than the rich sugary solution got from malt in the breweries, the distiller must use every precaution to cool his worts as quickly as possible, and to keep them clear from any acetous taint. The different schemes of cooling worts are considered under BEER and REFRIGERATION. As the worts cool, a quantity of starchy matter is precipitated, but it is all carefully swept along into the fermenting tun, and undoubtedly contributes to increase the production of alcohol. During the winter and temperate months, when the distilleries are most actively at work, the temperature at which the worts are set is usually about 70° F. When much farinaceous deposit is present, the heat may be only 65°, because, in this case, a slow fermentation seems to favour the conversion of that starch into sugar. In some German distilleries a little chalk is mixed with the worts, to check acidity.

3. *The fermentation.*

The yeast added to the worts as a ferment, ought to be the best top barm of the London porter breweries. About 1 gallon of it is requisite for every 2 bushels of meal and malt worked up in the mashing process; and of this quantity only a certain proportion is introduced at the beginning; the remainder being added by degrees, on the second and third day.

Should the fermentation flag, a little more may be added on the fourth or fifth day, and the contents of the tun may be roused by an agitator. About 8 or 9 gallons may be introduced four days in succession to the quantity of worts extracted from 60 bushels of the farinaceous materials; or the third day's dose may be intermitted, and joined to the fourth on the subsequent day.

Great diversity, and no little caprice prevail among distillers in respect of the periods of administering the yeast; but they should be governed very much by the appearance of the fermentation. This process continues from nine to twelve or even fourteen days, according to circumstances; the tuns being left quite open during the first five days, but being covered moderately close afterwards to favour the full impregnation of the liquor with carbonic acid, as a fermenting agent. In consequence of the great attenuation of the wort by the generation of so much alcohol, no good body of yeast continues to float on the surface, and what is formed is beat down into the liquor on purpose to promote the fermentation. The temperature of the wash gradually increases till towards the end of the fourth day, when it attains its maximum height of about 25° above the pitch of 55° or 60° at which it may have been set. The time of the greatest elevation of temperature, as well as its amount, depends conjointly upon the quality of the yeast, the nature of the saccharo-starchy matter, and the state of the weather. It is highly probable that the electrical condition of the atmosphere exercises a considerable influence upon fermentation. We know the power of a thunderstorm to sour vinous fluids. An experimental inquiry into the relation between electricity and fermentation, could not fail to prove both curious and profitable.

The diminution of the density of the wort is carefully watched by the distiller, as the true criterion of the success of his process. This *attenuation*, as he calls it, is owing partly to the decomposition of the sugar, which communicated its gravity to the solution, and partly to the introduction of the lighter alcoholic particles. Were all the saccharo-starchy matter resolved into gaseous compounds, the wort would become water; but since a part of it remains undecomposed, and a portion of alcohol is produced at the expense of the decomposed part, the degree of attenuation becomes a somewhat complicated problem in a theoretical point of view; the density due to the residuary sugar being masked and counteracted by the spirit evolved. Could the alcohol be drawn off as it is formed, the attenuation would probably become greater, because the alcohol checks the fermentative action, and eventually stops it, before all the saccharum is decomposed. After the wash has taken its highest degree of temperature, not much more spirit is found to be generated; were this therefore removed by proper means, the remaining vegetable matter would undoubtedly yield a further product of alcohol.

In the attenuation of raw-grain wash, the specific gravity seldom arrives at 1·000; but most commonly stops short at 1·002 or 1·004. When the vinous fermentation comes to an end, the acetous is apt to commence, and to convert a portion of the alcohol into vinegar; a result which is easily ascertained by the increasing specific gravity, sour smell, and acidulous reaction of the wash upon litmus paper, which remains after the paper is heated, showing that the red colour is not caused by carbonic acid.

Fermentation proceeds with more uniformity and success in the large tuns of the distiller, than in the experimental apparatus of the chemist; because the body of heat generated in the former case maintains the action. But I have succeeded in obviating this inconvenience in operating upon 80 or 90 gallons, by keeping up the temperature, when it begins to flag, by transmitting hot water through a recurved pipe plunged into the tun.

We have already mentioned that one gallon of spirits, one in ten over-proof, is upon the average generated from 11·04 libs. of starch sugar; hence we conclude that one pound water-measure of spirits at proof ($= \frac{1}{10}$ imperial gallon) is produced from one pound of the saccharum.

Malt whiskey. — The treatment and produce of malt distilleries are in some respects different from those of raw grain. Having been professionally employed by the proprietors of both, I am prepared to state the peculiarities of the latter, by an example. 500 bushels of ground malt are first mashed with 9000 gallons of water, heated to the temperature of 160° F.: 6000 gallons of worts are drawn off into the coolers, and let down into the fermenting tun at 68° From 3 to 4 per cent. of a mixture of London porter yeast with quick Scotch barm, are added, and well stirred through the mass. At the end of two or three days, in general, the fermentation is finished. On the residuary grains of the malt, from 4500 to 5000 gallons of water at 180° are run, which after proper mashing as before, are drawn off; then 4500 more are poured on, the drainage of which is added to the second. Both of these together, constituting 9000 gallons, are heated next day, and employed for the mashing of 500 bushels of fresh malt. During the fermentation, the wash which was set at the spec. grav. 1·065, comes down to water = 1·000.

The wash is distilled in two stills, appropriated to it, of about 800 gallons capacity each, provided with a rotatory chain apparatus for preventing the lees from adhering to the bottom of the still. Into about 800 gallons of wash 8 lbs. of soap are put. The liquor obtained at this first distillation is called low-wines. These low-wines are redistilled in the spirit stills; the first and last portions of liquid being more or less blue or milky in colour, and rank in flavour, are run into a separate receiver called the *faints-back*;

while the middle portion, constituting in a well-managed distillery, from three-fourths to four-fifths of the whole, are received into the spirit-back. The faints are mixed with a large quantity of water, and redistilled, in order to free them from the fetid oil derived from the husks of the grain. The interception of this noxious oil may be best effected by a self-regulating bath, between the capital of the still and the refrigeratory, as will be explained in treating of STILLS. The capitals of the common Scotch stills are made from 15 to 20 feet high, in order to prevent the chance of the wash boiling over into the worm; and they are, towards the beginning of the process, struck from time to time with a rod, and by the sound emitted it is known whether they be empty, partially filled, or in danger of an overflow; in which case the fire is damped, by a spout near the furnace door, connected by a leather pipe with an elevated reservoir of water. When very pure spirits are wished for, a third or even a fourth distillation is had recourse to; there being a quantity of water mixed each time with the spirit in the still, to prevent its acquiring a harsh alcoholic flavour.

According to some experienced distillers from raw grain, the mashing temperature of the first liquor should not exceed 140° F.; whereas with malt it may be safely and beneficially 165° or 170°. When rye is used instead of malt, 90 bushels of it are mixed with 190 bushels of raw grain, constituting 280 bushels in whole, for the mashing of which 5200 gallons of water are required. An hour and a half more time is necessary for settling the mashing of the above mixture, than of grain alone. Gin is made in this way.

The distiller of malt whiskey calculates on obtaining two gallons of proof spirits from one bushel of malt, in average years. The highest yield is 20 gallons per quarter of 8 bushels; and the lowest is 16, when the malt and fermentation are indifferent. The best temperature to set the fermenting tuns with malt wash is about 70° or 72° F.

When malt is 5*s.* the bushel, 6 bushels at 30*s.* will yield 12 gallons of proof spirits. These cost therefore 2*s.* 6*d.* per gallon for the malt; to which must be added 3*d.* per bushel for the amount of malt duty not returned, or 1½*d.* on the gallon; this added to the Scotch duty of 3*s.* 4*d.* the gallon, makes the price altogether 5*s.* 11½*d.*; besides the expenses in fuel, yeast, labour, and rent, which may be estimated at 8½*d.* per gallon. But 3*d.* may be deducted for what is paid by the dairymen for the spent wash and grains. The total cost, therefore, exclusive of use of capital, is 6*s.* 5*d.* per gallon in Scotland.

The following is the work of a Scotch distillery, where good malt whiskey was made.

One bushel of the malt weighed 35 libs., or the boll, = 6 bushels, 210 libs. In mashing each boll of malt, 110 gallons of water were run on it at 160° F. As soon as the fermenting tun of 3000 gallons capacity was charged with the wash at from 64° to 74° F., 2 gallons per cent. of barm were added. When the wash had become attenuated from 1·060 to 1·040, another gallon of barm was introduced.

The temperature of the fermenting wash sometimes rises to 96°, which is, however, an extreme case, and not desirable. When the bubbles of carbonic acid mount in rapid succession, it is reckoned an excellent sign. If the tun be small, and stand in a cool apartment, it should be started at a higher temperature than in the reverse predicament. Should the fermentation be suffered to flag, it is in general a hopeless task to restore vigorous action. Some try the addition of *bubs*, that is of some wort brought into a state of rapid fermentation in a tub, by a large proportion of yeast, but seldom with much success. Indeed the law prohibits the addition of any wort to the tun at a later period than 24 hours after it is set; so that if bubs are used afterwards, the distiller is apt to incur a penalty.

The maximum quantity of proof spirits obtained on the great scale at any time from raw grain mixed with from one-fourth to one-eighth of malt, seems to be 22 gallons per quarter.

By the British laws a distiller is not allowed to brew and distil at the same time; but he must work alternately, one week, for instance, at fermentation, and next week at distillation.

In fermenting solutions of sugar mixed with good yeast, the attenuation has been carried down to 0·984, and even 0·982, that is, in the language of the excise, 16 and 18 degrees below water, from 1·060, the density at which it was originally set in the tun. This was excellent work done on the scale of a great distillery nearly 30 years ago, when distillation from sugar was encouraged, in consequence of bad corn harvests.

In an experiment which I made in 1831 for the information of a committee of the House of Commons, on the use of molasses in the breweries and distilleries, I dissolved 1 cwt. of raw sugar in water, so as to form 74½ gallons, inclusive of 2 gallons of yeast. The specific gravity of the mixture was 1·0593 on the 31st of March. By the 6th of April, that is in 6 days, the gravity had sunk to 0·992, or 8 degrees under water, which was reckoned a good attenuation, considering the circumstances and the small quantity operated upon. By distillation it afforded at the rate of 14·875 gallons of proof spirits for 100 gallons of the wash.

When the distillers first worked from sugar, they only obtained upon an average from 1 cwt. 10·09 gallons imp. of proof spirit; but they afterwards got no less than 11·92 imp. gallons.

The following experiment, which I made upon the fermentation of West India molasses into spirits, for the information of the said committee, may prove not uninteresting to my readers. 150 libs. were dissolved in water and mixed with 2 gallons of yeast, weighing exactly 20 libs. The wash measured 70 gallons, and had a spec. gravity of 1·0647 at 60° F. In two days the gravity had fallen to 1·0055; in three days to 1·0022; and in five days to 1·001. The temperature was kept up at from 80° to 90° F., during the two last days, by means of a steam pipe, to favour the fermentation. The product of spirits was 11 gallons, and $\frac{35}{100}$ of a gallon. Now 150 libs. of the above molasses were found to contain of solid matter, chiefly uncrystallizable, 112 libs. And as 112 libs. of sugar are estimated by the revenue laws to afford by fermentation 11¼ gallons imp. of proof spirit, the result of that experiment upon molasses must be considered satisfactory, bearing in mind that the saccharine substance in molasses has been not only partially decomposed by heat, but is mixed with some of the glutinous or extractive matter of the cane.

Since the alteration of the excise laws relative to distillation in 1825 and 1826, when permission was given to set the wort at lower gravities, the quantity of spirits produced from 1 quarter of corn has been much increased, even up to fully 20 gallons; and the proportion of malt has been much diminished. The latter was soon reduced from three-sevenths malt, and four-sevenths barley, or two-fifths malt and three-fifths barley, to one-fifth of malt, and now to one-tenth or even one-sixteenth.

A discussion having lately taken place in Ireland between certain persons connected with the distilleries and the officers of the excise, whether, and to what extent, raw grain worts would pass spontaneously into the vinous fermentation, the Board in London requested me to superintend a series of researches in a laboratory fitted up at their office, to settle this important point. I shall content myself here with giving the result of one experiment, out of several, which seems to me quite decisive. Three bushels of mixed grains were taken, consisting of two of barley, one half of oats, and one half of malt, which, being coarsely ground by a hand-mill, were mashed in a new tun with 24 gallons of water at 155°. The mash liquor drawn off amounted to 18 gallons, at the density of 1·0465; and temperature of 82° F. Being set in a new tun, it began to ferment in the course of 12 hours, and in 4 days it was attenuated down to gravity 1·012. This yielded, upon distillation in low wines, 3·22 gallons, and by rectification, in spirits, 3·05; while the quantity equivalent to the attenuation by the tables was 3·31, being an excellent accordance in such circumstances.

The inquisitorial *regime* imposed by law upon our distilleries, might lead a stranger to imagine that our legislators were desirous of repressing by every species of annoyance the fabrication of the fiery liquid which infuriates and demoralizes the lower population of these islands. But alas! credit can be given them for no such moral or philanthropic motive. The necessity of the exchequer to raise a great revenue, created by the wasteful expenditure of the state, on the one hand, and the efforts of fraudulent ingenuity on the other, to evade the payment of the high duties imposed, are the true origin of that *regime*. Examinations in distilleries are constantly making by the officers of excise. There is a survey at 6 o'clock in the morning, when the officers take their accounts and gauges, and make calculations which occupy several hours. At 10 o'clock they again survey, going over the whole premises, where they continue a considerable time, frequently till the succeeding officer comes on duty; at 2 in the afternoon another survey takes place, but not by the same people; at 6 in the evening the survey is repeated; at 10 there comes another survey by an officer who had not been engaged in any of the previous surveys of that day. He is not relieved till 6 o'clock next morning. In addition to these regular inspections, the distilleries are subject to frequent and uncertain visits of the surveyor and general surveyor. "We are never," says Mr. Smith, the eminent distiller of Whitechapel, "out of their hands." *

Before the fermented wort goes into the still, a calculation is made of the quantity of wash drawn from the wash back, and which is first pumped into what is called the wash charger. If the quantity in the wash charger exceeds the quantity in the wash back, the distiller is charged upon the higher quantity; if it contains less, he must pay according to the wash back, as being the larger quantity. When the quantity of wash is all transferred to the charger, the discharge cock of the wash charger is unlocked, and the wash is allowed to be drawn off from the charger into the still, the charging and discharging cock of the still being locked by the officer. There can be no transfer of wash but through the pumps, which are locked also. The first distillation from the wash is worked into the low-wine receiver, which is also a locked-up vessel; then of

* Report of Committee on Molasses, 2198.

those low wines, the strength and quantity are ascertained by the excise. The account of them affords a comparison with the quantity which the contents of the wash-back had been estimated to produce; they are then pumped from the low-wine receiver, through pumps previously locked into the low-wine charger, which is also a locked-up vessel; from the locked-up charger, after the officer has done his duty regarding it, they are allowed to be drawn off into the low-wine still, which is a distillation of the second extraction; then that low wine still works into another locked-up cask, called the spirit receiver, for the receiving of raw spirits; when that distillation is finished, the officer, attending again on regular notice for that purpose, takes the quantity and strength of the spirits therein, and upon the quantity so ascertained he charges the duty. In distilling low wines, one portion of them goes into the spirit receiver, and a portion into what is called the faint receiver, which is another locked-up vessel. These faints are in the next distillation united with the low wines, from the succeeding wash-back on their second distillation, and are worked together; the united produce of these goes partly into the spirit cask, and partly back again into the faint cask. The operation is thus continued till all the backs in the house are emptied.*

There is a kind of ardent spirits manufactured in Holland, vulgarly called Dutch gin, Hollands, and sometimes *geneva*, from *genievre*, the French for juniper, a plant with the essential oil of whose berries it is flavoured. One cwt. of ground malt mixed with two cwt. of rye meal are mashed for two hours, with about 450 gallons of water at the temperature of 160° F. The mash drawn off is reduced with cold water till the liquid part has the density of 45 libs. per barrel, = specific gravity 1·047; and is then put altogether into the fermenting back at the temperature of 80° F. One or two gallons of yeast are added. The fermentation soon becomes so vigorous as to raise the heat to 90° and upwards, but it is not pushed far, being generally over in two days, when the gravity of the wash, still indicates 12 pounds of saccharum per barrel. By this moderate attenuation, like that practised by the contraband distillers of the Highlands of Scotland, it is supposed that the fetid oil of the husks is not evolved, or at least in very small quantity. The grains are put into the alembic along with the liquid wash, and distilled into low wines, which are rectified twice over, some juniper berries and hops being added at the last distillation. But the junipers are sometimes bruised and put into the mash. The produce of worts so imperfectly fermented, is probably little more than one half of what the British distiller draws from the same quantity of grain. But the cheapness of labour and of grain, as well as the superior flavour of the Skiedam spirits, enables the Dutch distiller to carry on his business with a respectable profit. In opposition to the above facts, Dubrunfaut says that about one third more spirits is obtained in Holland from grain than in France, because a very calcareous spring water is employed in the mashing operation. Were this account well founded, all that the distillers of other countries would have to do would be merely to introduce a portion of chalk into their mash tuns, in order to be on a par with the Dutch. But the statement is altogether a mistake.

In the vine countries, the inferior wines or those damaged by keeping, as also a fermented mash of the pressed grapes, mixed with water, are distilled to form the *eau de vie de Cognac* of the French, called Brandy in this country. It contains less essential oil, and that of a more agreeable flavour, than corn spirits. See BRANDY.

Berzelius says that there are distillers who are guilty of putting a little arsenious acid into the still; that the spirits contain pretty frequently traces of arsenic, which may be detected by adding to them a little muriatic acid, then evaporating off the alcohol, and passing a current of sulphuretted hydrogen gas through the residuary liquid, which will give it the characteristic orpiment yellow tinge, arsenic being present. Copper, which is sometimes introduced into distilled grain, or even malt spirits, in consequence of the soap employed in the process of distillation, may be detected best by the brown precipitate which it occasions with ferroprussiate of potash. No arsenic is ever used in this country.

When damaged grain has been mashed in making whiskey, a peculiar oily substance makes its appearance in it. On approaching the nostrils to such whiskey slightly heated, this volatile matter irritates the pituitary membrane and the eyes very powerfully. These spirits have exactly the smell of an alcoholic solution of cyanogene; they intoxicate more powerfully than pure alcohol of equal strength, and produce even temporary frenzy, with subsequent sickness and disordered functions. This volatile body is not cyanogene, though it be so like it, for it forms no such combinations as cyanogene does. It may be extracted from diluted alcohol by agitating it with an unctuous oil, and then distilling the oil along with water. At the end of 3 or 4 months, this volatile matter disappears in a great measure, even when the spirits impregnated with it are inclosed in well-corked bottles; obviously from its undergoing a spontaneous decomposition. It may be preserved much longer in the state of a watery solution.

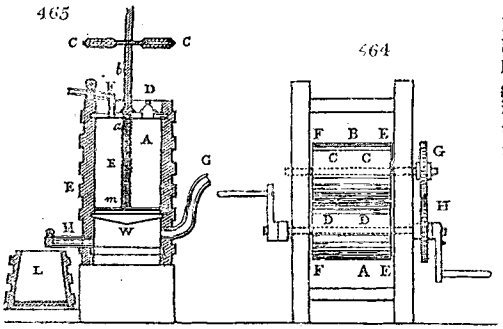
When acetic ether is added to well purified or clean spirits, such as the distillers call

* Thomas Smith, Esq., of Whitechapel Road, in Report of Molasses Committee, Part II. p. 149.

silent whiskey, it gives it somewhat of the flavour of brandy. For this purpose, also, the spirits are rectified from bruised prunes, or the lees of the cognac distilleries, whereby they acquire additional flavour. The astringent taste of old brandy is imitated by the introduction of a little catechu into the British spirits. Burned sugar is employed as a colouring in these imitations.

IV. *Of making whiskey from potatos.* — This root in certain localities where it abounds at a moderate price, is an excellent material for fermenting into alcohol. When sound, it possesses from 20 to 25 per cent. of solid substance, of which starch constitutes at least three-fourths; hence 100 pounds contain from 16 to 22 pounds of starch susceptible of being saccharified. In the expressed juice there is a small quantity of tartaric acid.

Previously to mashing, potatos must be first well washed in a horizontal cylindrical cage revolving partially in a trough of water, as will be described in treating of the manufacture of sugar from beet root. They must be then boiled in a close vessel with steam, provided with a perforated bottom a few inches above the real one. The top has an opening with a cover fitted tightly to it; through that the potatos are introduced; and immediately above the false bottom there is a similar aperture through which the boiled potatos are taken out. The steam-pipe enters at the top, runs down the side a little way, and terminates in a widened mouth. The large lids are secured by cross bars, the small hole by folds of linen. In the lower valve there are two small holes closed with pins, for inserting a wire to feel whether the potatos be sufficiently boiled. If so, the steam is immediately stopped off, the lower lid is removed, and the potatos pulled out with a hook into a tub. They must be immediately made into a homogeneous paste before they get cold. *Fig.* 464. represents, in plan, or horizontal section, the apparatus used in France for this purpose. A B are two cylinders covered with wire cloth, but open at the ends; C C and D D are two pieces of wood fixed on the two axes, in the form of two cones, with the adjoining surfaces truncated; upon which, as also upon iron rings E F, of the same diameter, made fast to the axes, the wire cylinder rests. Of the two wheels G, H, the smaller has 18, the greater has 21 teeth. The diameter of each cylinder is 14 inches, the length 18. Above and between the two cylinders, there is a hopper for the reception of the boiled potatos. This machine triturates 1200 pounds of potatos per hour. Their paste must be forthwith mashed with some ground wheat or barley, and a proportion of malt; then be set a fermenting.



As in the above mode of trituration, the potatos are apt to cool to such a degree as to obstruct their ready admixture with water, it is better to make them into a paste in the vessel in which they are steamed. The apparatus contrived by Siemens fully answers this end. It consists essentially of a tub A, represented in *fig.* 465. in section. It is cylindrical, and made of planks from 3 to 4 inches thick, joined firmly and steam-tight; the upper and under ends being well secured with iron hoops. The lower part is about 2 inches more in diameter than the upper. About a foot from the bottom, in a circular groove, a cast iron partition w or disc full of holes is made fast, which serves the purpose of a searce, the apertures being an inch asunder; above, from $\frac{1}{8}$ to $\frac{1}{10}$ of an inch in diameter, and below, scooped out to half an inch. This disc is half an inch thick in the edges, and five fourths of an inch in the middle.

Through the female screw *a* in the top of the cylinder, there passes the screwed rod *b*, one and a half inches thick, provided at top with a strong cross bar c c, for turning it round. The under end of this rod has a square piece terminating in a short screw, upon which a wrought iron cross is secured by means of a screw nut, so as to stand at right angles to the rod. This cross is composed of two distinct arms; of which one of them is mounted on the upper side with little knives an inch and a half long; the other, upon the under side, with a wire brush, that may be made to rub against the perforated cast iron disc. On the side of the cylinder at E, *fig.* 465., there is a narrow aperture provided with a bung secured by a cross bar, and near the bottom at H there is another like it. Both openings serve for taking out the residuary matter. Through the opening E, the above two arms are introduced; and secured to the square of the rod by the screw nut. In the top there is an opening, D,

for putting in the potatos which may be shut in the same way. From the lid there likewise issues a lateral tube F, which terminates in a tubful of water, for condensing the waste steam. G is the tube connected with the steam boiler, for conducting the steam into the space under the iron disc W.

With this apparatus the potatos are prepared as follows: when the screw rod is so fixed that the cross touches the disc, the cylinder is to be filled with washed potatos to within one foot of the top, leaving them some space to expand. The orifice D is to be then closed, and the steam admitted. When the potatos are boiled enough, two labourers lay hold of the lever handles c c, of the screw rod *b*, and turn it round with the effect of screwing up the spiked cross, and of triturating the potatos; an operation which may be still more effectually done by screwing it down again. The potato paste is now let off by the plug hole H, into the tub I, where it is mixed with about 30 per cent. of boiling water, and one thousandth part of potash, made caustic with quicklime, in order to dissolve the albuminous matter coagulated by the heat, and give complete fluidity to the mass. The alkali also neutralises the tartaric acid present. The mashed matter must now be mixed with the crushed malt diffused through 40 or 50 pounds of cold water for every 100 pounds of potatos, which lowers the temperature to 167°. The wort must be then diligently stirred during two hours; mixed with 40 or 50 pounds of cold water for 100 pounds of potatos, and when reduced to the temperature of 77° put into the fermenting tun along with the proper quantity (3 or 4 per cent.) of yeast. As potatos readily pass into the acetous fermentation, the admixture of the malt, the mashing, and the cooling should be rapidly performed, while the utmost cleanliness must be observed.

The fermentation is brisk, probably from the agency of the albumen, and furnishes a good head of barm, which answers well for the bakers; 100 pounds of potatos yield from 18 to 20 pounds measure of spirits, nine elevenths of our excise proof; or about 16 pounds measure of proof, = about $1\frac{2}{3}$ gallons.

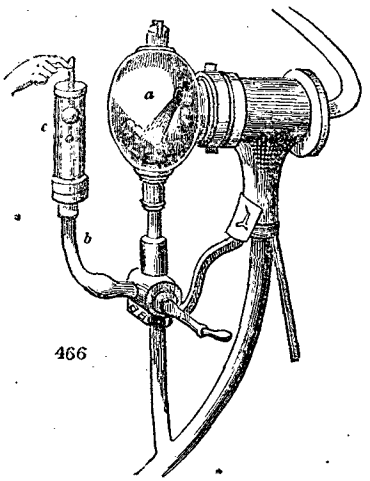
It has been observed that after the month of December potatos begin to yield a smaller product of fermented spirits; and when they have once sprouted or germinated, they afford very little indeed. From the difficulty of keeping and transporting potatos, distillation from them, even though our laws now permit it, can never become general till some plan be adopted for overcoming these disadvantages. A scheme of this kind, however, has been successfully practised in Vienna, which consists in subjecting the washed potatos to strong pressure in a perforated chest by a hydraulic or screw press, whereby they lose about three fourths of their weight, and may then be readily dried into a white flour, that may be kept for several years without injury, and transported to considerable distances with comparative ease. This flour, mixed with a moderate quantity of ground malt, and saccharified by mashing with water, at the temperature of 167° F., becomes capable of affording a sweet wort convertible by fermentation either into beer or whiskey.

Horse-chestnuts, according to Hermstaedt, are an eligible material for producing alcohol, as 128 pounds of them afford 100 pounds of meal; which 100 pounds yield, by proper treatment, 34 pounds of spirits, containing 36 per cent. of absolute alcohol, by Richter's tables. Barley to the extent of 10 pounds per 100 should be ground up with them, after they have been boiled in a steam apparatus, not only for the purpose of softening them, but freeing them from their bitter astringent matter. Acorns are productive of alcohol by similar treatment.

The best means hitherto discovered for depriving bad whiskey of its nauseous smell and taste, is to pass it through well-burned and coarsely pulverised charcoal, distributed as follows in a series of cylindrical casks. Each vessel must have a double bottom, the false one being perforated with conical holes, and placed a few inches above the true. Upon this perforated board a layer of chopped clean straw one inch thick is laid; and over the straw, a stratum of small river gravel, the size of large peas. This is to be covered with a pretty thick stratum of the charcoal, previously freed from dirt and dust by washing; upon which a piece of close canvass is to be spread, and pressed down by a thin bed of river sand. The cylinder or cask should be filled with these successive layers to within two inches of its top, and it is then to be closed air-tight. Immediately below the head, a round orifice is pierced in the side, for receiving an overflow tube, which is either screwed rectangularly to another elbow pipe, or is bent (when of block tin) so as to enter tight into an orifice beneath the false bottom of the second cylinder or cask. In this way, the series may be continued to any desired number of vessels; the last discharging the purified spirit into the store-back. The foul spirit must be made to flow into the bottom space of the first cylinder down through a pipe in communication with a charging-back placed upon such an elevated level as to give sufficient pressure to force the spirits up through the series of filters; the supply-pipe being provided with a regulating stop-cock. The spirit may be filtered *downwards* through sand and cloth in

its final passage to the receiver. It has been found, with very crude spirits, that eight successive cylinders were required to deprive them entirely of the rank flavour.

Fig. 466. represents one form of the worm-safe, which is a contrivance for permitting the distiller to observe and note at any period of the distillation the alcoholic strength or specific gravity of his spirits, without access to the still or the means of purloining the product before it has paid duty. The nose-pipe of the worm tub terminates in, and is firmly cemented to the side of the glass globe *a*, from whose bottom the discharge pipe descends vertically, but has a stop-cock upon it, and a branch small pipe *b*, turned up parallel to the former. This branch is surmounted with a glass cylinder, *c*, which, when the stop-cock is opened, gets filled with the spirits, and then receives a hydrometer to show the gravity of the fluid. The stop-cock mechanism is so contrived, that only one full of the small glass cylinder can be obtained at a time.



466

The following is the gross product of the Excise duties on British distilled spirits for the United Kingdom in the years 1847, 1848, 1849, and 1850:—1847, 5,235,031*l.*; 1848, 5,518,105*l.*; 1849, 5,767,985*l.*; and, 1850, 5,909,381*l.* The net produce is very nearly the same. In 1847, 20,642,689 gallons paid duty; in 1848, 22,237,352; in 1849, 23,016,613; and in 1850, 22,962,012*l.* See RUM, SPIRITS, and STILL.

DIVIDIVI, is an indigenous production of Jamaica. Mr. Rootsey obtained a mean produce of 6·625 grs. of leather from 60 grs. of dividivi, while the same quantity of the best Aleppo galls yielded only a mean produce of 4·625. Hence it appears from Sir Humphry Davy's estimate, that the 60 grs. of dividivi contain 3·0475 grs. or 5·079 per cent. of tannin and 60 grs. of galls, on 2·12704 grains, or 345 per cent. Sixty grs. of oak bark yielded only 1·75 grains of leather; whence it follows that it contains but 0·805 of a grain of tannin to the drachm, or not more than 1·34166.

DOCIMACY, from the Greek Δοκιμαζω, I prove; (*Docimasie*, Fr.; *Probierkunst*, Germ.) is the art by which the nature and proportions of an ore are determined. This analytical examination was originally conducted in the dry way, the metal being extracted from its mineralizers, by means of heat and certain fluxes. But this method was eventually found to be insufficient and even fallacious, especially when volatile metals were in question, or when the fluxes could absorb them. The latter circumstance became a very serious evil, whenever the object was to appreciate an ore that was to be worked at great expense. Bergmann first demonstrated, in an elaborate dissertation, that the humid analysis was much to be preferred; and since his time the dry way has been consecrated chiefly to the direction of metallurgic operations, or, at least, it has been employed merely in concert with the humid, in trials upon the small scale.

After discovering an ore of some valuable metal, it is essential to ascertain if its quantity and state of combination will justify an adventurer in working the mine, and smelting its products. The metal is rarely found in a condition approaching to purity; it is often disseminated in a mineralizing *gangue* far more bulky than itself; and more frequently still it is combined with simple non-metallic substances, such as sulphur, carbon, chlorine, oxygen, and acids, more or less difficult to get rid of. In these compound states its distinctive characters are so altered, that it is not an easy task either to recognize its nature, or to decide if it can be smelted with advantage. The assayer, without neglecting any of the external characters of the ore, seeks to penetrate, so to speak, into its interior; he triturates it to an impalpable powder, and then subjects it to the decomposing action of powerful chemical reagents; sometimes with the aid of alkalis or salts appropriate to its nature, he employs the dry way by fire alone; at others, he calls in the solvent power of acids with a digesting heat; happy, if after a series of labours, long, varied, and intricate, he shall finally succeed in separating a notable proportion of one or more metals either in a pure state, or in a form of combination such that from the amount of this known compound, he can infer, with precision, the quantity of fine metal, and thereby the probable value of the mine. The blow-pipe, skilfully applied, affords ready indications of the nature of the metallic

constituents, and is therefore usually the preliminary test. The separation of the several constituents of the ore can be effected, however, only by a chemist, who joins to the most extensive knowledge of the habitudes of mineral substances, much experience, sagacity, and precision, in the conduct of analytical operations. Under the individual metals, as also in the articles METALLURGY, MINES, and ORES, I have endeavoured to present such a copious and correct detail of docismastic processes, as will serve to guide the intelligent student through this most mysterious labyrinth of nature and art.

DONARIUM, *a recently discovered metal.*—Dr. Bergemann received through Mr. Krantz a mineral from Brerig in Norway, which is found in the same zircon-syenite that contains wöhlerite and eukolite, and he discovered in it the oxide of a new metal combined with silicic acid. This metal he calls *Donarium*, after the god Donar, and he assigns to it the symbol Do.

The silicate of the oxide of donarium, $Do_2\ O_3\ Si\ O_3 + 2\ H\ O$, is yellowish red, in some fragments passing into brown, in others into yellow; when scratched or powdered, it is light orange. In thin films it is almost transparent, the thicker ones translucid. Some pieces have a distinctly laminated structure, in others the fracture is more flat, or conchoidal. Its hardness is between that of fluor spar and apatite; its spec. grav. = 5·397.

Small films heated in a platina spoon break down into a dark brown mass, which reassumes an orange colour when cold; the larger pieces lose their transparency. By heating it in a glass tube, watery vapour is driven off. Fragments held by the platina forceps in the flame of a spirit lamp decrepitate. Heated by the blowpipe on charcoal, it does not melt, a slight vitrification being sometimes observed on the edges, perhaps in consequence of the intermixture of some foreign substance. Fused with soda, the silicic acid is dissolved. The other constituents are seen in the non-transparent mass, by the help of a glass, as small yellow particles. Borax yields a yellow bead, which is colourless when cold. The phosphates produce in the external part of the flame a reddish glass, which is colourless when cold; in the inner part of the flame the bead becomes yellow, and when cold is colourless.

The mineral is readily and completely decomposed by acids, and yields when treated by hydrochloric acid a clear and transparent gelatinous matter. At the same time some carbonic acid is evolved. The colour of the solution is deep yellow, like that of a concentrated solution of iron. The mineral is also affected by diluted acids, even by tartaric acid. After having been exposed to a strong heat, the essential parts of the mineral are no longer acted upon even by concentrated acids.

The analysis showed the presence of lime, water, and the new oxide, also some traces of magnesia, manganese, carbonate of soda, and iron.

The oxide of donarium belongs to the class of earthy bodies, and ranks next to zirconia and yttria. The hydrate, which is thrown down by ammonia of a beautiful white colour, becomes yellow, and at last yellowish red, losing its hydrate water in the air. By heat the latter is completely removed, and the oxide, which is insoluble in muriatic acid, can be perfectly deprived by this acid of the contained iron. The analysis showed the constituents to be:—

Silicic acid	17·695
Oxide of donarium	71·247
Carbonate of lime	4·042
Oxide of iron	0·310
Magnesia and oxide of manganese	0·214
Potash and a little soda	0·303
Water	6·900
	100·741

The metal is obtained as a black powder, by treating the oxide with potassium. If the alkaline solution be directly poured off and the powder washed with water, it can be kept for from 24 to 36 hours under water without alteration; but if it remains under hot water, a yellowish gray mass is gradually formed, in consequence of oxidation. The black metallic powder forms heavy flocculi, which soon conglomerate and are easily separated by filtration. When in the dried state they assume a metallic lustre when rubbed with an agate; and then can be preserved in this condition for several hours, even in a damp atmosphere, without developing any smell. The specific gravity is nearly = 7·35. The powder thrown into a flame burns with a reddish light, and yields the red oxide; so also, if the black powder be heated in a platina spoon, it burns, and moreover appears to glow, but only transitorily. Neither cold nor boiling muriatic acid affects the metal; nitric acid acts not when cold, and but slowly when heated; nitro-muriatic acid readily produces the red oxide, of which a small portion is dissolved; by the application of a few drops of sulphuric acid a sulphate is formed, whilst at the same time the smell of sulphurous acid is perceived. The grayish yellow substance

produced by potash water, quickly forms, when heated by itself or moistened with nitric acid, the red oxide. This powder also, when thrown into the flame of a spirit lamp, glows.

Hydrated Oxide of Donarium. — The precipitate produced by ammonia from the muriatic solution of the mineral is, by long digestion with sulphuric acid, converted into sulphate of the oxide of donarium, and from this the hydrated oxide is precipitated by ammonia. The voluminous precipitate, dried at ordinary temperatures, forms yellow gummy masses, the powder of which is reddish. In this condition the substance represents the pure hydrated oxide, which, like oxide of iron, probably combines with different proportions of water. The water is expelled by a slight increase of temperature. The hydrate is dissolved by all acids at common temperatures, and more so when heated. If muriatic acid be employed, no chlorine is developed.

Oxide of Donarium is obtained by heating the hydrate to redness. Its sp. grav. is 5·576, colour deep red; its form heavy glittering scales. Finely powdered it is orange; darker when strongly heated, and lighter again when cold. Muriatic acid, nitric acid, aqua regia, and even fluoric acid, have no effect upon the oxide which has been heated to redness. By the continued action of concentrated sulphuric acid it is rendered soluble, if it be afterwards mixed with much water. If the oxide, however, be exposed only to that temperature which expels the water from the hydrate, it is slightly acted upon by muriatic acid, without the development of chlorine.

DORNOCK is a species of figured linen of stout fabric, which derives its name from a town in Scotland, where it was first manufactured for table-cloths. It is the most simple in pattern of all the varieties of the diaper or damask style, and therefore the goods are usually of coarse quality for common household wear. It receives the figure by reversing the flushing of the warp and woof at certain intervals, so as to form squares, or oblong rectangles upon the cloth. The most simple of these is a succession of alternate squares, forming an imitation of a checker board or mosaic work. The coarsest kinds are generally woven as tweels of three leaves, where every thread floats over two, and is intersected by the third in succession. Some of the finer are tweels of four or five leaves, but few of more; for the six and seven leaf tweels are seldom or never used, and the eight leaf tweel is confined almost exclusively to damask. See TEXTILE FABRIC.

DRAGON'S BLOOD, (*Sang dracon*, Fr.; *Drachenblut*, Germ.) is a resinous substance, which comes to us sometimes in small balls of the size of a pigeon's egg, sometimes in rods, like the finger, and sometimes in irregular cakes. Its colour, in lump, is dark brown red; in powder, bright red; friable; of a shining fracture; sp. grav. 1·196. It contains a little benzoic acid, is insoluble in water, but dissolves readily in alcohol, ether, and oils. It is brought from the East Indies, Africa, South America, as the produce of several trees, the *Dracæna Draco*, the *Pterocarpus santalinus*, *Pterocarpus Draco* and the *Calamus Rotang*.

Dragon's blood is used chiefly for tingeing spirit and turpentine varnishes, for preparing gold lacquer, for tooth tinctures and powders, for staining marble, &c. According to Herbenger, it consists of 9·07 parts of red resin, 2 of fat oil, 3 of benzoic acid, 1·6 of oxalate, and 3·7 of phosphate of lime.

DRUGGET is a coarse, but rather slight, woollen fabric, used for covering carpets, and as an article of clothing by females of the poorer classes. It is now-a-days nearly superseded by coarse cotton goods.

DRYING HOUSE. An apartment fitted up in a peculiar manner for drying calicoes, and other textile fabrics. Mr. Southworth, of Sharples, a Lancashire bleacher, obtained a patent, in 1823, for the following ingenious arrangement, which has been since generally adopted, with certain modifications, in most of our extensive bleaching and printing works. *Fig.* 467. is a section of the drying-house, where *a* is a furnace and boiler for the purpose of generating steam; it is furnished with a safety valve in the tube *b*, at top, and from this tube the steam main *c* passes down to the floor of the basement story. From this main, a series of steam-pipes, as *d d*, extend over the surface of the floor, and from them heat is intended to be diffused for the purpose of warming the drying-house.

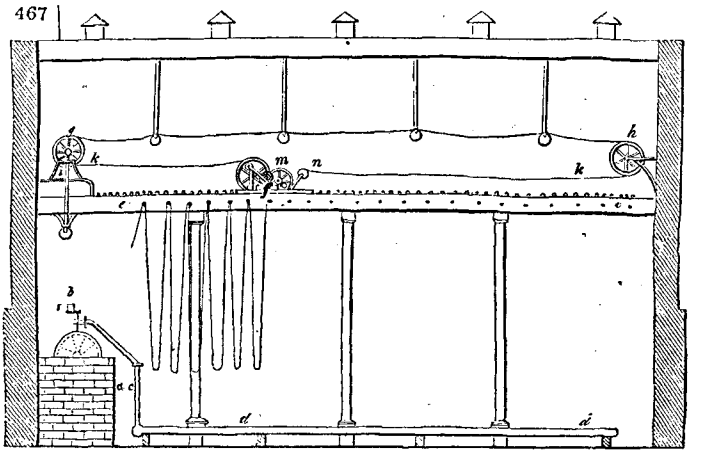
Along the middle of the building a strong beam of timber *e e* extends, and is supported by cast-iron pillars; from this beam, to bearings on the side walls, a series of rails are carried in a cross direction, over which rails the wet cloth is to be hung in folds, and the steam or evaporation emitted in drying is allowed to escape through apertures or ventilators in the roof.

The mode in which the cloth is delivered on to the rails, on either side of the beam, will be best understood by reference to the delivering carriage, which is shown, with its rollers partly in section.

The wet cloth is first to be coiled upon a roller, and then placed in the carriage, as at *f*, with its pivots bearing upon inclined planes. The carriage is to be placed at the

commencement of the rails, running upon the middle beam, and also upon the side-bearings or railways extending along the side walls of the building, parallel to and upon a level with the same beam. It is made to travel by means of an endless band

467



passing over two riggers, *g* and *h*, in *fig.* 467., and over pulleys and a band-wheel attached to the carriage, as will be explained. The rigger *g*, which moves this endless band, is actuated by bevel geer, seen at *i*, which is put in motion by a pinion at the end of a revolving shaft leading from a steam engine.

In the same *fig.*, *k k* is the endless band passing over a pulley under the band-wheel, and over the pulley *n*, by which it will be perceived that the traversing of the band, as described, would cause these pulleys and wheels to revolve. On the axle of the band-wheel *m*, there is a drum against which the roll of wet cloth *f* presses, and as this drum revolves, the roll of wet cloth is, by its friction, made to turn in a contrary direction, and to deliver off the cloth on to the periphery of the drum, whence it passes over a roller and descends to the rails. Upon the end of the axle of the band wheel *m*, there is a pinion which takes into the teeth of the large wheel, and upon the axle of this large wheel there is a pinion that actuates the intermediate wheel which turns another toothed wheel. This last-mentioned toothed wheel takes into cogs upon the side railway, and hence, as the train of wheels moves round, the carriage to which the wheels are attached is slowly impelled forward.

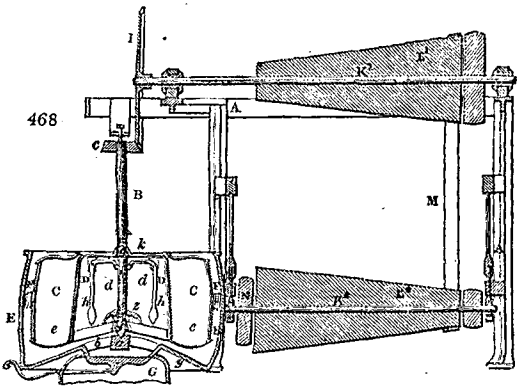
As soon as the wheels begin to move, and the carriage to advance, the wet cloth begins to uncoil, and to pass down over the first roller; a small roller attached to the carriage, as it passes over the rails in succession, holds the cloth against each rail for a short space of time, and prevents it from slipping, by which means the cloth descends in folds or loops between the rails, and is thereby made to hang in a series of folds or loops, as shown in the figure.

It will be perceived that as the pivots of the cloth roller *f* bear upon inclined planes, the roller will continually slide down as the cloth diminishes in bulk, keeping in contact with the drum, and delivering the cloth from the roller on to the several rails, as described.

In order to stop the carriage in any part of its course, or to adjust any of the folds of the cloth, a man is usually placed upon the platform travelling with the carriage, over which he has perfect command. This apparatus may be also employed for taking the cloth when dried off the rails; in which case the carriage must be made to travel backwards, and by first guiding the end of the cloth on to the rolier *f*, and then putting the wheels in a retrograde motion, the cloth will be progressively coiled upon the roller *f*, in a similar way to that by which it was uncoiled.

DRYING MACHINE (CENTRIFUGAL), (*Hydro-extracteur; Machine à essorer*, Fr.)—By this contrivance, Pentzoldt was enabled to deprive all kinds of wet clothes in a few minutes of their moisture, without compression or heat. Kelly, a dyer, and Alliott, a bleacher, have since obtained a patent for the above machine with improvements. *Fig.* 468. represents a partial section of the machine. A, A, is the frame; B, the vertical shaft turning in the step *a*, fixed on the bridge *b*. This shaft bears on its upper part a friction cone *c*, from which it receives its movement of rotation,

as will be shown presently; c is a drum containing two concentric compartments *d e*, of the form represented in the figure; this drum moves freely upon the shaft B, and



rests when it is not in motion upon two conical projections *f*, *g*, which form a part of the shaft. These two compartments are each composed mainly of metal, and their sides consist of tinned iron wire coiled circularly at very small distances from each other, and soldered together crosswise by small slips of metal. The top, which covers the inner compartment *d*, is secured by bolts and screws to a circle of iron which retains the wire sides of the same metal, but that which serves as a cover to the little compartment *e*, in which alone the goods are placed, is disposed so that it may be removed with ease, when these are to be introduced or withdrawn. It is furnished with an outer and inner border, disposed so that when the top is fixed the inner border presses upon the convex circumference of the central compartment, while the exterior border falls outside of the edges of the other compartment. While the machine is at work, the second plate is maintained in its place by pins or bolts, not shown in the figure.

The sides of the outer compartment *d*, are connected with the bottom by means of a prolongation of cross bands of metal which unite the wires and are riveted or soldered to the two outer plates. The wires of the interior compartment are attached by an iron hoop, to which they are riveted and soldered, and are united to the bottom plate by means of a rim upon this plate; a rim somewhat flattened upon the sides which are riveted and soldered.

D, is a regulator suspended in the inner compartment *d*, and whose two branches *h*, *h*, are loaded. These two branches having room to play around the bolts which serve as points of attachment, and which are fixed to the upper plate, terminate in kneed branches whose extremities rest upon a rope *g*, which projects from the shaft. E, is an exterior envelope secured to the frame A, A. It encloses the whole drum except at top, and serves to catch the water thrown out of the goods. At *y* there is a stopcock for the discharge of this water, and the bottom contains besides the end of a pipe by which hot air is introduced.

The vertical shaft B receives a movement of rotation and carries with it the drum. The more rapid this movement is the more does the centrifugal force tend to expel the water contained in the clothes or yarn to be dried. But as this force might also displace the central shaft, if the weight was not rightly distributed in the drum, and cause the dislocation of the machine when the great velocity requisite for quick drying is given to it, the regulator D is tested to prevent accident. The branches of this regulator spread wider the more the velocity is increased, and raise consequently the drum C above the conical enlargements, which permits the drum to be somewhat misplaced and to rectify its position conformably to the inequalities of its load, so that its centre of gravity may always coincide with its centre of rotation. The drum is connected with the shaft as is shown in *z*, leaving it free to take the requisite adjustment. To hinder it from rising too suddenly, a spiral spring *k* is fixed over the shaft immediately above the conical enlargement *g*. In order to maintain the equilibrium more certainly, the apparatus is surrounded with a hollow crown F, half filled with water, and if during the revolution of the machine the weight of the goods predominates on one side, that of the water which accumulates on the other side serves the more to counterbalance it. The effect of this crown may be increased by dividing it

into two compartments or more. G, is a large pipe by which steam or hot air is introduced into the belly of the drum, which is pierced in this place with a great number of small holes to receive it.

The rotary movement is transmitted to the drum in the following way.

I is a conical disc mounted upon the extremity of a shaft which actuates the cone C and the shaft B by means of friction; L is a cone fixed upon the extremity of the shaft. K L " is another cone of the same dimension, but whose base fronts the top of the other and which is placed on the shaft K " commanded by the prime mover. M is the belt which embraces the two cones, and whose lateral displacement, effected by means of a fork, permits the velocity of the machine to be regulated at pleasure. N is the pulley which directly receives the movement. In place of a single friction disc I, another may be employed, if judged necessary, and placed between the two, an additional friction pole in order better to equalize the friction. In this case the disc and additional cone should turn freely upon their own shafts. We may also adopt another arrangement for the bottom of the vertical shaft. The shaft immediately above the step is surrounded by a loose rim, around which a certain quantity of lead shot, or other granular matter, is contained in the rim in the box which serves for the step. The top of this box is pierced with an opening, into which, when the machine is at rest, a cord connected with the shaft sinks, controlled by the shaft, and when the drum is raised by the action of the regulator D, this cord quits its place, which allows the shaft to displace the shot a little, and to take a position conformably to the point of the centre of gravity.

But after all great attention should be paid to the proper working of the machine.

DUCTILITY, (*Streckbarkeit*, Germ.) is the property of being drawn out in length without breaking, possessed in a pre-eminent degree by gold and silver, as also by many other metals, by glass in the liquid state, and by many semifluid, resinous, and gummy substances. The spider and the silkworm exhibit the finest natural exercise of ductility upon the peculiar viscid secretions from which they spin their threads. When a body can be readily extended in all directions under the hammer, it is said to be malleable, and when into fillets under the rolling press, it is said to be laminable.

Table of the Ductility and Malleability of Metals.

Metals Ductile and Malleable in Alphabetical Order.	Brittle Metals in Alphabetical Order.	Metals in the Order of their Wire-drawing Ductility.	Metals in the Order of their Laminable Ductility.
Cadmium.	Antimony.	Gold.	Gold.
Copper.	Arsenic.	Silver.	Silver.
Gold.	Bismuth.	Platinum.	Copper.
Iron.	Cerium?	Iron.	Tin.
Iridium.	Chromium.	Copper.	Platinum.
Lead.	Cobalt.	Zinc.	Lead.
Magnesium.	Columbium?	Tin.	Zinc.
Mercury.	Iridium.	Lead.	Iron.
Nickel.	Manganese.	Nickel.	Nickel.
Osmium.	Molybdenum.	Palladium?	Palladium?
Palladium.	Osmium.	Cadmium?	Cadmium?
Platinum.	Rhodium.		
Potassium.	Tellurium.		
Silver.	Titanium.		
Sodium.	Tungsten.		
Tin.	Uranium.		
Zinc.			

There appears to be therefore a real difference between ductility and malleability; for the metals which draw into the finest wire are not those which afford the thinnest leaves under the hammer or in the rolling press. Of this fact iron affords a good illustration. Among the metals permanent in the air, 17 are ductile and 16 are brittle. But the most ductile cannot be wire-drawn or laminated to any considerable extent without being annealed from time to time during the progress of the extension, or rather the sliding of the particles alongside of each other, so as to loosen their lateral cohesion.

DUNGING, in calico-printing, is the application of a bath of cowdung, diffused through hot water, to cotton goods in a particular stage of the manufacture. Dunging and scouring are commonly alternated, and are two of the most important steps in the process. The operation of dunging has for its objects: —

1. To determine the entire combination of the aluminous sub-salts with the stuffs, by

separating almost all the acetic acid which was not volatilized in the stove-drying of the mordant.

2. To dissolve and carry off from the cloth a portion of the thickening matters.

3. To separate from the cloth the part of the mordant that is uncombined, and merely mixed mechanically with the gum or starch.

4. To prevent, by the peculiar action of the dung, the uncombined mordant, as well as the acetic acid with which the bath is apt to get loaded, from affecting the blank parts of the cloth, or being injurious to the mordant.

The aluminous base or mordant on the cloth, more or less neutralized by the dunging, is next subjected to the dash-wheel or fulling mill, where by the stream of water the remainder of the thickening and other impurities are washed away.

No very exact analysis has been made of cowdung. Morin's, which is the most recent and elaborate, is as follows: —

Water	70·00
Vegetable fibre	24·08
Green resin and fat acids	1·52
Undecomposed biliary matter	0·60
Peculiar extractive matter (*bubuline*)	1·60
Albumen	0·40
Biliary resin	1·80

According to M. Kœchlin's practical knowledge on the great scale, it consists of a moist fibrous vegetable substance, which is animalized, and forms about one-tenth of its weight; 2. of albumen; 3. of animal mucus; 4. of a substance similar to bile; 5. of muriate of soda, muriate and acetate of ammonia, phosphate of lime and other salts; 6. of benzoin or musk.

Probably the hot water in which the calico-printer diffuses the dung, exerts a powerful solvent action, and in proportion as the uncombined mordant floats in the bath it is precipitated by the albumen, the animal mucus, and the ammoniacal salts; but there is reason to think that the fibrous matter in part animalized or covered with animal matter, plays here the principal part; for the great affinity of this substance for the aluminous salts is well known.

All practical men are aware that the affinity of cotton for alumina is increased by its combination with oil or animal substances, to such a degree as to take it from the dung bath; which would not be possible without this combination. It would therefore appear that the principal function of dunging is to hinder the uncombined mordant, diffused in the dung bath, from attaching itself to the unmordanted portion of the cloth, as already observed; for if we merely wished to abstract the thickening stuffs, or to complete by the removal of acetic acid the combination of the aluminous base with the goods, dung would not be required, for hot water would suffice. In fact, we may observe, that in such cases the first pieces passed through the boiler are fit for dyeing; but when a certain number have been passed through, the mordant now dissolved in the water is attracted to the white portions of the cloth, while the free acid impoverishes the mordanted parts, so that they cannot afford good dyes, and the blank spaces are tarnished.

The cow dung may be in some measure replaced by bran, but not with perfect success. The former both answers the purpose better and is cheaper. The bran is only preferred for the most delicate yellows, for cochineal pinks and lilacs, to which the dung may sometimes impart a greenish cast. It is to be presumed that the action of the bran in this process has much analogy with that of the dung, and that the ligneous fibre is the most active constituent; with which the gluten and mucilage co-operate, no doubt, in seizing the aluminous salts.

It seems to be ascertained that the mordant applied to the cloth does not combine entirely with it during the drying; that this combination is more or less perfect according to the strength of the mordants, and the circumstances of the drying; that the operation of dunging, or passing through hot water, completes the combination of the cloth with the aluminous base now insoluble in water; that this base may still contain a very minute quantity of acetic acid or sulphate of alumina; that a long ebullition in water impoverishes the mordant but a little; and that even then the liquid does not contain any perceptible quantity of acetate or subsulphate of alumina.

The manner of immersing the goods, or passing them through the dung bath, is an important circumstance. They should be properly extended and free from folds, which is secured by a series of cylinders.

The cistern is from 10 to 12 feet long, 4½ feet wide, and 6 or 8 feet deep. The piece passes alternately over the upper rollers and under rollers near the bottom. There are two main squeezing rollers at one end, which draw the cloth through between them. Whenever the goods come out of the bath they are put into the dash-wheel.

The immersion should take place as fast as possible, for the moment the hot water penetrates the mordanted cloth, the acetic acid quits it; and, therefore, if the immersion was made slowly or one ply after another, the acid as well as the uncombined mordant become free, would spread their influence, and would have time to dissolve the aluminous subsalts now combined with the cloth; whence inequalities and impoverishment of the colours would ensue.

It is difficult to determine the number of pieces which may be passed through a given quantity of dung and water. This depends upon the state of the mordants, whether they are strong or acid, and on the quantity of the surface covered with the figures. The number varies usually from 20 to 60 pieces, for from 240 to 300 gallons of water and 6 gallons of dung. The time of the immersion varies with the concentration of the mordants, and the nature of their thickening. The temperature must be regulated by the same circumstances; for starch or flour paste a much warmer bath is needed than for gum. The heat varies usually from 130° to 212° F. When the printing is heavy and the thickening is starch or flour, the goods are usually twice dunged, with two washings between the two dungs. A strong acid mordant is more difficult to dung and to wash than a neutral mordant, especially when it is to receive the madder dye. Sometimes a little chalk is added to the bath, when the goods have been padded in an acid mordant. Too much dung is injurious to weak mordants, as well as to pinks. It has also been remarked that a mordant when neutralized does not produce as brilliant tints, especially yellows. The latter are obtained of a finer shade when, instead of dunging, they are exposed for an hour in a stream of water, provided its temperature is not too low. In winter they are passed through a slightly chalky water, then washed at the wheel, and dyed in quercitron or weld.

A very able and learned memoir upon this subject, by M. Penot, Professor of Chemistry, appeared in the Bulletin of the Society of Mulhausen, in October, 1834, with an ingenious commentary upon it, under the title of a Report by M. Camille Kœchlin, in March, 1835.

Experience has proved that dunging is one of the most important steps in the process of calico printing, and that if it be not well performed the dyeing is good for nothing. Before we can assign its peculiar function to the dung in this case, we must know its composition. Fresh cow's dung is commonly neutral when tested by litmus paper; but sometimes it is slightly alkaline, owing, probably, to some peculiarity in the food of the animal.

The total constituents of 100 parts of cow dung are as follows: Water, 69·58; bitter matter, 0·74; sweet substance, 0·93; chlorophylle, 0·28; albumine, 0·63; muriate of soda, 0·08; sulphate of potash, 0·05; sulphate of lime, 0·25; carbonate of lime, 0·24; phosphate of lime, 0·46; carbonate of iron, 0·09; woody fibre, 26·39; silica, 0·14; loss, 0·14.

In dunging calicoes the excess of uncombined mordant is in part attracted by the soluble matters of the cow's dung, and forms an insoluble precipitate, which has no affinity for the cloth, especially in presence of the insoluble part of the dung, which strongly attracts alumina. The most important part which that insoluble matter plays, is to seize the excess of the mordants, in proportion as they are dissolved by the water of the bath, and thus to render their reaction upon the cloth impossible. It is only in the deposit, therefore, that the matters carried off from the cloth by the dung are to be found.

M. Camille Kœchlin ascribes the action of cow dung chiefly to its albuminous constituent, combining with the alumina and iron, of the acetates of these bases dissolved by the hot water of the bath. The acids consequently set free, soon become evident by the test of litmus paper, after a few pieces are passed through, and require to be got rid off either by a fresh bath or by adding chalk to the old one. The dung thus serves also to fix the bases on the cloth, when used in moderation. It exercises likewise a disoxidating power on the iron mordant, and restores it to a state more fit to combine with colouring matter. See Cow dung.

DYEING, (*Teinture*, Fr.; *Fürberei*, Germ.) is the art of impregnating wool, silk, cotton, linen, hair, and skins, with colours not removable by washing, or the ordinary usage to which these fibrous bodies are exposed when worked up into articles of furniture or raiment. I shall here consider the general principles of the art, referring for the particular dyes, and peculiar treatment of the stuffs to be dyed, to the different tinctorial substances in their alphabetical places; such as cochineal, indigo, madder, &c.

Dyeing is altogether a chemical process, and requires for its due explanation and practice an acquaintance with the properties of the elementary bodies, and the laws which regulate their combinations. It is true that many operations of this, as of other chemical arts, have been practised from the most antient times, long before any just views were entertained of the nature of the changes that took place. Mankind, equally in the rudest and most refined state, have always sought to gratify the love of distinction

by staining their dress sometimes even their skin, with gaudy colours. Moses speaks of raiment dyed blue, and purple, and scarlet, and of sheep-skins dyed red; circumstances which indicate no small degree of tinctorial skill. He enjoins purple stuffs for the works of the tabernacle and the vestments of the high priest.

In the article Calico Painting, I have shown from Pliny that the antient Egyptians cultivated that art with some degree of scientific precision, since they knew the use of mordants, or those substances which, though they may impart no colour themselves, yet enable white robes (*candida vela*) to absorb colouring drugs (*colorem sorbentibus medicamentis*). Tyre, however, was the nation of antiquity which made dyeing its chief occupation and the staple of its commerce. There is little doubt that purple, the sacred symbol of royal and sacerdotal dignity, was a colour discovered in that city, and that it contributed to its opulence and grandeur. Homer marks no less the value than the antiquity of this dye, by describing his heroes as arrayed in purple robes. Purple habits are mentioned among the presents made to Gideon by the Israelites from the spoils of the kings of Midian.

The juice employed for communicating this dye was obtained from two different kinds of shell-fish, described by Pliny under the names of *purpura* and *buccinum*; and was extracted from a small vessel, or sac, in their throats, to the amount of only one drop from each animal. A darker and inferior colour was also procured by crushing the whole substance of the buccinum. A certain quantity of the juice collected from a vast number of shells being treated with sea-salt, was allowed to ripen for three days; after which it was diluted with five times its bulk of water, kept at a moderate heat for six days more, occasionally skimmed to separate the animal membranes, and when thus clarified was applied directly as a dye to white wool, previously prepared for this purpose by the action of lime-water, or of a species of lichen called fucus. Two operations were requisite to communicate the finest Tyrian purple; the first consisted in plunging the wool into the juice of the purpura; the second, into that of the buccinum. Fifty drachms of wool required one hundred of the former liquor, and two hundred of the latter. Sometimes a preliminary tint was given with coccus, the kermes of the present day, and the cloth received merely a finish from the precious animal juice. The colours, though probably not nearly so brilliant as those producible by our cochineal, seem to have been very durable, for Plutarch says, in his *Life of Alexander*, (chap. 36.), that the Greeks found in the treasury of the king of Persia a large quantity of purple cloth, which was as beautiful as at first, though it was 190 years old.*

The difficulty of collecting the purple juice, and the tedious complication of the dyeing process, made the purple wool of Tyre so expensive at Rome that in the time of Augustus a pound of it cost nearly 30*l.* of our money. † Notwithstanding this enormous price, such was the wealth accumulated in that capital, that many of its leading citizens decorated themselves in purple attire, till the emperors arrogated to themselves the privilege of wearing purple, and prohibited its use to every other person. This prohibition operated so much to discourage this curious art as eventually to occasion its extinction, first in the western and then in the eastern empire, where, however, it existed in certain imperial manufactories till the eleventh century.

Dyeing was little cultivated in antient Greece; the people of Athens wore generally woollen dresses of the natural colour. But the Romans must have bestowed some pains upon this art. In the games of the circus parties were distinguished by colours. Four of these are described by Pliny, the green, the orange, the grey, and the white. The following ingredients were used by their dyers. A crude native alum mixed with copperas, copperas itself, blue vitriol, alkanet, lichen rocellus, or archil, broom, madder, woad, nut-galls, the seeds of pomegranate, and of an Egyptian acacia.

Gage, Cole, Plumier, Reaumur, and Duhamel have severally made researches concerning the colouring juices of shell-fish caught on various shores of the ocean, and have succeeded in forming a purple dye, but they found it much inferior to that furnished by other means. The juice of the buccinum is at first white; it becomes by exposure to air of a yellowish green bordering on blue; it afterwards reddens, and finally changes to a deep purple of considerable vivacity. These circumstances coincide with the minute description of the manner of catching the purple-dye shell-fish which we possess in the work of an eye-witness, Eudocia Macrembolitissa, daughter of the Emperor Constantine VIII., who lived in the eleventh century.

The moderns have obtained from the New World several dye-drugs unknown to the antients; such as cochineal, quercitron, Brazil wood, logwood, annatto; and they have

* 'Among other things, there was purple of Hermione (?) to the amount of five thousand talents.' (Plutarch's Lives, translated by Langhorne, Wrangham's edition, vol. v. p. 240.) Horace celebrates the Laconian dye in the following lines:—

Nec Laconicas mihi
Trahunt honestæ purpuras clientæ.
(Carm., lib. ii., Ode 18.)

† Pliny says that a pound of the double-dipped Tyrian purple was sold in Rome for a hundred crowns.

discovered the art of using indigo as a dye, which the Romans knew only as a pigment. But the vast superiority of our dyes over those of former times must be ascribed principally to the employment of pure alum and solution of tin as mordants, either alone or mixed with other bases; substances which give to our common dye-stuffs remarkable depth, durability, and lustre. Another improvment in dyeing of more recent date is the application to textile substances of metallic compounds, such as Prussian blue, chrome yellow, manganese brown, &c.

"Indigo, the innoxious and beautiful product of an interesting tribe of tropical plants, which is adapted to form the most useful and substantial of all dyes, was actually denounced as a dangerous drug, and forbidden to be used, by our parliament in the reign of Queen Elizabeth. An act was passed authorizing searchers to burn both it and logwood in every dye-house where they could be found. This act remained in full force till the time of Charles II.; that is, for a great part of a century. A foreigner might have supposed that the legislators of England entertained such an affection for their native woad, with which their naked sires used to dye their skins in the old times, that they would allow no outlandish drug to come in competition with it. A most instructive book might be written illustrative of the evils inflicted upon arts, manufactures, and commerce, in consequence of the ignorance of the legislature.*

Colours are not, properly speaking, material; they are impressions which we receive from the rays of light reflected, in a decomposed state, by the surfaces of bodies. It is well known that a white sunbeam consists of an indeterminate number of differently coloured rays, which being separated by the refractive force of a glass prism, form the solar spectrum, an image distinguishable into seven sorts of rays; the red, orange, yellow, green, blue, indigo, and violet. Hence, when an opaque body appears coloured, for example, red, we say that it reflects the red rays only, or in greatest abundance, mixed with more or less of the white beam, which has escaped decomposition. According to this manner of viewing the colouring principle, the art of dyeing consists in fixing upon stuffs, by means of corpuscular attraction, substances which act upon light in a different manner from the surfaces of the stuffs themselves. The dyer ought, therefore, to be familiar with two principles of optics; the first relatively to the mixture of colours, and the second to their simultaneous contrast.

Whenever the different coloured rays, which have been separated by the prism, are totally reunited, they reproduce white light. It is evident, that in this composition of light, if some rays were left out, or if the coloured rays be not in a certain proportion, we should not have white light, but light of a certain colour. For example; if we separate the red rays from the light decomposed by a prism, the remaining coloured rays will form by their combination a peculiar bluish green. If we separate in like manner the orange rays, the remaining coloured rays will form by their combination a blue colour. If we separate from the decomposed prismatic light the rays of greenish yellow, the remaining coloured rays will form a violet. And if we separate the rays of yellow bordering on orange, the remaining coloured rays will form by their union an indigo colour.

Thus we see that every coloured light has such a relation with another coloured light that, by uniting the first with the second, we reproduce white light; a relation which we express by saying that the one is the complement of the other. In this sense, red is the complementary colour of bluish green; orange, of blue; greenish yellow, of violet; and orange yellow, of indigo. If we mix the yellow ray with the red, we produce orange; the blue ray with the yellow, we produce green; and the blue with the red, we produce violet or indigo, according as there is more or less red relatively to the blue. But these tints are distinguishable from the orange, green, indigo, and violet of the solar spectrum, because when viewed through the prism they are reduced to their elementary component colours.

If the dyer tries to realize the preceding results by the mixture of dyes, he will succeed only with a certain number of them. Thus, with red and yellow he can make orange; with blue and yellow, green; with blue and red, indigo or violet. These facts, the results of practice, have led him to conclude that there are only three primitive colours; the red, yellow, and blue. If he attempts to make a white, by applying red, yellow, and blue dyes in certain quantities to a white stuff, in imitation of the philosopher's experiment on the synthesis of the sunbeam, far from succeeding, he will deviate still further from his purpose, since the stuff will by these dyes become so dark coloured, as to appear black.

This fact must not, however, lead us to suppose that in every case where red, yellow, and blue are applied to white cloth, black is produced. In reality, when a little ultramarine, cobalt blue, Prussian blue, or indigo, is applied to goods with the view of giving them the best possible white, if only a certain proportion be used, the goods will appear whiter after this addition than before it. What happens in this case? The violet blue

* Author, in Penny Cyclopedia.

forms, with the brown yellow of the goods, a mixture tending to white, or less coloured than the yellow of the goods and the blue together were. For the same reason, a mixture of prussian blue and cochineal pink has been of late years used in the whitening or the azuring of silks, in preference to a pure blue; for on examining closely the colour of the silk to be neutralized, it was found by the relations of the complementary colours, that the violet was more suitable than the indigo blue formerly used. The dyer should know, that when he applies several different colouring matters to stuffs, as yellow and blue, for example, if they appear green, it is because the eye cannot distinguish the points which reflect the yellow from those which reflect the blue; and that, consequently, it is only where the distinction is not possible, that a mixture or combination appears. When we examine certain gray substances, such as hairs, feathers, &c., with the microscope, we see that the gray colour results from black points, disseminated over a colourless or slightly coloured surface. In reference to compound colours, this instrument might be used with advantage by the dyer.

The dyer should be acquainted also with the law of the simultaneous contrast of colours. When the eye views two colours close alongside of each other, it sees them differing most in their optical composition, and in the height of their tone, when the two are not equally pale or full-bodied. They appear most different as to their optical composition, when the complementary of the one of them is added to the colour of the other. Thus, put a green zone alongside of an orange zone; the red colour complementary of green, being added to the orange, will make it appear redder; and in like manner the blue, complementary of orange, being added to the green, will make it appear more intensely blue. In order to appreciate these differences, let us take two green stripes and two orange stripes, placing one of the green stripes near one of the orange; then place the two others so that the green stripe may be at a distance from the other green stripe, but on the same side, and the orange at a distance from the other orange, also on the same side.

As to the contrast in the height of the tone, we may satisfy ourselves by taking the tones No. 1. No. 2. No. 15. and No. 16. from a graduated pallet of reds: for example, by placing No. 2. and No. 15. close alongside, putting No. 1. at a distance from No. 2. on the same side, and No. 16. at a distance from No. 15. on the same side, — we shall see (if the pallet is sufficiently lowered in tone) No. 2. equal to No. 1., and No. 15. equal to No. 16.; whence it follows that No. 2., by the vicinity of No. 15., will appear to have lost some of its colour; while No. 15. will appear to have acquired colour. When black or gray figures are printed upon coloured grounds, these figures are of the colour complementary of the ground. Consequently, in order to judge of their colour, we must cut out spaces in a piece of gray or white paper, so as to allow the eye to see nothing but the figures; and if we wish to compare figures of the same colour, applied upon grounds of different colours, we can judge rightly of the figures only by insulating them from the grounds.

The relations of dyeing with the principles of chemistry, constitute the theory of the art, properly speaking; this theory has for its basis, the knowledge — 1. of the species of bodies which dyeing processes bring into contact; 2. of the circumstances in which these species act; 3. of the phenomena which appear during their action; and 4. of the properties of the coloured combinations which are produced. These generalities may be specified under the ten following heads: —

1. The preparation of the stuffs to be dyed, whether fibres, yarn, or cloth; under the heads of ligneous matter, cotton, hemp, flax; and of the animal matters, silk and wool.
2. The mutual action of these stuffs, and simple bodies.
3. The mutual action of these stuffs, and acids.
4. The mutual action of these stuffs, and salifiable bases, as alumina, &c.
5. The mutual action of these stuffs, and salts.
6. The mutual action of these stuffs, and neutral compounds not saline.
7. The mutual action of these stuffs, and of one or more definite compounds.
8. Of dyed stuffs considered in reference to the fastness of their colour, under the influence of heat, light, water, oxygen, air, boilings with soap, and reagents.
9. Of dyeing, considered in its connections with chemistry.
10. Of dyeing, considered in its relations with caloric, mechanics, hydraulics, and optics.

1. The preparation of stuffs.

The operations to which stuffs are subjected before dyeing, are intended — 1. to separate from them any foreign matters; 2. to render them more apt to unite with the colouring tinctures which the dyer proposes to fix upon them, in order to give them a more agreeable, or more brilliant aspect, or to lessen their tendency to assume a soiled appearance by use, which white surfaces so readily do. The foreign matters are either naturally inherent in the stuffs, or added to them in the spinning, weaving, or other

manipulations of manufacture. The ligneous fibres must be freed from the coloured azotized varnish on their surface, from a yellow colouring matter in their substance, from some lime and iron, from chlorophylle or leaf-green, and from pectic acid; all natural combinations. Some of these principles require to be oxygenized, before alkaline lyes can cleanse them, as I have stated in the article BLEACHING, which may be consulted in reference to this subject. See also SILK and WOOL. A weak bath of soda has the property of preparing wool for taking on a uniform dye, but it must be well rinsed and aired before being put into the dye-vat.

2. Mutual action of stuffs, and simple bodies.

Stuffs chemically considered being composed of three or four elements, already in a state of reciprocal saturation, have but a feeble attraction for simple substances. We know in fact, that the latter combine only with each other, or with binary compounds, and that in the greater number of cases where they exert an action upon more complete compounds, it is by disturbing the arrangement of their elements, and not by a resulting affinity with the whole together.

3, 4. Although stuffs may in a general point of view be considered as neutral in relation to colouring reagents, yet experience shows that they are more disposed to combine with acid than with alkaline compounds; and that consequently their nature seems to be more alkaline than acid. By steeping dry wool or other stuff in a clean state in an alkaline or acid solution of known strength, and by testing the liquor after the stuff is taken out, we shall ascertain whether there be any real affinity between them, by the solution being rendered more dilute in consequence of the abstraction of alkaline or acid particles from it. Wool and silk thus immersed, abstract a portion of both sulphuric and muriatic acids; but cotton and flax imbibe the water, with the rejection of a portion of the acid. The acid may be again taken from the stuffs by washing them with a sufficient quantity of water.

5. The affinity between saline bodies and stuffs may be ascertained in the same way as that of acids, by plunging the dry stuffs into solutions of the salts, and determining the density of the solution before the immersion, and after withdrawing the stuffs. Wool abstracts alum from its solution, but it gives it all out again to boiling water. The sulphates of protoxide of iron, of copper and zinc resemble alum in this respect. When silk is steeped for some time in solution of protosulphate of iron, it abstracts the oxide, gets thereby dyed, and leaves the solution acidulous. Wool put in contact with cream of tartar decomposes a portion of it; it absorbs the acid into its pores, and leaves a neutral salt in the liquor. The study of the action of salts upon stuffs is at the present day the foundation of the theory of dyeing; and some of them are employed immediately as dye-drugs.

6. Mutual action of stuffs, and neutral compounds not saline.

Several sulphurets, such as those of arsenic, lead, copper, antimony, tin, are susceptible of being applied to stuffs, and of dyeing them in a more or less fast manner. Indigo, hematine, breziline, carmine, and the peculiar colouring principles of many dyes belong to this division.

7. Mutual action of goods with one or more definite compounds, and dye-stuffs.

I shall consider here in a theoretical point of view, the most general results which a certain number of organic colouring matters present, when applied upon stuffs by the dyer.

Indigo. This dye-drug, when tolerably good, contains half its weight of indigotine. The cold vat is prepared commonly with water, copperas, indigo, lime, or sometimes carbonate of soda, and is used almost exclusively for cotton and linen; immersion in acidulated water is occasionally had recourse to for removing a little oxide of iron which attaches itself to the cloth dyed in this vat.

The indigo vat for wool and silk is mounted exclusively with indigo, good potashes of commerce, madder and bran. In this vat, the immediate principles with base of carbon and hydrogen, such as the extracts of madder and bran, perform the disoxidizing function of the copperas in the cold vat. The pastel vats require most skill and experience, in consequence of their complexity. The greatest difficulty occurs in keeping them in a good condition, because they vary progressively as the dyeing goes on, by the abstraction of the indigotine, and the modification of the fermentable matter employed to disoxygenate the indigo. The alkaline matter also changes by the action of the air. By the successive additions of indigo, alkali, &c., this vat becomes very difficult to manage with profit and success. The great affair of the dyer is the proper addition of lime; too much or too little being equally injurious.

Sulphate of indigo or Saxon blue is used also to dye silk and wool. If the wools be ill sorted it will show their differences by the inequalities of the dye. Wool dyed in this bath put into water saturated with sulphuretted hydrogen, becomes soon colourless, owing to the disoxygenation of the indigo. The woollen cloth when exposed to the air for some time, resumes its blue colour, but not so intensely as before.

The properties of hematine explain the mode of using logwood. When stuffs are dyed in the infusion or decoction of this wood, under the influence of a base which acts upon the hematine in the manner of an alkali, a blue dye bordering upon violet is obtained. Such is the process for dyeing cotton and wool a logwood blue by means of verdigris, crystallized acetate of copper, and acetate of alumina.

When we dye a stuff yellow, red, or orange, we have always bright tints; with blue we may have a very dark shade, but somewhat violet; the proper black can be obtained only by using the three colours, blue, red, and yellow, in proper proportions. Hence we can explain how the tints of yellow, red, orange, blue, green, and violet, may be browned, by applying to them one or two colours which along with themselves would produce black; and also we may explain the nature of that variety of blacks and grays which seems to be indefinite. Nutgalls and sulphate of iron, so frequently employed for the black dye, give only a violet or bluish gray. The pyrolignite of iron, which contains a brown empyreumatic matter, gives to stuffs a brown tint, bordering upon greenish yellow in the pale hues, and to chestnut brown in the dark ones. By galling cotton and silk, and giving them a bath of pyrolignite of iron, we may after some alternations dye them black. Galls, logwood, and a salt of iron; produce merely a very deep violet blue; but by boiling and exposure to air, the hematate of iron is changed, becoming red-brown, and favours the production of black. Galls and salts of copper, dye stuffs an olive drab, logwood and salts of copper a violet blue; hence their combination should produce a black. In using sumach as a substitute for galls, we should take into account the proportion of yellow matter it contains. When the best possible black is wanted upon wool, we must give the stuff a foundation of indigo, then pass it into a bath of logwood, sumach, and proto-sulphate of iron. The sumach may be replaced by one third of its weight of nutgalls.

8. Of dyed stuffs considered in reference to the fastness of their colours, when exposed to water, light, heat, air, oxygen, boiling and reagents.

Pure water without air has no action upon any properly dyed stuff.

Heat favours the action of certain oxygenized bodies upon the carbonaceous and hydrogenous constituents of the stuff; as is seen with regard to chromic acid, and peroxide of manganese upon cotton goods. It promotes the solvent action of water, and it even affects some colours. Thus Prussian blue applied to silk, is reduced to peroxide of iron by long boiling.

Light without contact of air affects very few dyes.

Oxygen, especially in the nascent state, is very powerful upon dyes. See BLEACHING.

The atmosphere in a somewhat moist state affects many dyes, at an elevated temperature. Silk dyed pink, with safflower, when heated to 400° F. becomes of a dirty white hue in the course of an hour. The violet of logwood upon alumed wool becomes of a dull brown at the same temperature in the same time. But both stand a heat of 300° F. Brazil red dye, turmeric, and weld yellow dyes display the same phenomena. These facts shew the great fixity of colours commonly deemed tender. The stuffs become affected to a certain degree, under the same circumstances as the dyes. The alterability even of indigo in the air is shewn in the wearing of pale blue clothes; in the dark blue cloth there is such a body of colour, that it resists proportionally longer; but the seams of coats exhibit the effect very distinctly. In silk window curtains, which have been long exposed to the air and light, the stuff is found to be decomposed as well as the colour.

Boiling was formerly prescribed in France as a test of fast dyes. It consisted in putting a sample of the dyed goods in boiling water, holding in solution a determinate quantity of alum, tartar, soap, and vinegar, &c. Dufay improved that barbarous test. He considered that fast-dyed cloth could be recognized by resisting an exposure of twelve hours to the sunshine of summer, and to the midnight dews; or of sixteen days in winter.

In trying the stability of dyes, we may offer the following rules: —

That every stuff should be exposed to the light and air; if it be intended to be worn abroad, it should be exposed also to the wind and rain; that carpets moreover should be subjected to friction and pulling, to prove their tenacity; and that cloths to be washed should be exposed to the action of hot water and soap.

In examining a piece of dyed cotton goods, we may proceed as follows: —

Suppose its colour to be orange-brown. We find first that it imparts no colour to boiling water; that protochloride of tin takes out its colour; that plunged into a solution of ferroprussiate of potash it becomes blue; and that a piece of it being burned, leaves a residuum of peroxide of iron; we may thence conclude that the dyeing matter is peroxide of iron.

Suppose we have a blue stuff which may have been dyed either with indigo or with Prussian blue, and we wish to know what it will become in use. We inquire first into the nature of the blue. Hot water slightly alkaline will be coloured blue by it, if

it has been dyed with sulphate of indigo; it will not be coloured if it was dyed in the indigo vat, but it will become yellow by nitric acid. Boiling water, without becoming coloured itself, will destroy the Prussian blue dye; an alkaline water will convert its colour into an iron rust tint; nitric acid, which makes the indigo dye yellow, makes that of Prussian blue green. The liquor resulting from boiling alkaline water on the Prussian blue cloth, will convert sulphate of iron into Prussian blue.

9. Division. Of dyeing viewed in its relation to chemistry.

The phenomena of dyeing have been ascribed to very different causes; by some they were supposed to depend upon mechanical causes, and by others upon the forces from which chemical effects flow. Hellot, in conformity with the first mode of explanation, thought that the art of dyeing consisted essentially in opening the pores in order to admit colouring matters into them, and to fix them there by cooling, or by means of a mordant imagined to act like a cement.

Dufay in 1737, Bergmann in 1776, Macquer in 1778, and Berthollet in 1790, had recourse to chemical affinities, to explain the fixation of the colouring principles upon stuffs, either without an intermedium, like indigo, walnut peels, annotto; or by the intervention of an acid, a salifiable base, or a salt, which were called mordants. When bodies present phenomena which we refer to an attraction uniting particles of the same nature, whether simple or compound, to form an aggregate, or to an affinity which unites the particles of different natures to form them into a chemical compound, these bodies are in apparent contact. This happens precisely in all the cases of the mutual action of bodies in an operation of dyeing; if their particles were not in apparent contact, there would be absolutely no change in their respective condition. When we see stuffs and metallic oxides in apparent contact, form a mutual union of greater or less force, we cannot therefore help referring it to affinity. We do not know how many dyes may be fixed upon the same piece of cloth; but in the operations of the dye-house sufficiently complex compounds are formed, since they are always stuffs, composed of three or four elements, which are combined with at least binary acid or basic compounds; with simple salts compounded themselves of two immediate principles at least binary; with double salts composed of two simple salts; and finally with organic dye-stuffs containing three or four elements. We may add that different species belonging to one of these classes, and different species belonging to different classes, may unite simultaneously with one stuff. The union of stuffs with colouring matters appears, in general, not to take place in definite proportions; though there are probably some exceptions.

We may conclude this head by remarking, that, besides the stuff and the colouring matter, it is not necessary, in dyeing, to distinguish a third body, under the name of *mordant*; for the idea of mordant does not rest upon any definite fact; the body to which this name has been given being essentially only one of the immediate principles of the coloured combination which we wish to fix upon the stuff.

10. Division. Of dyeing in its relation with caloric, mechanics, hydraulics, pneumatics, and optics.

Dyeing baths, or coppers, are heated directly by a furnace, or by means of steam conducted in a pipe from a boiler at a certain distance from the bath. In the first case, the vessels are almost always made of copper; only, in special cases, for the scarlet and some delicate silk dyes, of tin; in the second case, they are of copper, iron, or wood. A direct fire is more economical than heating steam pipes, where there is only one or two baths to heat, or where the labours are often suspended. Madder and indigo vats, when heated by steam, have it either admitted directly into the liquor, or made to circulate through pipes plunged into it, or between the copper and an exterior iron or wood case. See the end of this article.

Every thing else being equal, dyeing with heat presents fewer difficulties towards obtaining an evenly colour, than dyeing in the cold; the reason of which may be found in the following facts: — The air adhering to the surface of stuffs, and that interposed between the fibres of their constituent yarns, is more easily extricated in a hot bath than a cold one, and thus allows the dye liquor to penetrate more easily into their interior: in the second place, the currents which take place in a hot bath, and which tend incessantly to render its contents uniform, by renewing continually the strata of liquid in contact with the stuff, contribute mainly to render the dyeing evenly. In cold dyeing, it is necessary to stir up the bath from time to time; and when goods are first put in, they must be carefully dipped, then taken out, pressed, and wrung, several times in succession till they be uniformly moistened.

The mechanical relations are to be found in the apparatus employed for wincing, siring, and pressing the goods, as we have described under Calico Printing and Bandana. The hydraulic relations refer to the wash-wheels and other similar apparatus, of which an account is given under the same articles. The optical relations

have been already considered. In the sequel of this article an automatic dyeing vat will be described.

The extracts of solutions of native dye-stuffs may be divided into two classes, in reference to their habitudes with the oxygen of the atmosphere; such as continue essentially unaltered in the air, and such as suffer oxidation, and thereby precipitate a determinate colouring matter. The dyes contained in the watery infusions of the different vegetable and animal substances which do not belong to the second class, are feebly attached to their solvents, and quit them readily for any other bodies that possess an attraction for them. On this principle, a decoction of cochineal, logwood, brazil wood, or a solution of sulphate of indigo, by digestion with powdered bone black, lose their colour, in consequence of the colouring particles combining by a kind of capillary attraction with the porous carbon, without undergoing any change. The same thing happens when well-scoured wool is steeped in such coloured liquids; and the colours which the wool assumes by its attraction for the dye, is, with regard to most of the above coloured solutions, but feeble and fugitive, since the dye may be again abstracted by copious washing with simple water, whose attractive force therefore overcomes that of the wool. The aid of a high temperature, indeed, is requisite for the abstraction of the colour from the wool and the bone-black, probably by enlarging the size of the pores, and increasing the solvent power of the water.

Those dye-baths, on the contrary, whose colouring matter is of the nature of extractive or apothème, form a faster combination with stuffs. Thus the yellow, fawn, and brown dyes, which contain tannin and extractive, become oxygenated by contact of air, and insoluble in water; by which means they can impart a durable dye. When wool is impregnated with decoctions of that kind, its pores get charged by capillarity, and when the liquid becomes oxygenated, they remain filled with a colour now become insoluble in water. A similar change to insolubility ensues when the yellow liquor of the indigo vat gets oxidized in the pores of cotton and wool, into which it had been introduced in a fluid state. The same change occurs when protosulphate of iron is converted into persulphate, with the deposition of an insoluble peroxide in the substance of the stuff. The change here effected by oxidation can, in other circumstances, be produced by acids which have the power of precipitating the dye-stuff in an insoluble state, as happens with decoction of fustic.

Hence we perceive that the dyeing of fast colours rests upon the principle, that the colours dissolved in the vat, during their union with the stuff, should suffer such a change as to become insoluble in their former menstruum. The more this dye, as altered in its union with the stuff, can resist other menstrua or agents, the faster it will be. This is the essential difference between dyeing and painting; or applying a coat of pigment devoid of any true affinity for the surface.

If we mix a clear infusion of a dye with a small quantity of a solution of an earthy or metallic salt, both in water, the limpid liquids soon become turbid, and there gradually subsides sooner or later, according to the nature of the mixture, a coloured precipitate, consisting of the altered dye united with a basic or subsalt. In this compound the colouring matter seems to act the part of an acid, which is saturated by a small quantity of the basis, or in its acid relationship is feeble, so that it can also combine with acids, being in reference to them a base. The decomposition of a salt, as alum, by dyes, is effected principally through the formation of an insoluble subsalt, with which the colour combines, while a supersalt remains in the bath, and modifies, by its solvent reaction, the shade of the dyed stuff. Dyed stuffs may be considered as composed of the fibrous body intimately associated with the colouring matter, the oxide, and acid, all three constituting a compound salt. Many persons have erroneously imagined, that dyed goods contained none of the acid employed in the dye bath; but they forget that even potash added to alum does not throw down the pure earthy basis, but a subsalt; and they should not ascribe to colouring matter a power of decomposition at all approaching to that of an alkali. Salts, containing strong acids, saturate a very large quantity of colouring matter, in proportion to their place in the scale of chemical equivalents. Mere bases, such as pure alumina, and pure oxide of tin, have no power of precipitating colouring matter; when they seem to do so, they always contain some acid.

Such salts, therefore, as have a tendency to pass readily into the basic state, are peculiarly adapted to act as mordants in dyeing, and to form coloured lakes. Magnesia affords as fine a white powder as alumina, and answers equally well to dilute lakes, but its soluble salts cannot be employed to form lakes, because they do not pass into the basic state. This illustration is calculated to throw much light upon dyeing processes in general.

The colour of the lake depends very much upon the nature of the acid, and the basis of the precipitating salt. If it be white, like alumina and oxide of tin, the lake will have, more or less, the colour of the dye, but brightened by the reflection of white

light from the basis; while the difference of the acid occasions a difference in the hue. The coloured bases impart more or less of their colour to the lakes, not merely in virtue of their own tints, but of their chemical action upon the dye.

Upon these principles a crimson precipitate is obtained from infusions of cochineal by alum and salt of tin, which becomes scarlet by the addition of tartar; by acetate of lead, a violet blue precipitate is obtained, which is durable in the air; by muriate of lime, a pink brown precipitate falls, which soon becomes black, and at last dirty green; by the solution of a ferruginous salt, the precipitates are dark violet, and black; and, in like manner, all other salts with earthy or metallic bases, afford diversities of shade with cochineal. If this dye stuff be dissolved in weak water of ammonia, and be precipitated with acetate of lead, a green lake is obtained, which, after some time, will become green on the surface by contact of air, but violet and blue beneath. Hence it appears, that the shade of colour of a lake depends upon the degree of oxidation or change of the colour caused by the acid of the precipitating salt, upon the degree of oxidation or colour of the oxide which enters into union with the dye, and upon its quantity in reference to that of the colouring principle.

Such lakes are the difficultly soluble salts which constitute the dyeing materials of stuffs. Their particles, however, for the purposes of dyeing, must exist in a state of extremely fine division in the bath liquor, in order that they may penetrate along with it into the minute pores of textile fibres, and fill the cavities observed by means of the microscope in the filaments of wool, silk, cotton, and flax. I have examined these stuffs with an achromatic microscope, and find that when they are properly dyed with fast colours, the interior of their tubular texture is filled, or lined at least, with colouring matter. When the bath contains the colouring particles, so finely divided that they can pass through filtering paper, it is capable of dyeing; but if the infusion mixed with its mordant be flocculent and ready to subside, it is unfit for the purpose. In the latter case, the ingredients of the dye have already become aggregated into compounds too coherent and too gross for entering into combination with fibrous stuffs. Extractive matter and tannin are particularly liable to a change of this kind, by the prolonged action of heat in the bath. Hence also an alkaline solution of a colouring matter, affords no useful dye bath, when mixed with the solution of a salt having an earthy or metallic basis.

These circumstances, which are of frequent occurrence in the dye-house, render it necessary always to have the laky matter in a somewhat soluble condition, and to effect its precipitation within the pores of the stuffs, by previously impregnating them with the saline solutions by the aid of heat, which facilitates their introduction.

When a mordant is applied to any stuff, the portion of it remaining upon the surface of the fibres should be removed; since, by its combination with the colouring matter, it would be apt to form an external crust of mere pigment, which would block up the pores, obstruct the entrance of the dye into the interior, and also exhaust to no purpose the dyeing power of the bath. For this reason the stuffs, after the application of the mordant, are drained, squeezed, washed, and sometimes (particularly with cotton and linen, in calico printing), even hard dried in a hot stove.

The saline mordants, moreover, should not in general possess the crystallizing property in any considerable degree, as this opposes their affinity of composition for the cloth. On this account the deliquescent acetates of iron and alumina are more ready to aid the dyeing of cotton than copperas and alum.

Alum is the great mordant employed in wool dyeing. It is frequently dissolved in water, holding tartar equal to one fourth the weight of the alum in solution; by which addition its tendency to crystallize is diminished, and the resulting colour is brightened. The alum and tartar combine with the stuff without suffering any change, and are decomposed only by the action of the colouring matters in the dye bath. The alum operates solely in virtue of its sulphuric acid, and earthy basis; the sulphate of potash present in that salt being rather injurious. Hence, if a sulphate of alumina free from iron could be readily obtained, it would prove a preferable mordant to alum. It is also probable, for the reasons above assigned, that soda alum, a salt much less apt to crystallize than potash or ammonia alum, would suit the dyer very well. In order to counteract the tendency of common alum to crystallize, and to promote its tendency to pass into a basic salt, one eighth part of its weight of potash is added to its solution, or the equivalent in chalk or soda.

We shall conclude this account of the general principles of dyeing, with Mr. Delaval's observations on the nature of dyes, and a list of the different substances used in dyeing, in reference to the colours produced by them.

Sir Isaac Newton supposed coloured matters to reflect the rays of light; some bodies reflecting the more, others the less, refrangible rays most copiously; and this he conceived to be the true, and the only reason of their colours. Mr. Delaval, however, proved in the 2d vol. of the "Memoirs of the Philosophical and Literary Society of Manchester," that, "in transparent coloured substances, the colouring substance does not reflect any

light; and that when, by intercepting the light which was transmitted, it is hindered from passing through substances, they do not vary from their former colour to any other colour, but become entirely black;" and he instances a considerable number of coloured liquors, none of them endued with reflective powers, which, when seen by transmitted light, appeared severally in their true colours; but all of them, when seen by incident light, appeared black; which is also the case of black cherries, black currants, black berries, &c., the juices of which appeared red when spread on a white ground, or otherwise viewed by transmitted instead of incident light; and he concludes, that bleached linen, &c. "when dyed or painted with vegetable colours, do not differ in their manner of acting on the rays of light, from natural vegetable bodies; both yielding their colours by transmitting through the transparent coloured matter, the light which is reflected from the white ground:" it being apparent, from different experiments, "that no reflecting power resides in any of their components, except in their white matter only," and that "transparent coloured substances, placed in situations by which transmission of light through them is intercepted, exhibit no colour, but become entirely black."

The art of dyeing, therefore, (according to Mr. Delaval) "consists principally in covering white substances, from which light is strongly reflected, with transparent coloured media, which, according to their several colours, transmit more or less copiously the rays reflected from the white," since "the transparent media themselves reflect no light; and it is evident that if they yielded their colours by reflecting, instead of transmitting the rays, the whiteness or colour of the ground on which they are applied, would not in anywise alter or affect the colours which they exhibit."

But when any opaque basis is interposed, the reflection is doubtless made by it, rather than by the substance of the dyed wool, silk, &c., and more especially when such basis consists of the white earth of alum, or the white oxide of tin; which, by their strong reflective powers, greatly augment the lustre of colours. There are, moreover, some opaque colouring matters, particularly the acetous, and other solutions of iron, used to stain linen, cotton, &c., which must necessarily themselves reflect, instead of transmitting the light by which their colours are made perceptible.

The compound or mixed colours, are such as result from the combination of two differently coloured dye stuffs, or from dyeing stuffs with one colour, and then with another. The simple colours of the dyer, are red, yellow, blue, and black, with which, when skilfully blended, he can produce every variety of tint. Perhaps the dun or fawn colour might be added to the above, as it is directly obtained from a great many vegetable substances.

1. Red with yellow, produces orange; a colour, which upon wool, is given usually with the spent scarlet bath. To this shade may be referred flame colour, pomegranate, capuchin, prawn, jonquil, *cassis*, chamois, *café au lait*, aurora, marigold, orange peel, *mordorés*, cinnamon, gold, &c. Snuff, chesnut, musk, and other shades are produced by substituting walnut peels or sumach for bright yellow. If a little blue be added to orange, an olive is obtained. The only direct orange dyes are annotto, and subchromate of lead; see Silk and Wool Dyeing.

2. Red with blue produces purple, violet, lilac, pigeon's neck, mallow, peach-blossom, *bleu de roi*, lint-blossom, amaranth.

3. Red with black; brown, chocolate, marone, &c.

4. Yellow with blue; green of a great variety of shades; such as nascent green, gay green, grass green, spring green, laurel green, sea green, celadon green, parrot green, cabbage green, apple green, duck green.

5. Mixtures of colours, three and three, and four and four, produce an indefinite diversity of tints; thus red, yellow and blue, form brown olives, and greenish grays; in which the blue dye ought always to be first given, lest the indigo vat should be soiled by other colours. Red, yellow, and gray, (which is a gradation of black), give the dead-leaf tint, as well as dark orange, snuff colour, &c. Red, blue and gray give a vast variety of shades; as lead gray, slate gray, wood-pigeon gray, and other colours, too numerous to specify. See Brown Dye.

The following list of dyes, and the colouring substances which produce them, may prove useful.

Red. Cochineal, kermes, lac, madder, archil, carthamus or safflower, brazil wood, logwood, periodide of mercury, alkanet.

Yellow. Quercitron, weld, fustic (yellow wood), annotto, sawwort, dyer's broom, turmeric, fustet (*rhus cotinus*), Persian and Avignon berries (*rhamnus infectorius*), willow, peroxide of iron; chromate of lead (chrome yellow), sulphuret of arsenic, hydrosulphuret of antimony; nitric acid on silk.

Blue. Indigo, woad or pastel, Prussian blue, turnsole or litmus, logwood with a salt of copper.

Black. Galls, sumach, logwood, walnut peels, and other vegetables which contain tannin and gallic acid, along with ferruginous mordants. The anacardium of India.

Green. These are produced by the blue and yellow dyes skilfully combined; with the exception of the chrome green, and perhaps the copper green of Schweinfurt.

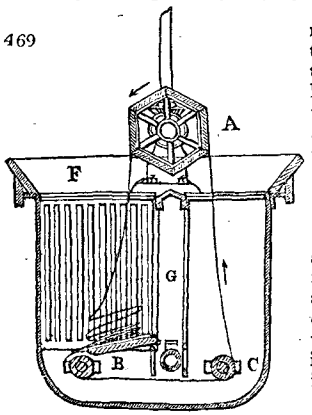
Orange. Annotto, and mixtures of red and yellow dyes; subchromate of lead.

Brown. See the remarks at the beginning of this article; BROWN in its alphabetical place; CALICO PRINTING, CATECHU, and MANGANESE.

Fawn, Dun or Root. Walnut peels, sumach, birch tree, henna, sandal wood. See CALICO PRINTING, for a great variety of these dyes.

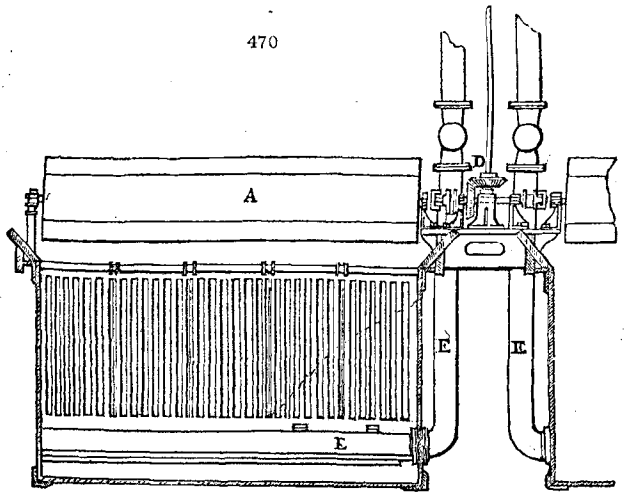
Fig. 469. and 470. represent in a cross and longitudinal section the automatic dyeing steam copper, so generally employed in the well-appointed factories of Lancashire.

469



A is the long reel, composed at each end of six radial iron arms or spokes, bound at their outer extremities with a six-sided wooden frame; these two terminal hexagons are connected by long wooden laths, seen above and below A in *fig.* 470. F shows the sloping border or ledge of the copper. B and C are rollers laid horizontally, for facilitating the continuous motion of the series of pieces of goods stitched together into an endless web, which are made to travel by the incessant rotations of the reel. Immediately above the roller B in *fig.* 469., all the spare foldings of the web are seen resting upon the sloping wooden grating, which guides them onwards in the direction indicated by the arrow. The dye-stuffs are put within the middle grating, like a hen-coop, marked G. Each copper is 6 feet long, 3½ feet wide, 3½ feet deep, exclusive of the top ledge, 9 inches high. Such steam coppers are usually erected in pairs, and moved by a common horizontal bevel wheel seen at D in *fig.* 407., fixed upon a vertical shaft,

470



shifted into geer by a wheel at its top, with one of the driving shafts of the factory. Upon each side of D, the two steam pipes for supplying the right and left hand coppers are seen; each provided with a stop cock for admitting, regulating, or cutting off the steam. These steam pipes descend at E E, the horizontal branch having several orifices in its upper surface. The horizontal shaft in a line with the axes of the reels, and which turns them, is furnished upon each side with a clutch for putting either of the reels into or out of geer, that is to say, setting it a going, or at rest, in a moment by the touch of a forked lever.

The steam pipe of distribution E lies horizontally near the bottom of the middle coop, as shown under G in *fig.* 469., and sends up the steam through its numerous orifices, among the dye-stuffs and water by which it is covered. Thus the infusion or decoc-

tion is continually advancing in the copper, during the incessant locomotion of the endless web. The horizontal pipe traverses the copper from end to end, and is not stopped short in the middle. Each of these coppers can receive two, three or more parallel pieces of goods at a time, the reel and copper being divided into so many compartments by transverse wooden spars.

E.

EARTHS. (*Terres*, Fr.; *Erden*, Germ.) Modern science has demonstrated that the substances called primitive earths, and which prior to the great electro-chemical career of Sir H. Davy, were deemed to be elementary matter, are all compounds of certain metallic bases and oxygen, with the exception of silica, whose base, silicon, being analogous to boron, has led that compound to be regarded as an acid; a title characteristic of the part it extensively performs in neutralizing alkaline bodies, in mineral nature, and in the processes of art. Four of the earths, when pure, possess decided alkaline properties, being more or less soluble in water, having (at least 3 of them) an acrid alkaline taste, changing the purple infusion of red cabbage to green, most readily saturating the acids, and affording thereby neutro-saline crystals. These four are *baryta*, *strontia*, *lime* (*calcia*), and *magnesia*. The earths proper are five in number; *alumina*, *glucina*, *yttria*, *zirconia*, and *thorina*. These do not change the colour of infusion of cabbage or tincture of litmus, do not readily neutralize acidity, and are quite insoluble in water. The alkalis are soluble in water, even when carbonated; a property which distinguishes them from the alkaline earths. *Lithia* must for this reason be considered to be an alkali. See the above substances in their alphabetical places.

EAU DE COLOGNE. This well known perfume is a solution of different volatile oils in pure strong spirit. The principal condition for the preparation of a fine water, is the employment of a spirit quite devoid of fusel-oil (oil of grain), and of all foreign odour.

In respect to the proportion and kind of oils employed, we have numerous formulæ. It is of importance that these oils, which are usually purchased of the druggists of the south of France, should be of the finest quality, and that no oil should be used in sufficient quantity to allow of its peculiar odour being recognizable in the mixture. The oils are to be dissolved in spirit, and the mixture allowed to stand for some weeks (or still better for some months) to improve its odour. Distillation does not effect this; on the contrary a fresh distilled water requires to be kept a much longer time. Distillation is indeed objectionable, for on account of the greater volatility of the spirit, the oils in part remain behind in the still. Distillation can improve the odour only when the less volatile oil has been used in too great a quantity, and we wish to obtain a better proportion. Before all things, we should employ a pure, old, strong spirit, and not too much of, nor a too strongly smelling oil.

The different sorts of volatile oil which are obtained from varieties of citrons, oranges, and lemons, in different states of maturity, are the most important; and, therefore, it is most important to ascertain their purity and goodness.

Forster gives the following formula for the preparation of a fine eau de Cologne: Take of rectified spirit of 82 per cent. of Tralles (=sp. gr. 0·855), 6 (wine) quarts; essence of oranges, essence of bergamot, essence of citron, essence of limette, and essence of petits grains, of each, ℥j; essence of cedro, essence of cedrat, essence de Portugal, and essence de neroli, of each ℥ss; oil of rosemary, ℥ij; and oil of thyme, ℥j.

Otto gives the following formula for a good eau de Cologne: Rectified spirit of 86 per cent. Tralles (=0·846 sp. gr.), 200 (wine) quarts; oil of citrons, lb. iv; oil of bergamot, lb. ij; oil of neroli, ½ lb.; oil of lavender, lb. ss; oil of rosemary, ¼ lb.; and spirit of ammonia, ℥ss. Mix. Don't distil.

This preparation has long possessed great celebrity, in consequence chiefly of the numerous virtues ascribed to it by its venders; and is resorted to by many votaries of fashion as a panacea against ailments of every kind. It is, however, nothing more than aromatized alcohol, and as such, an agreeable companion of the toilet. Numerous fictitious recipes have been offered for preparing *eau de Cologne;* the following may be reckoned authentic, having been imparted by Farina himself to a friend.

Take 60 gallons of silent brandy; sage, and thyme, each 6 drachms; balm-mint and spearmint, each 12 ounces; calamus aromaticus, 4 drachms; root of angelica, 2 drachms; camphor, 1 drachm; petals of roses and violets, each 4 ounces; flowers of lavender, 2 ounces; flowers of orange, 4 drachms; wormwood, 1 ounce; nutmegs, cloves, cassia, lignea, mace, each 4 drachms. Two oranges and two lemons, cut in pieces. Allow the whole to macerate in the spirit during 24 hours, then distil off 40 gallons by the heat of a water bath. Add to the product:

Essence of lemons, of cedrat, of balm-mint, of lavender, each 1 ounce 4 drachms;

neroli and essence of the seed of anthos, each 4 drachms; essence of jasmin, 1 ounce; of bergamot, 12 ounces. Filter and preserve for use.

Cadet de Gassincourt has proposed to prepare *eau de Cologne* by the following recipe: Take alcohol at 32° B., 2 quarts; neroli, essence of cedrat, of orange, of lemon, of bergamot, of rosemary, each 24 drops; add 2 drachms of the seeds of lesser cardamoms, distil by the heat of a water bath a pint and a half. When prepared as thus by simple mixture of essences without distillation, it is never so good.

EAU DE LUCE, is a compound formed of the distilled oil of amber and water of ammonia.

EBULLITION. (Eng. and Fr.; *Kochen*, Germ.) When the bottom of an open vessel containing water is exposed to heat, the lowest stratum of fluid immediately expands, becomes therefore specifically lighter, and is forced upwards by the superior gravity of the superincumbent colder and heavier particles. The heat is in this way diffused through the whole liquid mass, not by simple communication of that power from particle to particle as in solids, called the *conduction* of caloric, but by a translation of the several particles from the bottom to the top, and the top to the bottom, in alternate succession. This is denominated the *carrying* power of fluids, being common to both liquid and gaseous bodies. These internal movements may be rendered very conspicuous and instructive, by mingling a little powdered amber with water, contained in a tall glass cylinder, standing upon a sand-bath. A column of the heated and lighter particles will be seen ascending near the axis of the cylinder, surrounded by a hollow column of the cooler ones descending near the sides. That this molecular translation or locomotion is almost the sole mode in which fluids get heated, may be demonstrated by placing the middle of a pretty long glass tube, nearly filled with water, obliquely over an argand flame. The upper half of the liquid will soon boil, but the portion under the middle will continue cool, so that a lump of ice may remain for a considerable time at the bottom. When the heat is rapidly applied, the liquid is thrown into agitation, in consequence of elastic vapour being suddenly generated at the bottom of the vessel, and being as suddenly condensed at a little distance above it by the surrounding cold columns. These alternate expansions and contractions of volume become more manifest as the liquid becomes hotter, and constitute the *simmering* vibratory sound which is the prelude of ebullition. The whole mass being now heated to a pitch compatible with its permanent elasticity, becomes turbulent and explosive under the continued influence of fire, and emitting more or less copious volumes of vapour is said to boil. The further elevation of temperature, by the influence of caloric, becomes impossible in these circumstances with almost all liquids, because the vapour carries off from them as much heat in a latent state as they are capable of receiving from the fire.

The temperature at which liquids boil in the open air varies with the degree of atmospheric pressure, being higher as that is increased, and lower as it is diminished. Hence boiling water is colder by some degrees in bad weather or in an elevated situation, with a depressed barometer, than in fine weather, or at the bottom of a coal-pit, when the barometer is elevated. A high column of liquid also, by resisting the discharge of the steam, raises the boiling point. In *vacuo*, all liquids boil at a temperature about 124° F. lower than under the average atmospheric pressure. For a table of elasticities, see VAPOUR. Gay Lussac has shown that liquids are converted into vapours more readily, or with less turbulence, when they are in contact with angular or irregular than with smooth surfaces; that they therefore boil at a heat 2° F. lower in metallic than in glass vessels, probably owing to the greater polish of the latter. For example, if into water about to boil in a glass matrass, iron filings, ground glass, or any other insoluble powder be thrown, such a brisk ebullition will be instantly determined, as will sometimes throw the water out of the vessel; the temperature at the same time sinking two degrees F. It would thence appear that the power of caloric, like that of electricity, becomes concentrated by points.

The following table exhibits the boiling heat, by Fahrenheit's scale, of the most important liquids: —

Ether, specific gravity 0·7365 at 48°	-	100°
Carburet of sulphur, - - -	-	113
Alcohol, sp. grav. 0·813 - - -	Ure, - - -	173·5
Nitric acid, 1·500 - - -	Dalton - - -	210
Water, - - - - -	- - - -	212
Saturated solution of Glauber salt, - -	Biot, - - -	213½
do. do. Acetate of lead -	do. - - -	215⅔
do. do. Sea salt - -	do. - - -	224⅓

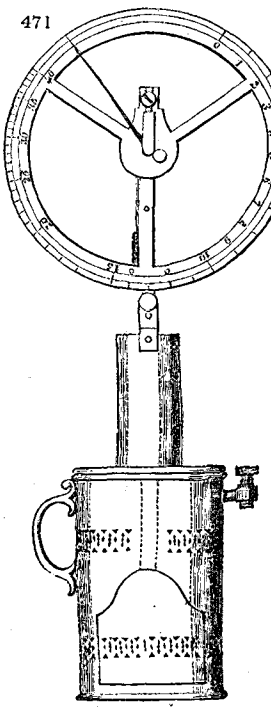
471

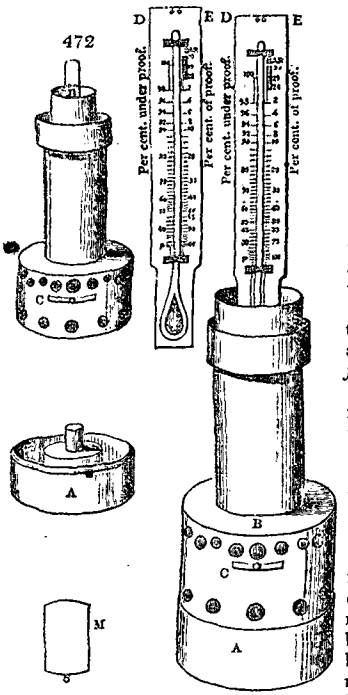


EBULLITION ALCOHOLMETER. That the boiling temperature of water is increased by holding neutro-saline and saccharine substances in solution has been long known, and has been the subject of many experiments, made partly with the view of ascertaining from that temperature the proportion of the salt or sugar, and partly with the view of obtaining a practical liquid bath. But it seems to have been reserved for the Abbé Brossard-Vidal, of Toulon, to have discovered that the boiling temperature of alcoholic liquors is, in most cases, proportional to the quantity of alcohol, irrespectively of the quantity of neutro-saline or saccharine matter dissolved in them. When, however, such a quantity of dry carbonate of potash, or sugar, is added to a spirituous liquor as to abstract or fix in the solid state a portion of the water present, then the boiling temperature of that mixture will be lowered in proportion to the concentration of the alcohol, instead of being raised, as would be the case with water so mixed. But, generally speaking, it may be assumed as a fact, that the boiling point of an alcoholic liquor is not altered by a moderate addition of saline, saccharine, or extractive matter. On this principle, M. Brossard-Vidal constructed the instrument represented in *fig.* 471., for determining by that temperature the proportion of alcohol present. His chief object was to furnish the revenue boards of France with a means of estimating directly the proportion of alcohol in wines, so as to detect the too common practice of introducing brandy into their cities and towns under the mask of wine, and thereby committing a fraud upon the *octroi*; as the duty on spirits is much higher than on wines.

The above instrument consists of a spirit-lamp, surmounted by a small boiler, into which a large cylindric glass bulb is plunged, having an upright stem of such calibre, that the quicksilver contained in them may, by its expansion and ascent when heated, raise before it a little glass float in the stem, which is connected by a thread with a similar glass bead, that hangs in the air. The thread passes round a pulley, which turning with the motion of the beads causes the index to move along the graduated circular scale. The numbers on this scale represent per centages of absolute alcohol, so that the number opposite to which the index stops, when the liquor in the cylinder over the lamp boils briskly, denotes the per centage of alcohol in it.

That instrument was placed in my hands three years ago by Mr. Field, who had obtained a patent in this country for determining thereby the strength of spirituous liquors. I have made a great many experiments on the boiling points of alcohol at various successive degrees of watery dilution, and verified the general utility of the contrivance; but I found the construction of the instrument subject to several defects. The mass of mercury to be heated in the large bulb was so great as to occasion some loss of alcohol in the course of the experiment; the length of the thread was liable to be affected by the moisture of the air; it occasionally failed to move the pulley with sufficient delicacy on account of friction, and when the spirit in the lamp got heated in its case, it flared up and burned the thread, thus rendering the apparatus useless till a fresh thread was experimentally adjusted to the beads.

472



On these accounts I renounced the construction of M. Vidal, and adopted the more simple and direct form of indication represented in *fig.* 472.

It consists, 1, of a flat spirit-lamp A, surrounded by a saucer for containing cold water to keep the lamp cool, should many experiments require to be made in succession; 2, of the boiler B, which fits by its bottom cage C, upon the case of the lamp. At the point C, is seen the edge of the damper-plate for modifying the flame of the lamp, or extinguishing it when the experiment is completed. D is the thermometer, made with a very minute bore, in the manner of the Rev. Mr. Wollaston's instrument for measuring the height of a mountain by the boiling point of water on its summit. The bottom of the scale in the ebullition thermometer, is marked F for proof on the left side, and 100 (of proof spirit) on the right side. It corresponds to 178·6 Fahr. very nearly, or the boiling point of alcohol of 0·920 specific gravity. The following table gives the boiling points corresponding to the indicated densities: —

Temp. Fahr.	Specific gravity.		Temp. Fahr.	Specific gravity.	
178·6	0·9200	P.	185·6	0·9665	50 U. P.
179·75	0·9321	10 U. P.	189·0	0·9729	60 „
180·4	0·9420	20 „	191·80	0·9786	70 „
181·00	0·9516	30 „	196·4	0·9850	80 „
183·40	0·960	40 „	202·0	0·992	90 „

The above table is the mean of a great many experiments. When alcohol is stronger than 0·92, or the excise proof, its boiling point varies too little with its progressive increase of strength, to render that test applicable in practice. In fact, even for proof spirits, or spirits approaching in strength to proof, a more exact indication may be obtained by diluting them with their own bulk of water, before ascertaining their strength, and then doubling it.

The boiling point of any alcoholic liquor is apt to rise if the heat be long-continued, and thereby to lead into error in using this instrument. This source of fallacy may be in a great measure avoided by adding to the liquor in the little boiler about a teaspoonful (thirty-five grains) of common culinary salt, which has the curious effect of arresting the mercury in the thermometer at the true boiling point of the spirit, wine,

or beer, to enable a correct reading to be had. The small measure marked M, holds the requisite quantity of salt.

The thermometer is at first adjusted to an atmospheric pressure of 29·5 inches. When that pressure is higher or lower, both water and alcohol boil at a somewhat higher or lower temperature. In order to correct the error which would hence arise in the indications of this instrument under different states of the weather, a barometrical equation is attached by means of the subsidiary scale E, to the thermometer D.

Having stated the principles and the construction of the ebullition alcoholmeter, I shall now describe the mode of its application.

First. — Light the spirit lamp A.

Second. — Charge the boiling vessel B, with the liquid to be tested (to within an inch of the top), introducing at the same time a paper of the powder; then place the vessel B (the damper plate being withdrawn) on to the lamp A.

Third. — Fix the thermometer D on the stem attached to B, with its bulb immersed in the liquid. The process will then be in operation.

The barometrical scale indicated on the thermometer is opposite the mean boiling point of water. Prior to commencing operations for the day, charge the boiler B with water only, and fix the instrument as directed; when the water boils freely, the mercury will become stationary in the stem of the thermometer, opposite to the true barometrical indication at the time. Should the mercury stand at the line 29·5, this will be the height of the barometer, and no correction will be required; but should it stand at any other line, above or below, then the various boiling points will bear reference to that boiling point.

In testing spirituous or fermented liquors of any kind, when the mercury begins to rise out of the bulb of the thermometer into the stem, push the damper-plate half-way in its groove to moderate the heat of the flame. When the liquor boils freely, the mercury will become stationary in the stem; and opposite to its indication, on the left, the under-proof per-centage of spirit may be read off at once, if the barometer stand that day at 29·5 inches; while on the right hand scale, the per centage of proof spirit is shown; being the difference of the former number from 100. The damper-plate is to be immediately pushed home to extinguish the flame.

The alcoholmeter will by itself only indicate the per centage of alcohol contained in any wine, but by the aid of the hydrometer, the proportionate quantity of saccharum in all wines may be readily and easily determined. The hydrometer will show the specific gravity of the liquid upon reference to table No. 1., annexed. In testing a sample of wine, first take the specific gravity, and suppose it to be 989, then charge the boiler of the alcoholmeter with the wine, as directed, and at the boiling point it indicates the presence of alcohol at 69·6 per cent.^{up}, whose specific gravity will be found to be 979; deduct that gravity from the gravity of the bulk, or 989, and 10 will remain, which 10 degrees of gravity, upon reference to the wine table, will be found to represent 25 lbs. of saccharine or extractive matter in every 100 gallons, combined with $30\frac{4}{10}$th gallons of proof spirit.

Sikes's hydrometer will only show the sp. gr. of liquids lighter than water (or 1000), and for wines in general use, the gravities being lighter than that article, will answer every purpose; but there are wines whose gravities are heavier than water, such as mountain, tent, rich Malagas, lachrymæ Christi, &c., to embrace which additional weights to the hydrometer will be required, as for cordialized spirits, &c. In testing a sample of rich mountain, its sp. gr. was found to be 1039, or 39 degrees heavier than water, that wine at the boiling point indicated the alcohol 72·5 per cent.^{up}; but 980 sp. gr. deducted from 1039 leaves 59 degrees of sp. gr.; against 59 of the wine tables will be found 147–5 or $147\frac{1}{2}$ lbs. of saccharine or extractive matter, combined with $27\frac{1}{2}$ gallons of proof spirit to every 100 gallons.

Should the barometer for the day show any other indication above or below the standard of 29·5, the thermometer scale will then only show the apparent strength, and reference must be had to the small ivory indicator, E, it being the counterpart of the barometrical scale of the thermometer; thus, should the barometer indicate 30, place 30 of the indicator against the boiling point of the liquid, and opposite the line of 29·5 will be found the true strength.

Example 1. Barometer at 30. — Suppose the mercury to stop at the boiling-point 72·^{up}, place 30 of the indicator against 72 on the thermometer, and the line of 29·5 will cut 69·6·^{up}, the true strength.

Example 2. Barometer at 29. — Suppose the mercury to stop at the same point, 72·^{up}, place 29 of the indicator against 72 on the thermometer, and the line of 29·5 will cut 74·3·^{up}, the true strength.

For malted Liquors. — To all brewers and dealers in fermented liquors, this principle, by its application, will supply a great desideratum, as it will not only show the alcohol created in the wort by the attenuation, as well as the original weight of the wort prior

to fermentation, but it will indicate the value of malt liquors in relation to their component parts. It will likewise be a ready means of testing the relative value of worts from sugar compared with grain, as well as being a guide to the condition of stock beers and ales.

To ascertain the strength of malt liquors and their respective values, the instrument has been supplied with a glass saccharometer, testing-glass, and slide-rule. Commence by charging the testing-glass with the liquid, then insert the saccharometer, to ascertain its present gravity or density per barrel, and at whatever number it floats, that will indicate the number of pounds per barrel heavier than water.

Example 1. — Suppose the saccharometer to float at the figure 8, that would indicate 8 lbs. per barrel; then submit the liquid to the boiling test, with the salt as before directed, and suppose it should show (the barometrical differences being accounted for) 90° up, that would be equivalent to 10 per cent. of proof alcohol. Refer to the slide rule,

and place A on the slide against 10 on the upper line of figures, and facing B on the lower line will be 18, thus showing that 18 lbs. per barrel have been decomposed to constitute that per centage of spirit; then, by adding the 18 lbs. to the present 8 lbs. per barrel, the result will be 26 lbs., the original weight of the wort after leaving the copper.

Example 2.— The saccharometer marks 10 lbs. per barrel, and at the boiling point it indicates 88°UP, equivalent to 12 gallons of proof spirit per cent.; place A against 12, and opposite B will be $21\frac{1}{2}$ lbs. per barrel, when, by adding that to the 10 lbs. present, $31\frac{1}{2}$ lbs. will be the result.

To ascertain the relative Value. — Suppose the price of the 26 lbs. beer to be 36*s.* per barrel, and the $31\frac{1}{2}$ lbs. beer to be 40*s.* per barrel, to ascertain which beer will be the cheapest, place 26 on the opposite side of the rule against 36, and opposite $31\frac{1}{2}$ lbs. will be 43*s.* 7*d.*, showing that the latter beer is the cheapest by 3*s.* 7*d.* per barrel.

By taking an account of the malt liquors by this instrument prior to stocking, it may be ascertained at any time whether any alteration has taken place in their condition, either by an increase of spirit by after fermentation and consequent loss of saccharum, or whether, by an apparent loss of both, acetous fermentation has not been going on towards the ultimate loss of the whole.

This instrument will likewise truly indicate the quantity of spirit per cent. created in distillers' worts, whether in process of fermentation or ready for the still, the only difference will be in the allowances on the slide-rule.

N.B. — The saccharometers applicable to the foregoing rules for beers, ales, &c., have been adjusted at the temperature 60° Fahrenheit, and will be found correct for general purposes; but where extreme minuteness is required, the variation of temperature must be taken into account, therefore for every 10 degrees of temperature above 60, $\frac{3}{10}$ths of a pound must be added to the gross amount found by the slide-rule; on the contrary, for every 10 degrees below 60, $\frac{3}{10}$ths of a pound must be deducted.

For cordialized Spirits.— The operation in this instance is somewhat different from that of beers, which have the alcohol created in the original worts; whereas, in cordialized spirits, gins, &c., the alcohol is the original, and the saccharine matter, or sugar, is an addendum.

If 100 gallons of spirit are required at a given strength, say 50 per cent. under proof, 50 gallons of proof spirit, with the addition of 50 gallons of water, would effect that object, and upon testing it by the alcoholmeter, it would be found as correct as by the hydrometer. But in cordializing spirits it is different, for to the 50 gallons of proof spirit 50 gallons of sugar and water would be added, thereby rendering the hydrometer useless, except for taking the specific gravity of the bulk, and, according to the quantity of sugar present, so a relative quantity of water must have been displaced; and as the sugar has no reducing properties, the alcoholmeter will only show the strength of the cordial in relation to the water contained in it, as the principle indicates, irrespectively of saccharine or extractive matter present.

Suppose, in making 100 gallons of cordial at 50°UP, 3 lbs. of sugar are put to the gallon, or 300 lbs. to the 100 gallons, that 300 lbs., displacing $18\frac{67}{100}$th gallons of water, only $31\frac{33}{100}$th gallons of water instead of 50 have been applied; the sugar, without reducing properties, making up the bulk of 100 gallons, which is meant to represent 50 per cent. UP.

The alcoholmeter will only show at the full point of ebullition the alcoholic strength in relation to the water in the 100 gallons of the mixture, or 35 per cent.°UP, leaving 15 per cent. to be accounted for on the bulk.

As the quantity of sugar present must be determined before that per centage can be arrived at, a double object will be effected by so doing, namely, eliciting in all instances the quantity of sugar present, as well as the per centage of spirit to be accounted for.

Example 1.— In taking the sp. gr. of a cordial, suppose it to be found 1076, then submit the liquid to the boiling point, and having ascertained the per centage of alcohol, and it proves to be 35°UP, the sp. gr. of alcohol at that strength will be found to be 956; deduct 956 from the sp. gr. of the bulk, or 1076, and 120 will remain: refer that to its amount on the head line of table No. 2., namely, 120, under which will be found 3, representing 3 lbs. of sugar to the gallon; and by running the eye down its column to opposite the alcoholic strength indicated (35°UP) will be found 14·9, which represents the per centage of water displaced by the sugar, and which amount of 14·9, added to the 35 per cent. ascertained, makes the total upon the bulk 49·9 per cent.°UP, with 3 lbs. of sugar to the gallon.

For Gins, &c.— *Example* 3. In taking the sp. gr., suppose it to be found 957; then submit to the boiling point, and it proves to be 14°UP, whose sp. gr. is 937, which, deducted from 957, leaves sp. gr. 20; on the head-line of table No. 2., under 20, will be found $\frac{1}{2}$, or $\frac{1}{2}$ lb. of sugar to the gallon, and on running the eye down to opposite

14-up, will be found 3·0, which, added to the 14, makes the total on the bulk 17 per cent.-up, with 50 lbs. of sugar to the 100 gallons.

To chemists for their tinctures, &c., this instrument will be found essentially useful.

N.B. — Care must be taken that the mercury is entirely in the bulb of the thermometer before it is fixed on the stem for operation, and in all cases (except for water) the salt must be used.

Conclusion. —Wines are peculiarly subject to be mystified by adulterations of various kinds. It will prove of great advantage to the public when the relative quantity of fruit, or *saccharum*, and alcohol requisite to constitute the normal wine of each species is well ascertained.

Some beers possess a remarkable narcotic power, by which they cause drowsiness and stupor without corresponding previous exhilaration. Such beverages may justly be suspected of having been sophisticated with *cocculus indicus*, opium, or some analogous drug; and this suspicion may become certainty, if they be shown by the alcoholmeter to contain only a few per cents. of fermented spirit.

The instrument in its complete state is made and sold by Mr. Joseph Long, Little Tower Street. The tables, of which the above is only a portion, and the barometric indicator, have been constructed by him and Mr. Atlee.

EDGE TOOLS. Mr. James Bouydell welds iron and steel together in such a manner that when cut up to form edge tools, the steel will constitute a thin layer to form the cutting edge. He piles a slab or plate of steel upon two or more similar plates of iron, heats in a furnace to a good welding heat, and then passes between grooved or other suitable rollers, to convert it into bars; the steel being in a thin layer either on one of the outer surfaces of the bar, or between two surfaces of iron according to the kind of tool to be made therefrom. The bars thus produced are cut up and manufactured into the shape of the desired articles by forging. If the cutting edge is to extend but a short distance, the steel is applied only near one edge of the pile. In this manner hatchets, adzes, choppers, knives of all kinds, scissors, scythes, chisels, gouges, &c., may be economically manufactured; the steel being used merely for forming the edge, while the requisite stiffness of the tools is obtained by the iron. The compound bars which have the steel on one side are suitable for chisels and other tools, which have a cutting edge on one side, the iron being ground away when making or sharpening the tool. Mr. B. manufactures spades on a somewhat similar plan. — *Newton's Journal*, vol. xxvi. p. 183. See Cutlery and Steel.

EDULCORATE, (*Edulcorer*, Fr.; *Aussüssen*, Germ.) is a word introduced by the alchemists to signify the sweetening, or rather rendering insipid, of acrimonious pulverulent substances, by copious ablutions with water. It means, in modern language, the washing away of all particles soluble in water, by agitation or trituration with this fluid, and subsequent decantation or filtration.

EFFERVESCENCE. (Eng. and Fr.; *Aufbrausen*, Germ.) When gaseous matter is suddenly extricated with a hissing sound during a chemical mixture, or by the application of a chemical solvent to a solid, the phenomenon, from its resemblance to that of simmering or boiling water, is called effervescence. The most familiar example is afforded in the solution of sodaic powders; in which the carbonic acid gas of sesquicarbonate of soda is extricated by the action of citric or tartaric acid.

EFFLORESCENCE, (Eng. and Fr.; *Verwittern*, Germ.) is the spontaneous conversion of a solid, usually crystalline, into a powder, in consequence either of the abstraction of the combined water by the air, as happens to the crystals of sulphate and carbonate of soda; or by the absorption of oxygen and the formation of a saline compound, as in the case of alum schist, and iron pyrites. Saltpetre appears as an efflorescence upon the ground and walls in many situations.

EGGS, HATCHING. See Incubation, Artificial.

EIDER-DOWN, is a kind of precious down, so called because it is obtained from the *Eider*-duck. These birds build their nests among precipitous rocks, and the female lines them with fine feathers plucked from her breast, among which she lays her five eggs. The natives of the districts frequented by the eider-ducks let themselves down by cords among the dangerous cliffs, to collect the down from the nests. It is used to fill coverlets, pillows, cushions, &c.

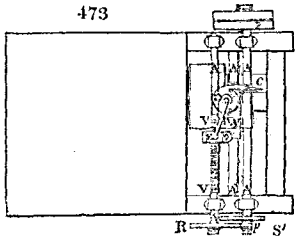
ELAINE is the name given by Chevreul to the thin oil, which may be expelled from tallow, and other fats, solid or fluid, by pressure either in their natural state or after being saponified, so as to harden the *stearine*. It may be extracted also by digesting the fat in 7 or 8 times its weight of boiling alcohol, spec. grav. 0·798, till it dissolves the whole. Upon cooling the solution, the stearine falls to the bottom, while the elaine collects in a layer like olive oil, upon the surface of the supernatant solution, reduced by evaporation to one eighth of its bulk. If this elaine be now exposed to a cold temperature, it will deposit its remaining stearine, and become pure. See Fat, Oils, and Stearine.

ELASTIC BANDS. (*Tissus Elastiques*, Fr. ; *Federharz-zeige*, Germ.) The manufacture of braces and garters, with threads of caoutchouc, either naked or covered, seems to have originated, some time ago, in Vienna, whence it was a few years since imported into Paris, and thence into this country. At first the pear-shaped bottle of Indian rubber was cut into long narrow strips by the scissors ; a single operative turning off only about 100 yards in a day, by cutting the pear in a spiral direction. He succeeded next in separating with a pair of pincers the several layers of which the bottle was composed. Another mode of obtaining fine threads was to cut them out of a bottle which had been rendered thin by inflation with a forcing pump. All these operations are facilitated by previously steeping the caoutchouc in boiling water, in its moderately inflated state. More recently, machines have been successfully employed for cutting out these filaments, but for this purpose the bottle of caoutchouc is transformed into a disc of equal thickness in all its parts, and perfectly circular. This preliminary operation is executed as follows : 1. the bottle, softened in hot water, is squeezed between the two plates of a press, the neck having been removed beforehand, as useless in this point of view ; 2. the bottle is then cut into two equal parts, and is allowed to consolidate by cooling before subjecting it to the cutting instrument. When the bottle is strong enough, and of variable thickness in its different points, each half is submitted to powerful pressure in a very strong cylindrical mould of metal, into which a metallic plunger descends, which forces the caoutchouc to take the form of a flat cylinder with a circular base. The mould is plunged into hot water during the compression. A stem or rod of iron, which goes across the hollow mould and piston, retains the latter in its place, notwithstanding the resilience of the caoutchouc, when the mould is taken from the press. The mould being then cooled in water, the caoutchouc is withdrawn.

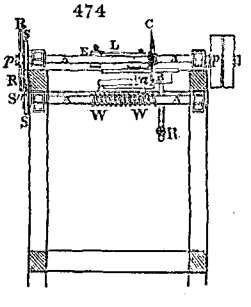
The transformation of the disc of caoutchouc into fine threads is performed by two machines ; the first of which cuts it into a riband of equal thickness in its whole extent, running in a spiral direction from the circumference to the centre ; the second subdivides this riband lengthwise into several parallel filaments much narrower but equally thick.

The following *figs.* 473, 474, 475, represent the machine for cutting the spiral riband. The disc D, placed horizontally, turns round its vertical axis, so as to present its

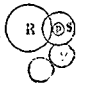
473



474



475



periphery to the edge of a knife c, formed like a circular blade, whose plane is perpendicular to that of the bases of the disc. This knife turns round its centre, which is fixed. The rotary motion of the disc forces the knife to penetrate further and further into its mass, and the motion of the knife itself makes it cut the riband more easily. It is obvious, that if the disc alone revolved, the motionless knife could act only by pressure, and would meet with an enormous resistance. A third movement becomes necessary. In proportion as the disc is diminished by the removal of the spiral band, the centre of this disc must advance upon the knife in order that the riband may have always the same breadth. The inspection of *fig.* 475. will make the accordance of the three motions intelligible.

The knife c is placed upon a shaft or axis A, which carries a pulley, round which a belt or cord runs which drives the whole machine. This knife is six inches in diameter. In order that by being kept cool it may cut the caoutchouc better, it is plunged at its lower part into a trough B, full of water ; a stopcock B serves to empty this trough.

The shaft A bears a pinion P, which takes into a wheel R, placed upon the shaft A' ; upon which there is cut a worm or endless screw, V, V. This worm bears a nut K,

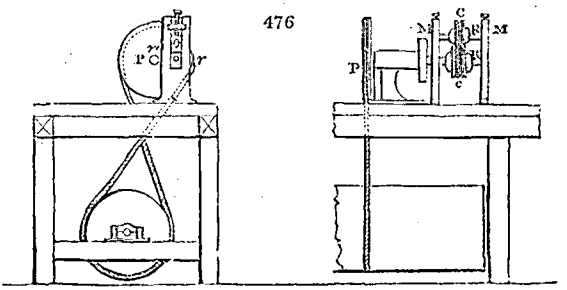
which advances as the screw turns, and carries with it a tie L, which in its turn pushes the disc D, carried upon a shoulder constantly towards the knife. This shoulder is guided by two ears which slide in two grooves cut in the thickness of the table. The diameter of the pinion p is about one fifth of that of the wheel R; so that the arbour A turns five times less quickly than the arbour A′; and the fineness of the screw v contributes further to slacken the movement of translation of the disc.

When the disc is all cut down, the shoulder, the tie, and the nut, are brought back to their original position by lifting the nut, which is hinged on. The disc is fixed upon the shoulder by means of sharp points, and an upper washer. The shoulder and the washer have a very small diameter, in order that the knife may, in cutting down the disc, advance as near as possible to the centre.

The rotatory movement of the disc and its shoulder, is given by an endless screw w, w, which governs a pinion p′, provided with 10 teeth, and carried by the shaft A, upon which the shoulder is mounted. The arbour A′ of this endless screw receives its motion from the first shaft A, by means of the wheels s and s′ mounted upon these shafts and of an intermediate wheel s″. This wheel, of a diameter equal to that of the shaft A″, is intended merely to allow this shaft to recede from the shaft A. The diameter of the wheel of this last shaft is to that of the two others in the ratio of 10 to 8.

Second machine for subdividing the ribands. Fig. 476. — The riband is engaged between the circular knives, C, C, which are mounted upon the rollers R, R; thin brass washers keep these knives apart at a distance which may be varied, and two extreme washers mounted with screws on each roller maintain the whole system. The axes of these rollers traverse two uprights M, M, furnished with brasses, and with adjusting screws to approximate them at pleasure. The axis of the lower roller carries a wheel

476



r, which takes into another smaller wheel r′, placed upon the same shaft as the pulley P, which is driven by a cord. The diameter of the wheel r is three times greater than the wheel r′. The pulley P is twice the size of the wheel r′; and its cord passes round a drum B, which drives the rest of the machine.

The threads, when brought to this state of slenderness, are put successively into tubs filled with cold water; they are next softened in hot water, and elongated as much as possible in the following manner: — They are wound upon a reel turned quickly, while the operative stretches the caoutchouc thread with his hand. In this way it is rendered 8 or 10 times longer. The reels when thus filled are placed during some days in a cold apartment, where the threads become firm, and seem to change their nature.

This state of stiffness is essential for the success of the subsequent operations. The threads are commonly covered with a sheath of silk, cotton, or linen, by a braiding machine, and are then placed as warp in a loom, in order to form a narrow web for braces, garters, &c. If the gum were to exercise its elasticity during this operation, the different threads would be lengthened and shortened in an irregular manner, so as to form a puckered tissue. It is requisite therefore to weave the threads in their rigid and inextensible, or at least incontractile condition, and after the fabric is woven to restore to the threads of caoutchouc their appropriate elasticity. This restoration is easily effected by passing a hot smoothing iron over the tissue laid smoothly upon a table covered with blanket stuff. See BRAIDING MACHINE.

ELECTIVE AFFINITY, (*Wahlverwandtschaft*, Germ.) denotes the order of preference, so to speak, in which the several chemical substances *choose* to combine; or really, the gradation of attractive force infused by Almighty Wisdom among the different objects of nature, which determines perfect uniformity and identity in their compounds

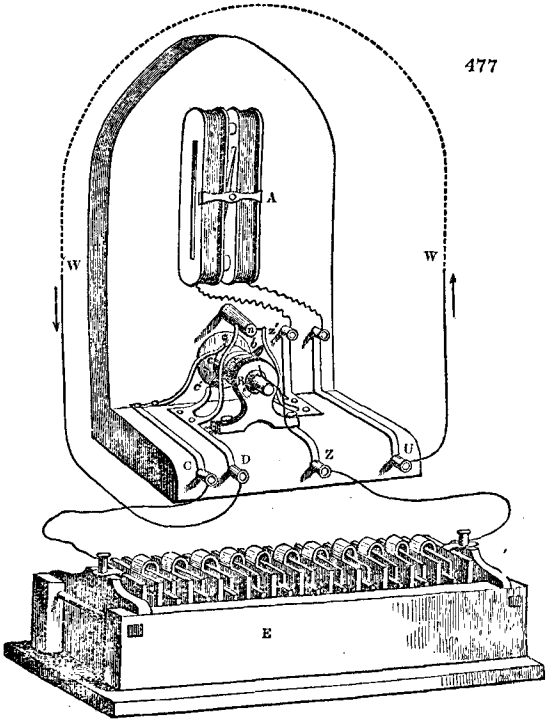
amidst indefinite variety of combination. The discussion of this interesting subject belongs to pure chemistry. See DECOMPOSITION.

ELECTRO-TELEGRAPHY. *Magnetic Needle Telegraphs.* — After Œrsted had discovered the mutual action of electric currents and magnetic needles, Ampere "proposed, in consequence of an idea suggested to him by the illustrious Laplace, to employ as many circuits as there were letters of the alphabet, and to make each of them act on a separate needle."

Schweiger's invention of the galvanometer, followed more recently by Wheatstone's discovery of the velocity of electricity, gave renewed impulse to these inquiries. Professor Ritchie illustrated Ampere's idea on a small scale, but rather with a view of pointing out the difficulties which enveloped it than to propose it for practical purposes. Alexander's telegraph had thirty galvanometric needles and thirty-one wires; each needle supported a screen, which it carried with it when deflected, and thus exposed a letter. Davy's first telegraph was of the same character, only the letters were illuminated. Baron Schelling and Fechner proposed to limit this number by employing fewer needles and observing their combined motions, a different character being indicated according to the number of needles in motion.

Mr. Bain has proposed to fix the magnet and deflect the coil. The arrangements peculiar to Mr. Wheatstone's needle telegraph are, that he has one wire only for each needle; that two needles are thus always included in the circuit; that the combination of the two needles out of five, which he generally used, will produce 20 signals, and that by a key-board, peculiarly his contrivance, these several circuits can be readily formed. By combining three or four needles, 200 signals could be given. As the motion of these deflected needles was not of itself sufficiently violent to ring a bell, in order to call attention, arrangement was made that one of the needles by its deflection should complete the circuit of a distant battery, and this would then make an electromagnet, and liberate the detent of an alarm. Other modes of sounding an alarm were adopted on account of the difficulties which attended the early experiments on that form of telegraph which we shall presently describe. As it is not the intention to give here a history of telegraphs, the above illustrations of the chief applications of the galvanometer to this purpose will suffice.

"The instruments to be first described are the inventions of Messrs. W. Fothergill



Cooke and Charles Wheatstone, F.R.S. They are of two kinds: the one, in which a single galvanometer is employed; the other, in which there is a pair of galvanometers. The former will serve our present purpose, as the mechanical adjustments of the latter are merely the double of this. I have removed the case from the instrument in order to give a clear view of all the essential parts; and have engraved a back view of it (*fig.* 477.) with the battery E attached as if for use; and the circuit of the galvanometer A completed by the wire w w.

"The instrument is possessed of a two-fold character; it is *passive*, or ready for receiving signals from another instrument; it is *active*, or ready for transmitting signals to another instrument. By describing first how it is fitted for *receiving* signals, and then how it is arranged for *transmitting* them, we shall be better able conveniently to analyze it, and to comprehend its general structure. The frame of the coil B is of brass, or (which is in many respects better) of polished wood or of ivory; it is screwed upon the face of the instrument, which face is a brass plate varnished on the inner side. Looking at the coil, a short wire from its right-hand end comes to a screw terminal, which latter, by a slip of brass neatly laid on the instrument case, is connected with another terminal U. The left-hand end of the coil comes also to a terminal, from which a slip of brass descends to a brass plate here, partly hidden; but its form may be gathered from a similar plate, visible on the left side. These twin plates are in metallic connection by means of the two upright springs, plainly shown in the drawing. The springs are of stout steel, and press strongly on two points in a short insulated brass rod *n*, which is screwed into the wooden framework of the instrument. The left-hand plate is connected with the terminal D, also by a slip of brass. If now, the two terminals U and D are connected by a wire w w, the circuit will be complete, as follows: from the terminal U into the coil at the right-hand side; out of the coil, at the left side downwards to the right-hand plate; up the right hand steel spring, across the brass rod *n* to the left-hand steel spring; downward by this spring to the left-hand plate, thence by the slip of brass to the terminal D, and thence by the wire w w to the terminal U, whence we started. If now the wire from U went up the line of railway, and the wire from D down the line, and the circuit were in some way kept complete on the large scale, as it has been here described on the small scale, any electric current passing along the wire from a distant station, would traverse this coil in its course, and would deflect the needle, and so make a signal. I should here mention that for the sake of regularity, we adopt one unvaried order in attaching wires to the instrument; it is, to put the up wire on the terminal, shown by U in the figure, the coils being all uniformly wound.

"So far for receiving a signal—now for sending one. Were we to go out on the open railway, taking with us a battery, and to cut any one of the wires, and place its two ends, thus obtained, upon the two terminal ends of the battery, a current would pass along the line, and the needles on that wire would be deflected; and if we changed hands so as to reverse the connections, the deflections of the needle would be reversed. The same would happen were we to cut a wire inside the office, or inside the telegraph, and to treat it in a similar way. Now, in every apparatus contrived for transmitting signals, we have a *place corresponding to such a cut wire*; and near this place are the poles of the battery, mounted and movable, so that they may be readily applied in the breach, one way or other as required. The place here (*fig.* 477.) is the top of the springs. They are not *joined* to the brass rod *n*; but, as I said before, *press hard* upon it, and can readily be raised with the finger, or otherwise. It is obvious that, when either of them is raised, the circuit is broken. Now, near this place is a mechanical contrivance, by which the poles of the battery may make a breach in the circuit, and be applied in the breach in either direction. The drum B is of box-wood, the ends *c* and *z* being capped with brass, and insulated from each other by the wood, *b*, left between them. The drum is movable by a handle, not in sight here, and is supported as shown in the present figure. A stout steel wire *c'* is screwed beneath into the *c* end of the drum; and a similar wire *z'* is screwed above into the *z* end. These two wires are the poles of the battery, *z'* being connected with the zinc end, and *c'* with the copper, thus:—from the copper end of the battery a wire is led to the terminal c; thence a slip of brass leads to a curved brass spring which presses closely on the drum at *c*; from the zinc end of the battery a wire goes to the terminal *z*, and thence a slip of brass leads to a similar curved spring, pressing on the *continuation* of the *z* end of the drum, as shown in the figure. It will be seen that, whenever the drum is moved, the steel wire *z'* will lift up one or other of the upright steel springs; it is now lifting up the right-hand one, and so breaks the circuit; but, by a little further motion of the drum, the wire *c'* will press upon the boss below, as shown in the figure, and thus there will be a battery pole on each side of the breach, and a signal will be made on this, and on all instruments connected with it. And, from the peculiar arrangement with the drum, the motion can be changed as rapidly as the hand can move. I have shown the battery connections exactly as they occur in practice; and the connections are such that, if the right-hand spring is moved off, the needle moves to the right, and, if the left, to the left. The needle on the face of the instrument always

has its north end upward, and the needle within the coil its north end downward, so that if we look at the face of an instrument, and see the top end of the needle move to the right, we may be sure that in the half of the coil nearest to us the current is *ascending*."

Thus the wires are the channels through which electric influences are conveyed to great distances with inconceivable velocity, and the movable magnets, or galvanometers, to which the wires are attached at the stations, are the parts of the apparatus by which signals are made. The mode of interpreting these signals is thus described by the author: —

"Double-needle Code. — Having described the apparatus and means employed for producing at pleasure the transmission of signals to distant places, it now remains to us to explain the manner of interpreting these signals, so that each person shall understand the ideas the other would convey.

"We have to describe how, out of only *two* needles, each of which has but *two* movements, the telegraph alphabet is formed. On the face of the instrument are the letters of the alphabet, arranged, as it will be seen, *seriatim* in two lines, beginning at the left, and ending at the right, as in writing. The commencing series from A to P is above the top end of the needles; and the concluding series from R to Y below the bottom end. It will also be seen that some letters are engraved *once*, some *twice*, and others *three* times. To make a letter engraved once, requires *one* motion of the needle; to make one engraved twice, *two* motions of the needle; and to make one engraved three times, *three* motions. In respect to the upper row, the needle *nearest* to the letter is moved, and it is moved so as to point *towards* the letter. In respect to the lower row, *both* needles are moved, and their *lower* end is made to point in the direction of the letter required. Six of the letters, C, D, L, M, and U, V, require a twofold motion of the needle or needles, first to the right then to the left for C, L, and U, and first to the left then to the right for D, M, and V. These six letters are engraved *intermediate*, and with a double row between. The alphabet produced by this arrangement is of a simple character, and is very readily acquired. To the stranger it appears confused; but when he has the key to it, the difficulty disappears; it might at first sight appear that a dial instrument — a telegraph, that is, provided with alphabets engraved on a circular dial, and an index made to revolve, and point to any required letter, is more simple; several such telegraphs exist, and among them are some very happily arranged; and there is something so simple in the fact of being able to point to any desired letter, that it is no wonder the public generally may, on a hasty glance, and before studying the practical merits of the case, be ready to decide in their favour, and prefer them to any other plan, the A, B, C of which is less obvious.

"But is it such a *very* serious matter to learn another alphabet? Every school-boy, now-a-days, knows some half-dozen alphabets: there are ROMAN letters large, and Roman letters small; *MANUSCRIPT* letters large, and *manuscript* letters small; Old English large, and *Old English* small; Greek large, and *Greek* small, and so on, and all different, and not one of them in which the letters are represented by so few *strokes of the pen* as are the telegraph letters by *beats of the needle*. Take one of our plainest alphabets as an example; the ROMAN CAPITALS, for instance, and place a few of them in juxta-position with the corresponding telegraph signals: —

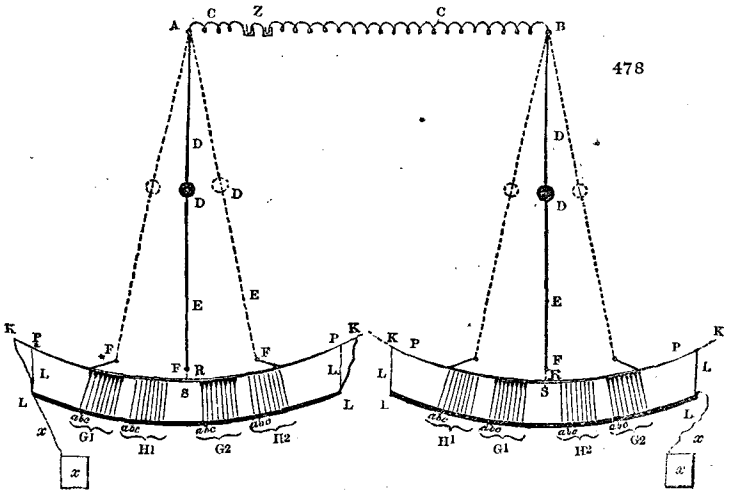
"The simplicity of these symbols is obvious. Two diagonal and one horizontal line are required for the Roman A; two diagonal lines for the telegraph A; one vertical and three horizontal lines make the Roman E; one diagonal the telegraph E, and so on; the difference being that all the world have learned the Roman alphabet, and only a chosen few have studied the telegraph symbols. That the latter really are simple and distinctive; that they are full of meaning and very legible; that they are applicable to ordinary language, and good, ay, very good! no one will for a moment doubt, who has seen the rapidity and accuracy with which a telegraph officer receives a dispatch.

"To one who sees a telegraph in operation for the first time, the effect borders on the marvellous; setting out of the question the fact that the needles are caused to move by an individual perhaps a hundred miles off; the motion of the needles hither and thither; quicker than the untrained eye can follow; the want of all apparent order and rule in their movement; the ringing of the changes between one and the other, and both; the quiet manner in which the clerk points his needle to the letter E, in rapid intervals, implying that he understands the word; while, to the uninitiated looker-on, all is wonder, and mystery, and confusion; and the rare occurrence of the clerk pointing to ✠, implying he did *not understand*; and, finally, the quiet manner with which the clerk tells you, very coolly, as the result of his operations, "That the very pretty girl, with bright blue eyes and long curls, *has* sailed for Boulogne in the *Princess Clementine*, now leaving Folkstone Harbour; and that she *is* accompanied by

the tall, handsome man, with the dark moustache and military cloak." As he tells you this, and says, "Message and answer, forty words two rates at 10*s.* 6*d.*, one guinea, porterage a shilling — one pound two." If you happen to be the papa of the pair of blue eyes, you are bewildered, and wish you were an electric current, and could be sent after them."— *From Electric Telegraph Manipulation, by C. V. Walker.*

An invention apparently very simple and comprehensive for electro-telegraphic correspondence, was made the subject of a patent in February, 1851, in Newton's Journal. It consists in the use of such parts or arrangements of apparatus as will allow two or more persons, by the agency of electricity, to send or receive signals or intelligence by one common wire of communication or main conductor, whilst the rapidity or closeness in the order of succession of the signals, consequent on the indefinite short time the main conductor is in actual use in conveying the electric current for transferring the signal shall be such, that all the persons so employed in these telegraphic operations can be continually and simultaneously occupied, in like manner as if each one of them had a distinct wire of communication all the time waiting for or appropriated to his particular use. By this invention the same practical telegraphic results are obtained, through agency of the one wire or main conductor, as, in the varieties of the electric telegraph before known or used, would require several distinct wires of communication. According to this improved plan of working, the wire of communication or electric conductor may be considered as a public word road, or an omnitelegraphic way; whereas, in contradistinction, the conductor, as heretofore used, may be considered a private word road, or a unitelegraphic way. In addition to the ability of allowing divers parties simultaneously to telegraph at will either all in the same or in contrary directions, over or along one wire of communication, this improvement enables each one of the operators, so employed, to have and to use as many distinct short wires or accessory conductors, all related to the main conductor, as the operators may desire to have separate signals; whereby the facility of making and receiving or recording signals or intelligence is greatly increased. Thus, for example,—suppose ten men at each end of the wire of communication are all using the same wire of communication which connects the distant places, their practical telegraphic facilities would be greater than could be had by the old system, if these twenty men had twenty different wires of communication in place of only one such wire; and would be as great as could be had by the old system, if each of these twenty men had as many such wires as they might desire to make or receive different signals. Thus, supposing twenty-five signals to be made and twenty-five to be received, for each of these twenty men, 1,000 separate wires or main conductors would be required, in order to accomplish what, by the new system, requires only one such main conductor, aided by 1,000 short wires or accessory conductors, or signal-making and signal-receiving wires, which need be of but a few inches in length severally, or so long as to reach to, or be systematically put into, electric relation with the respective ends of the main conductor or wire of communication; or, otherwise by motion, be successively brought into electric communication with, and so momentarily forming in succession, portions of the conductor, by which the electric current, circuit, or line of inductive action is established, maintained, or broken, from time to time. It may be stated that this improvement rests upon taking advantage of the circumstance that, practically speaking, no sensible portion of the time employed in working the telegraph is expended in the actual transmission of the electric influence, which is the medium or agent of the communication, but that it is due to the operation of making or recording the signals. One wire, reaching between the distant places, is therefore capable of being the instrument of transmitting an indefinite number of different signals in a second of time, provided that suitable adaptations are made to enable so many different signals to be separately placed upon one end of the main conductor, and received or recorded at the other end of the conductor, in an intelligible manner. There are an indefinite number of methods of applying to practice this improvement, differing more or less in kinds of apparatus used, and in modifications of electrical actions applied. But all are substantially the same improvement; inasmuch as their action would be to set apart distinct and small and successive fractions of a second or other period, and assign and apply such small fractions of time to different uses or for different persons; so that, although many persons should all simultaneously be employed in using one common wire of communication, yet all the signals so transmitted by it may be successive; the rapidity of the electric conduction admitting, by this invention, the divers signals to be transmitted successively along the wire, and yet so quickly the one after the other, as to give a like practical result, as if they were simultaneously transmitted by separate wires or main conductors. A convenient mode of applying this improvement to practice, and for illustrating the principle of the invention, may be understood by referring to the diagram (*fig.* 478.), wherein two pendulums, supposed to be actuated by clock work or other suitable means, are indicated; such pendulums being made to vibrate as nearly as possible together in position and in time of vibration. At the chief station A, the

standard pendulum is situate; and the dependent telegraphic station is also provided with a pendulum, as at B. D, D, are the pendulum rods, with these balls or weights; E, the prolonged end of the pendulum rods, which should be much longer in proportion than represented in the drawing; F, slight springs, united to the prolonged end of the



pendulum rods; and P, R, P, and P, S, P, are two grooves or pathways, so made that the spring F shall fall into the groove P, R, P, when the pendulum makes the vibration from left to right, and shall fall into the groove P, S, P, when making the vibration from right to left; C, C, is the main conductor or wire of communication, connecting the two telegraphic stations A and B together; X, X, are ground plates and ground wires. At station A, there are metallic points over which the spring F passes, touching the surface each vibration, — which points are connected with the conductors L, X. The groove P, R, P, at station B, is of metal, and in electric communication with L and X. The spring F, in moving in either of the grooves P, R, P, or in the P, S, P, of station A, is kept in its path by an insulated or non-conducting guide; Z is a Leyden jar, prime conductor of an electrical machine, or galvanic pile, kept constantly charged, or capable of giving a great number of visible sparks or electric pulsations per second, on making or breaking the electric circuit or line of inductive action. The wire C, C, C, has a metallic connection with the upper end of the pendulum rods, which are also metallic as well as their prolonged terminations. In this condition of things, whenever the spring F, at station A, passes over K, K, in its vibrations, there will be an electric communication or circuit from Z to K, through L, X, to the ground at station A; also from Z, to the metallic groove P, R, P, at station B, and to the ground there; provided the pendulum at station B is making its vibration from left to right, when the pendulum at station A carries its spring F over the conducting point K. At K on the left hand side of the standard pendulum, there are two metallic faces near together; by this arrangement it can be known at station B when the pendulum at station A is in motion, and the position of its vibrations exactly determined; so that the pendulum at B can be from time to time set in motion, accelerated or retarded, in order to maintain that degree of synchronism in the action of the pendulums, and similarity in position, which are necessary for success of the telegraphic operations. When the pendulum at B is correctly timed in its motions, there will be visible two sparks on the left hand side, and one spark on the right hand side, of the conducting groove at K, K, station B, equal distance from the centre of vibration; but when this pendulum is not in its proper position or motion, these sparks can be seen at other places along the groove. H^1 and H^2, at both stations, are signal-making wires; and G^1, G^2, at both stations, are signal-receiving wires. These signal wires are to be supposed as numerous in each set as the number of different signals desired to be used, — say not less than the letters of the alphabet; a smaller number is, however, shown in the drawing, for distinctness sake. All the signal-receiving wires reach into the groove or pathways P, S, P, in such a manner that the spring F shall touch and slide over the flattened faces or ends of these wires in succession each time the pendulum moves from right to left. The signal-making wires, on the contrary,

stand a little off, out of the groove or pathway, but are intended to be so mounted that each may be raised by the pressure of the finger, and brought into the line of the groove or pathway, to be touched by the spring F, when the pendulum swings from left to right. All these signal wires are united by one end to the conductor L, L, but are free and independent at the other end. The free end of the signal-receiving wires may have a width of half an inch, more or less, where F passes over them. The corresponding ends of the signal-making wires may be put on edge or line; so that the signal-making wires can be touched by F but for a moment, whilst the signal-receiving wires will be touched for a sensible time by F, in passing over them.

Under these circumstances, if any one of the signal-making wires H^1, at station A, be touched and brought into contact with the end F, of the vibrating pendulum, a conducting circuit or electric current will be established for the moment, the corresponding pendulum at station B will be in front of the group of signal-receiving wires H^1 of that station. Therefore, from the electric circuit existing for that moment of contact, there would be a spark visible upon the flattened end of that one of the signal-receiving wires which corresponds to that one of the signal-making wires at the other station, which may have been pressed upon and brought into the pathway of F; all these signal wires in each set being marked by and signifying the different letters of the alphabet, &c. It is obvious, that if the left hand wire of each set be marked *a*, the next *b*, next *c*, &c., then, should *a*, *b*, or *c*, of a signal-making group H^1, station A, be pressed upon and touched by F, this act will be known at station B, by the appearance of a spark on the end of that one of the signal-receiving wires, *a*, *b*, or *c*, of group H^1 station B, corresponding to that wire which may have been so touched at station A. Thus, at will, can any signal or letter be sent from station A to station B, and during the operation of signal-making, by one person at station A, to another at station B. It will now be seen that another person, or the same person at station B, by the use of the wires H^1, can telegraph in reply to station A, by making use of the set of wires H^1 of each station, in a manner similar to those in which the wires H^1, before described, were used. Suppose that the time of a double vibration of these pendulums is equal to the time necessary for conveniently making and observing a signal, then, by the use of the four sets of signal wires above named, a person may send to or receive signals from or between stations A and B reciprocally; or four persons may be continually and simultaneously employed in making and receiving signals at each station. The use of these signal-wires referred to, as able to employ four persons in continual telegraphic intercourses, will in no way interfere with the simultaneous employment of two or four other operators using the other signal wires on the right-hand half of the vibrations marked H^2 and G^2; so also by lengthening out the ends of the pendulum rods, or increasing the angular motion of the pendulums, more space or places may be had for carrying out a larger number of telegraphic operations indefinitely.

It has been said that the pendulum at station B may be kept adjusted to the motions of the regulating pendulum, by the appearance of sparks at K, K; but this synchronism may be more perfectly maintained by using any of the known forms of electro-magnets. In the above illustration the electric spark from an electrical machine has for simplicity been chosen as the visible signal; but should it be desired to make signals by the hydro-electric current and the deflection of a needle, then each one of the signal-receiving wires, before uniting with the common conductor L, may be lengthened out sufficiently to form the coil of a galvanometer; and the current passing through any one of these wires can make itself known, or a signal be so given, by the deflection of the needle of the galvanometer belonging to that particular signal-receiving wire so signalized; or, in like manner, these prolonged signal-receiving wires may each one enclose a bar of iron, in place of a magnetic needle, so as to have an electro-magnet and keeper belonging to each one of these wires: then the passage of the current through any of the wires may give magnetism to the bar, or actuate the magnet or its keeper; and from this motion the signals may be perceived, or recorded and printed in any convenient form. From the above explanations, it will be obvious that divers stations and complex systems of telegraphic lines of communications can be established on the principle of this invention; and it will be also understood, that the invention is susceptible of an indefinite number of modifications or forms, as respects the apparatus employed in carrying it into use. The patentee claims, rendering available the conducting power of electric telegraph wires, so that they may transmit one or more electric currents (in the same or opposite directions) during the time that must necessarily elapse between the transmission of succeeding signals which have reference to one and the same communication.—*Newton's Journal*, xl. 36.

ELECTRO-GILDING AND SILVERING. According to Le Docteur Philipp, the vessel required for this purpose should be made of the same material as that commonly employed for flower-pots: before being used it must be tested in the following manner. On being filled with water, if it becomes simply damp, without allowing the water to filter through it, it is fit for use, but not otherwise. This vessel is sur-

rounded by a cylinder of zinc, and then introduced into another vessel (a wooden tub for instance) containing dilute sulphuric acid. The earthen vessel is intended to contain the solution of gold or silver, and is furnished with a web of copper wire, which is made to communicate with the zinc by means of one or more conducting wires. The objects to be gilt or silvered are placed upon the net-work. The earthen vessel containing a zinc cylinder, and some hydrochloric acid, is introduced into another vessel, containing the solution of gold or silver, placed in the centre of a wire web partition, which communicates with the zinc cylinder by means of a conducting wire. In the first case, the articles which are to receive the thickest coating are placed nearest the outer sides of the apparatus; in the second, nearest to the earthen vessel: in both cases it is advisable to shift their position occasionally. By combining these different arrangements, the deposit obtained is more abundant, and more equally distributed upon the surface to be gilded or to be silvered. For this purpose an opening is made in the centre of the web in which the zinc cylinder is inserted, with connecting wires to the web. When the articles to be operated upon can be easily suspended from a given point, the web of the apparatus may be made with wider meshes, and the articles suspended vertically between them. Dr. Philipp prefers a single galvanic arrangement to a battery, as it affords more solid deposition.

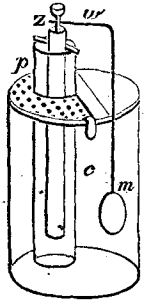
ELECTRO-METALLURGY. By this elegant art perfectly exact copies of any object can be made in copper, silver, gold, and some other metals, through the agency of voltaic electricity. The earliest application of this kind seems to have been practised about 16 years ago, by Mr. Bessemer, of Camden Town, London, who deposited a coating of copper on lead castings, so as to produce antique heads in relief, about 3 or 4 inches in size. He contented himself with forming a few such ornaments for his mantelpiece; and though he made no secret of his purpose, he published nothing upon the subject. A letter of the 22d of May, 1839, written by Mr. J. C. Jordan, which appeared in the *Mechanics' Mag.* for June 8, following, contains the first printed notice of the manipulation requisite for obtaining electro-metallic casts; and to this gentleman, therefore, the world is indebted for the first discovery of this new and important application of science to the uses of life. It appears that Mr. Jordan had made his experiments in the preceding summer, and having become otherwise busily occupied, did not think of publishing till he observed a vague statement in the Journals, that Professor Jacobi, of St. Petersburg, had done something of the same kind. Mr. Jordan's apparatus consisted of a glass tube closed at one extremity with a plug of plaster of Paris, and nearly filled with a solution of sulphate of copper. This tube, and its contents, were immersed in a solution of common salt. A plate of copper was plunged in the cupreous solution, and was connected by means of a wire and solder, with a zinc plate dipped in the brine. A slow electric action was thus established through the moist plaster, and copper was deposited on the metal in a thin plate, corresponding to the former in smoothness and polish; so that when he used an engraved metal matrix, he obtained an impression of it by this electric agency. "On detaching the precipitated metal," says he, "the most delicate and superficial markings, from the fine particles of powder used in polishing to the deeper touches of a needle or graver, exhibited their correspondent impressions in relief with great fidelity. It is, therefore, evident that this principle will admit of improvement, and that casts and moulds may be obtained from any form of copper. This rendered it probable that impressions might be obtained from those other metals having an electro-negative relation to the zinc plate of the battery. With this view a common printing type was substituted for the copper-plate, and treated in the same manner. This, also, was successful; the reduced copper coated that portion of the type immersed in the solution. This, when removed, was found to be a perfect matrix, and might be employed for the purpose of casting, where time is not an object." "Casts may probably be obtained from a plaster surface surrounding a plate of copper," &c.

On the 12th of September following the above publication, Mr. Thomas Spencer read a paper "On Voltaic Electricity applied to the purpose of working in Metal," before the Polytechnic Society of Liverpool, which he had intended to present to the British Association at Birmingham in the preceding August, but not being well received there, he exhibited merely some electro-metallic casts which he had prepared. The Society published Mr. Spencer's Paper, and thereby served to give rapid diffusion to the practice of electro-metallurgy.

One of the most successful cultivators of this art has been Mr. C. V. Walker, Secretary to the London Electrical Society. He has published an ingenious little work in two parts, entitled *Electrotype Manipulation*, where he presents, in a lucid manner, the theory and practice of working in metals, by precipitating them from their solutions, through the agency of voltaic electricity. His first part is devoted to the explanation of principles, to the preparation of moulds, to the description of the voltaic apparatus to be used, to bronzing, to coating busts with copper, to the multiplication of engraved plates, and to the deposition of other metals.

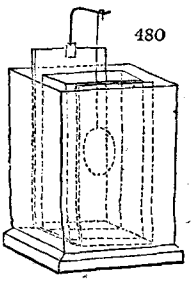
Fig. 479. represents a single-cell voltaic apparatus for electro-metallurgy. *z* is a rod of amalgamated zinc, *m* is the mould on which the metal is to be deposited; *w*, is the wire joining them; *c* is a strong solution of sulphate of copper in the large vessel; *p* is a tube or cylinder of porous earthenware, standing in the other, and containing dilute sulphuric acid. The solution of blue vitriol is kept saturated, during the progress of its depositing copper, by piling crystals of the salt upon the shelf, shown by the dots under *p*. The mould to be coated should not be too small in reference to the surface of zinc under voltaic action. The time for the deposition to be effected depends upon the temperature; and is less the higher this is within certain limits; and at a freezing temperature it ceases almost entirely. When a mould of fusible metal is used, it should not be placed in the voltaic apparatus till every thing is arranged, otherwise oxide will be deposited upon it, and spoil the effect. When the circuit is completed the mould may be immersed, but not before. Wax moulds are rendered electric conductors, and thereby depositors as follows: — After breathing on the wax, rub its surface with a soft brush dipped in plumbago; breathing and rubbing alternately till the surface be uniformly covered. Attach a clean wire to the back of the mould, connecting it by plumbago with the blackened wax. Sealing-wax is coated in like manner. Casts of Paris plaster are first well imbued with melted wax or tallow, and then black-leaded. Objects in Paris plaster should be thoroughly penetrated with hot water, but not wet on the surface, before wax casts are made from them. Moulds are best taken from medals in stearine (stearic acid). For plating and gilding by electro-chemical agency, the following simple plan of apparatus is used. *Fig.* 480. is a rectangular porcelain vessel, which contains in its centre a porous cell for containing the solution of oxide of silver or gold, by means of cyanide of potassium; and this porous cell is surrounded at a little distance by a similarly formed vessel of zinc. The connection is formed between the zinc and the suspended object to be coated, either by a pinching screw, or by the pressure of its weight upon the wire. The dilute acid which excites the zinc should, in this case, be very weak, in reference to the strength of the cyanide solution, which should be recruited occasionally by the addition of oxide.

479

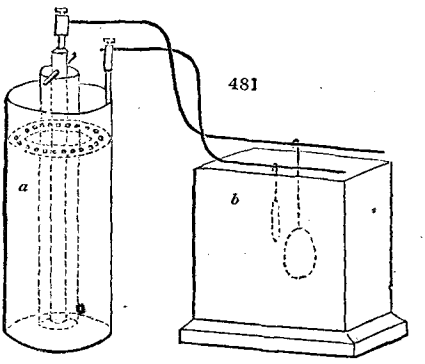


It has been found that with cyanide solutions of gold and silver in the electro-chemical apparatus, the nascent cyanogen at the positive pole or plate, in a decomposition cell, will act upon and dissolve gold and silver. Two or three of Daniell's cylindric cells, as shown at *a* in *fig.* 481., of a pint size, for acting upon solutions of

480



481



gold or silver, will in general suffice. The decomposition cell *b* is made of glass or porcelain. The zinc may be amalgamated, and excited with brine; the copper cell contains, as usual, a solution of blue vitriol. To the end of the wire attached to the copper cylinder of the battery, a plate of silver or gold is affixed; and to the end of the wire attached to the zinc cylinder is affixed the mould, or surface, to be plated or gilt. The plates of silver or gold and zinc should be placed face to face as shown in the figure in the decomposition cell; which is filled by the cyanide solution. A certain degree of heat favours the processes of electro-gilding and plating. The surface is dead as first obtained, but it may be easily polished with leather and plate-powder, and burnished in whole or in parts with a steel or agate tool.

In March, 1840, Messrs. Elkington obtained a patent for the use of *prussiate of potash*, as a solvent for the oxides of gold and silver in the electro-chemical apparatus for plating and gilding metals. They also "sometimes employ a solution of protoxide (purple of Cassius) in the muriates of potash," &c. The chemical misnomers, in their specification, are very remarkable, and do great discredit to the person employed to draw it up. Prussiate of potash is the ordinary commercial name of a salt very different from the cyanide of potassium,—the substance really meant by the patentees,—and the purple of Cassius is very different from protoxide of gold.

In plating or gilding great care must be bestowed in making the articles clean, bright, and perfectly free from the least film of grease. For this purpose, they should be boiled in a solution of caustic alkali, then scoured with sand and water, next dipped into a dilute acid, and finally rinsed with water. A solution of the nitrate or cyanide of mercury may also be used with advantage for cleaning surfaces. The following metals have been deposited by electro-chemistry:—

Gold, platinum, silver, copper, zinc, nickel, antimony, bismuth, cobalt, palladium, cadmium, lead, and tin; of these, the first five are the most important and valuable. The gilding solution may be prepared by placing slips or sheets of gold in a solution of cyanide of potassium, and attaching to the negative pole of a voltaic battery a small plate of gold, but to the positive pole a much larger one; whereby the latter combines with the cyanogen, under the influence of positive electricity, and forms a solution. Or, oxide of gold, precipitated from the chloride by magnesia, may be dissolved in the solution of the cyanide.

For making copper medals, &c., a plate of amalgamated zinc is to be put into a vessel of unglazed earthenware, or of any other porous substance, filled with dilute sulphuric acid; which vessel is set into a trough of glass, glazed pottery, or pitched wood, containing blue vitriol in the state of solution, as well as in the state of crystals upon a perforated shelf, near the surface of the liquid.

The moulds to be covered with copper are to be attached by a copper wire to the zinc plate. The surface of zinc excited by the acid should be equal to that of the moulds; with which view a piece of zinc, equivalent in size to the mould, should be suspended in front of it.

For depositing copper upon iron, Messrs. Elkington use a solution of ferrocyanide of copper in cyanide of potassium in the decomposition trough, instead of sulphate of copper, neutralized from time to time with a little caustic alkali, as in the common practice of making medals, &c., of copper. I should imagine that the black oxide of copper dissolved in solution of cyanide of potassium would answer better; as the iron in the ferrocyanide might be rather injurious. The iron to be coppered being previously well cleaned from rust, &c., with the aid of a dilute acid, is to be plunged into the cyanide solution heated to 120° Fahrenheit, and connected by a wire with the negative pole of a voltaic battery, as formerly described. In from five to ten minutes, the iron will be completely coated. It is then to be scoured with sand, and plunged into solution of sulphate of copper; whereby it will show black spots wherever there are any defective places. In this case, it is to be cleaned and replaced under the cyanide solution, in the decomposition cell for a minute or two. Zinc may be deposited from a solution of its sulphate by a like arrangement.

Metallic cloth may be made as follows:—On a plate of copper attach quite smoothly a stout linen, cotton, or woollen cloth, and connect the plate with the negative pole of a voltaic battery; then immerse it in a solution of copper or other metal, connecting a piece of the same metal as that in the solution with the positive pole; decomposition takes place, and the separated metallic particles in their progress towards the metal plate or negative pole, insinuate themselves into the pores of the tissue, and form a complete sheet of flexible metal. Lace is metallized by coating it with plumbago, and then subjecting it to the electro-metallurgic process.

The gilding solution should be used in the electric process at a temperature of 130° F. The more intense the electric power, the denser and harder is the metallic coat deposited.

Metallic silver may be combined with cyanogen by subjecting it to the joint action of a solution of cyanide of potassium and positive electricity. Or cyanide of silver may be precipitated from the nitrate by a little cyanide of potassium, and afterwards dissolved by means of an excess of cyanide of potassium. The *quantity* of electric power or surface-size of the battery should in all cases be proportioned to the surface of the articles to be plated or gilt, and the electric intensity or number of sets of jars proportioned to the density of the solution. Plating is accomplished in from 4 to 6 hours. The articles should be weighed before and after this operation, to ascertain how much silver they have taken on.

Messrs. Elkington make their moulds with wax, combined with a little phosphorus, which reduces upon their surfaces a thin film of gold or silver, from solutions of these

metals, which films are better than the black-leaded surfaces for receiving the copper deposit. They also recommend to add a little alkali to the solution of sulphate of copper, intended to afford a deposit of metal. The single cell, first described above, is best adapted for this purpose.

M. Ruolz employs for gilding, a solution of sulphuret of gold in sulphuret of potassium, which he prepares by precipitating a solution of gold in *aqua regia*, by sulphuretted hydrogen, and re-dissolving the precipitate with sulphuret of potassium. By the use of this solution of gold, he obtains a very beautiful and solid gilding, and at less expense than with cyanide of potassium. Every metal which is a negative electrode to gold may be gilded.

Platinizing is effected best by means of a solution of the potash-chloride of platinum in caustic potash. 1 milligramme (0·015 grain) covers completely a surface of 50 square centimetres (2 inches square); the film of platinum is only one hundredth of a milligramme thick.

M. Bœttger has shown that we may easily tin copper and brass in the moist way by dissolving peroxide of tin (putty) in hydrate of potash (caustic potash ley), putting at the bottom of the vessel holding that solution some turnings of tin, setting the piece of copper or brass upon the turnings, and making the liquor boil. An electric current is produced by the contact of the dissimilar metals; and as the tin is withdrawn by the copper or brass from the solution, it is restored to it by the turnings. Zinking may be done in the same way; by putting pieces of zinc into a concentrated solution of chlorine, by setting the piece of metal to be zinked in contact with these pieces, and applying heat to the vessel containing the whole.

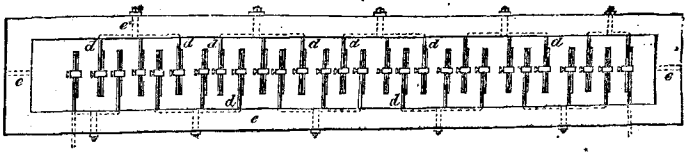
For certain new methods of constructing and arranging voltaic batteries for electro-metallurgic operations, a patent was obtained by Dr. Leeson in June, 1842.

Fig. 482. is a longitudinal section of the battery, and *fig.* 483. a plan view of the frame to which the metal plates are attached. *a* is a rectangular wooden trough, containing a wooden frame *b*, formed with vertical grooves in its sides, to receive a series of porous cells *c*, *c*, *c*. The plates of the battery are suspended in the fluid or fluids by brass forks *d*, *d*, fastened to a wooden frame *e*, *e*, which rests upon the trough *a*, and is connected to the other frame *b*, by two pins *f*, when they are required to be raised together out of the trough *a*, *a*.

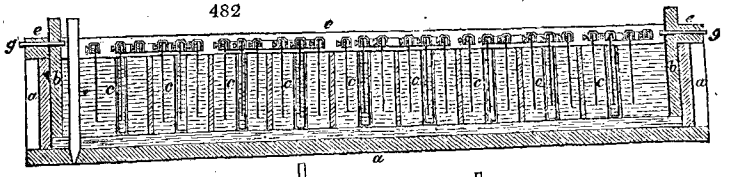
The battery may be charged as usual with one or two fluids; one of them in the latter case being contained in the porous cells *c*, *c*, *c*; and plates of copper and zinc, or any other suitable metals may be employed.

The second improvement consists in cleaning copper and zinc plates after they have been used in a battery, by the employment of a voltaic battery; and also in amalga-

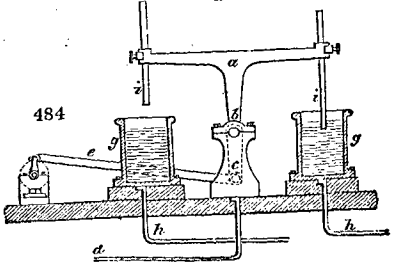
483



482



484



mating or coating with mercury the surfaces of zinc plates, by the same means to render them suitable for being used in the construction of the voltaic apparatus.

The third improvement consists in exciting electricity by a combination of nitric, sulphuric, or muriatic acid, with any of the following substances; viz. impure ammoniacal or lime liquor of the gas works, solutions of alkaline and earthy sulphurets, the alkalies and their carbonates, or lastly, the acidulous sulphate of iron generated from iron pyrites.

Another of Dr. Leeson's manifold improvements for depositing metallic alloys consists in the employment of one battery, with the "alternating cathode," represented in *fig.* 484. It is composed of a beam, *a*, mounted on the shaft, *b*, which turns in bearings carried by standards, *c*; the beam communicates with the anode of the battery by the wire, *d*, and a vibrating motion is given to it by the rod, *e*, from the shaft, *f*, which is driven by an electro-magnetic engine, or any other suitable prime mover. *g*, *g* are two vessels containing mercury, connected by wires, *h*, *h*, with the cathode plates of the two metals composing the alloy (but if the alloy is to consist of more than two metals, then more vessels, *g*, will be required, one for each cathode plate); these plates are immersed in a solution composed of similar salts of the different metals to be deposited, together with the anode, or surface to be deposited upon, which is connected by a wire with the cathode of the battery. A communication is established between the two cathode plates, or supply metals, and the anode of the battery, by means of the rods, *i*, *i*, which are caused, by the vibration of the beam, *a*, to dip alternately into either the one or the other of the vessels, *g*; and thus each metal will be deposited on the article to be coated, during the time that the connection is established between it and the battery, by the immersion of its rod into the vessel of mercury. The relative proportions of the two metals is adjusted by lengthening or shortening the rods, *i*, *i*, as shown in the figure, so that they may be immersed for a longer or shorter period in the mercury.

Where the electrical current enters the electrolyte, is the *anode*; where it leaves it, is the *cathode*.

The patentee describes ten other improvements, which seem to be ingenious. See *Newton's Journal*, xxii. 292.

ELECTROTYPIE BY THERMO-ELECTRICITY. 1. *For silvering.* — Dissolve 1 troy pound of silver in nitric acid, dilute with a gallon of water, precipitate the silver by solution of carbonate of soda (1 lib.) at 100° Fahr.; wash the precipitate on the filter with warm water. In another vessel dissolve 8 libs. of hyposulphite of soda in 2½ gallons of water at 100°, add 1 lib. of carbonate of soda with the carbonate of silver, stirring until the silver be dissolved. Filter the solution for use. It is advantageous to add 1 lib. avoirdupois of hyposulphite, and one-third of a pound of carbonate of soda for every pound troy of silver that may be deposited.

2. *Gold solution.* — One ounce troy of fine gold is dissolved in nitro-muriatic acid, and the solution is evaporated till it assumes a deep red colour, and crystallizes upon cooling. Dilute with a pint of pure water and filter. Heat this solution to about 200° Fahr., and precipitate the gold by water of ammonia. Wash the precipitate well on the filter with hot water. Dissolve this gold in 1 gallon of water containing 8 ounces of hyposulphite of soda, and boil together for an hour. The solution when filtered is fit for use. In gilding, this solution may be warmed to about 130° Fahr. A small anode of gold, of about one-tenth the size of the article to be gilded, and a current of two pairs of common galvanic plates, are used.

3. *Copper solution.* — Dissolve 1 pound of carbonate of copper in 8 pounds of hyposulphite of soda, and 1 pound of carbonate of soda dissolved in 2½ gallons of distilled water at 100° Fahr., or thereabouts, and filtered to obtain a clear solution. It is then fit for use, with currents of electricity at 100° Fahr.

Description of the thermo-electric battery. — 100 pieces of German silver, containing from 20 to 25 per cent. of nickel, and 100 pieces of iron, each piece being 1 inch broad, 1 foot long, and one-eighth of an inch in thickness. These 200 pieces are soldered to each other, so that iron is always combined with German silver. To get a compact form, 10 rows must be first arranged (every one of 20 pieces or 10 pairs), and these rows must be so soldered to each other that they are parallel, and the whole take the form of a square; taking care that the several pieces are soldered together in such a way that iron will always be in connection with German silver. When the whole is united, it is placed in a rim or frame of iron plate, 1 foot 2 inches high, but so that the metals do not touch each other, nor the iron rim or frame, and fill the rim with plaster of Paris or clay, so that all soldered parts of the series of plates or bars are uncovered, that is, the under ends 1 inch, and the upper ends 3 inches. The clay is covered at the surface with a layer of pitch. The frame containing the series of bars or plates, is so placed that the lower ends of the series (1 inch) dip into a sand bath which is heated nearly to redness. The upper ends (3 inches) are to be kept as cold as possible, and for this purpose a current of cold water is caused to

flow from one vessel over this battery to another vessel. The upper end of the metals (3 inches) may be covered with a lac or varnish. There is an *anode* wire leading from the German silver plate; and an *artule* wire leading from the iron plate.

The thermo-electric apparatus is intended for the deposition of metals, from the above described solutions.

ELEMENTS (Eng. and Fr.; *Grundstoffe*, Germ.) The ancients considered fire, air, water, and earth, as simple substances, essential to the constitution of all terrestrial beings. This hypothesis, evidently incompatible with modern chemical discovery, may be supposed to correspond, however, to the four states in which matter seems to exist; namely, 1. the unconfinable powers or fluids,—caloric, light, electricity; 2. ponderable gases, or elastic fluids; 3. liquids; 4. solids. The three elements of the alchemists, salt, earth, mercury, were, in *their* sense of the words, mere phantasms.

In modern science, the term *Element* signifies merely a substance which has not yet been resolved by analysis into any simpler form of matter; and it is therefore synonymous

with undecompounded. This class comprehends 62 different bodies, of which no less than 52 are metallic. Five may be styled *Archæal*, from the intensity and universality of their affinities for the other bodies, which they penetrate, corrode, and apparently consume, with the phenomena of light and heat. These 5 are *chlorine, oxygen, iodine, bromine, fluorine*. Eight elements are eminently inflammable when acted upon by any of the preceding five, and are thereby converted into incombustible compounds. The simple non-metallic inflammables are *hydrogen, azote, sulphur, phosphorus, selenium, carbon, boron, silicon*.

The preceding table exhibits all the undecompounded bodies in alphabetical order, with their prime equivalent numbers, atomic weights, or reciprocal combining and saturating proportions, in reference to oxygen and hydrogen, reckoned 100,000, or 1·0.

The numbers contained in columns I. and II. are deduced from those given by Berzelius, in the fifth edition of his *Lehrbuch;* and in column III. those atomic weights are added which Gerhardt and Laurent have quoted in the first number of the fifth volume of the *Comptes Rendus*.

The following is a table of atomic weights corrected and fixed by various chemists in recent times: —

Denomination of the Substances.	Symbols.	Equivalents.		Atomic Weights.	
		O=100.	H=1.	O=100.	H=1.
Calcium (Erdmann and Marchand)	Ca.	250·000	20·000	250·000	40·000
Carbon (ditto)	C.	75·000	6·000	75·000	12·000
Hydrogen	H.	12·000	1·000	6·250	1·000
Iron (Erdmann and Marchand)	Fe.	350·000	28·000	350·100	56·000
Mercury (ditto)	Hg.	1250·000	100·000	1250·000	200·000
Phosphorus (Pelouze)	P.	400·300	32·024	200·150	32·024
Sodium (ditto)	Na.	287·170	22·973	287·170	45·946
Strontium (ditto)	Sr.	548·020	43·841	548·020	87·682
Sulphur (Erdmann and Marchand)	S.	200·000	16·000	200·000	32·000

Within the last few years the following atomic weights have been revised: —

Barium	Ba.	856·770	Marignac.
Calcium	Ca.	350·000	Erdm. and March.
Chromium	Cr.	333·500	Lefort.
Chromium	Cr.	335·091	Moberg.
Fluorine	Fl.	237·500	Louyet.
Magnesium	Mg.	152·550	Jacquelain.
Magnesium	Mg.	154·490	Svanberg.
Magnesium	Mg.	150·000	March. and Scheer.
Molybdenum	Mo.	574·750	Berlin.
Molybdenum	Mo.	574·829	Svanb. and Struve.
Tungsten	W.	1150·780	Schneider.

ELEMI is a resin which exudes from incisions made during dry weather through the bark of the *amyris elemifera*, a tree which grows in South America and Brazil. It comes to us in yellow, tender, transparent esmps, which readily soften by the heat of the hand. They have a strong aromatic odour, a hot spicy taste, and contain 12½ per cent. of ethereous oil. The crystalline resin of elemi has been called *Elémine*. It is used in making lacquer, to give toughness to the varnish.

ELUTRIATE. (*Soutirer*, Fr.; *Schlemmen*, Germ.) When an insoluble pulverulent matter, like whitening or ground flints, is diffused through a large body of water, and the mixture is allowed to settle for a little, the larger particles will subside. If the supernatant liquid be now carefully decanted, or run off, with a syphon, it will contain an impalpable powder, which on repose will collect at the bottom, and may be taken out to dry. This process is called elutriation.

ELVAN. The name given by the Cornish miners to porphyry, as also to the heterogeneous rocky masses which occur in the granite or in the clay slate, deranging the direction of their metallic veins, or even the mineral strata; but elvan generally indicates a felspar porphyry.

EMBALMING. (*Embaument*, Fr.; *Einbalsamen*, Germ.) Is an operation in which balsams (*baumes*, Fr.) were employed to preserve human corpses from putrefaction; whence the name.

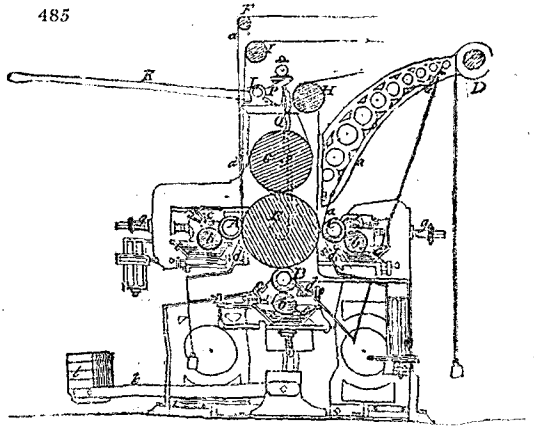
The ancient Egyptians had recourse to this process for preserving the bodies of numerous families, and even of the animals which they loved or worshipped. An excellent account of their methods is given in Mr. Pettigrew's work upon Mummies. Modern chemistry has made us acquainted with many means of counteracting putre-

faction more simple and efficacious than the Egyptian system of salting, smoking, spicing, and bitumenizing. See PUTREFACTION.

EMBOSSING CLOTH. Mr. Thomas Greig, of Rose Bank, near Bury, patented an invention, in November, 1835, which consists in an ingenious construction of machinery for both embossing and printing silk, cotton, woollen cloth, paper, and other fabrics, in one or more colours, at one operation.

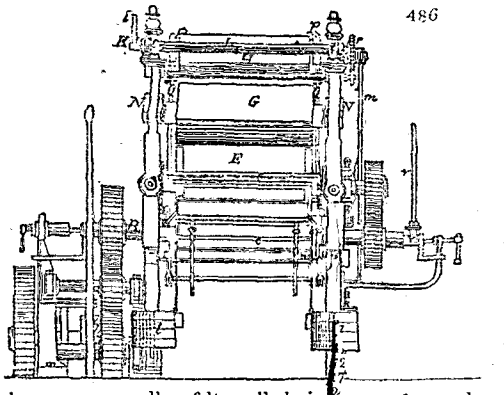
Figs. 485, 486. represent three distinct printing cylinders of copper, or other suitable material, A, B, C, with their necessary appendages for printing three different colours upon the fabric as it passes through the machine: either of these cylinders A, B, or C, may be employed as an embossing cylinder, without performing the printing process, or may be made to effect both operations at the same time.

485



The fabric or goods to be operated upon being first wound tightly upon a roller, that roller is to be mounted upon an axle or pivot, bearing in arms or brackets at the back of the machine, as shown at D. From this roller the fabric *a a a a* is conducted between tension rails, and passed under the bed cylinder or paper bowl E, and from thence proceeds over a carrier roller F, and over steam boxes not shown in the drawing, or it may be conducted into a hot room, for the purpose of drying the colours.

486



The cylinders A, B, and C, having either engraved or raised surfaces, are connected to feeding rollers *b, b, b,* revolving in the ink or coloured troughs *c, c, c*; or endless felts, called sieves, may be employed, as in ordinary printing machines, for supplying the colour, when the device on the surface of the cylinders is raised; these cylinders may be furnished with doctors or scrapers when required, or the same may be applied to the endless felts.

The blocks have adjustable screws *g, g,* for the purpose of bringing the cylinders up against the paper bowl with any required degree of pressure; the cylinder B is supported by its gudgeons running in blocks, which blocks slide in the lower parts of the side frames, and are connected to perpendicular rods *i*, having adjustable screw nuts.

The lower parts of these rods bear upon weighted levers *k, k*, extending in front of the machine; and by increasing the weights *l, l*, any degree of upward pressure may be given to the cylinder B.

The colour boxes or troughs *c, c, c*, carrying the feeding rollers *b, b, b*, are fixed on boards which slide in grooves in the side frames, and the rollers are adjusted and brought into contact with the surface of the printing cylinders by screws.

If a back cloth should be required to be introduced between the cylindrical bed or paper bowl E, and the fabric *a a a*, as the ordinary felt or blanket, it may, for printing and embossing cotton, silk, or paper, be of linen or cotton; but if woollen goods are to be operated upon, a cap of felt, or some such material, must be bound round the paper

bowl, and the felt or blanket must be used for the back cloth, which is to be conducted over the rollers H and I.

For the purpose of embossing the fabric, either of the rollers A, B, or C, may be employed, observing that the surface of the roller must be cut, so as to leave the pattern or device elevated for embossing velvets, plain cloths, and papers; but for woollens the device must be excavated, that is, cut in recess.

The pattern of the embossing cylinder will, by the operation, be partially marked through the fabric on to the surface of the paper bowl E; to obliterate which marks from the surface of the bowl, as it revolves, the iron cylinder roller G is employed; but as in the embossing of the same patterns on paper, a counter roller is required to produce the pattern perfectly, the iron roller is in that case dispensed with, the impression given to the paper bowl being required to be retained on its surface until the operation is finished.

In this case the relative circumferences of the embossing cylinder, and of the paper bowl, must be exactly proportioned to each other; that is, the circumference of the bowl must be equal, exactly, to a given number of circumferences of the embossing cylinder, very accurately measured, in order to preserve a perfect register or coincidence, as they continue revolving between the pattern on the surface of the embossing cylinder and that indented into the surface of the paper bowl.

The axle of the paper bowl E, turns in brasses fitted into slots in the side frames, and it may be raised by hand from its bearings, when required, by a lever *k*, extending in front. This lever is affixed to the end of a horizontal shaft L, L, crossing the machine seen in the figures, at the back of which shaft there are two segment levers P, P, to which bent rods Q, Q, are attached, having hooks at their lower ends, passed under the axle of the bowl. At the reverse end of the shaft L, a ratchet-wheel *r*, is affixed, and a pall or click mounted on the side of the frame takes into the teeth of the wheel *r*, and thereby holds up the paper bowl when required.

When the iron roller G, is to be brought into operation, the vertical screws *t*, *t*, mounted in the upper parts of the side frames, are turned, in order to bring down the brasses N, which carry the axle of that roller and slide in slots in the side frames.

The cylinders A, B, and C, are represented hollow, and may be kept at any desired temperature during the operation of printing, by introducing steam into them; and under the colour boxes c, c, c, hollow chambers are also made for the same purpose. The degree of temperature required to be given to these must depend upon the nature of the colouring material, and of the goods operated upon. For the purpose of conducting steam to these hollow cylinders and colour boxes, pipes, as shown at *v*, *v*, *v*, are attached, which lead from a steam boiler. But when either of these cylinders is employed for embossing alone, or for embossing and printing at the same time, and particularly for some kinds of goods where a higher temperature may be required, a red-hot heater is then introduced into the hollow cylinder in place of steam.

If the cylinder B, is employed as the embossing cylinder, and it is not intended to print the fabric by that cylinder simultaneously with the operation of embossing, the feeding roller *b*, must be removed, and also the colour box *c*, belonging to that cylinder; and the cylinders A and C are to be employed for printing the fabric, the one applying the colour before the embossing is effected, the other after it. It is however to be remarked, that if A and C are to print colours on the fabric, and B to emboss it, in that case it is preferred, where the pattern would allow it. A and C are wooden rollers having the pattern upon their surfaces, and not metal, as the embossing cylinders must of necessity be.

It will be perceived that this machine will print one, two, or three colours at the same time, and that the operation of embossing may be performed simultaneously with the printing, by either of the cylinders A, B, or C, or the operation may be performed consecutively by the cylinders, either preceding or succeeding each other.

The situations of the doctors, when required to be used for removing any superfluous colour from the surface of the printing cylinder, are shown at *d*, *d*, *d*; those for removing any lint which may attach itself, at *e*, *e*, *e*. They are kept in their bearings by weighted levers and screws, and receive a slight lateral movement to and fro, by means of the vertical rod *m*, which is connected at top to an eccentric, on the end of the axle of the roller H, and at its lower end to a horizontal rod mounted at the side of the frame; to this horizontal rod, arms are attached, which are connected to the respective doctors; and thus by the rotation of the eccentric, the doctors are made to slide laterally.

When the cylinders A, B, or C, are employed for embossing only, those doctors will not be required. The driving power is communicated to the machine from any first mover through the agency of the toothed geer, which gives rotatory motion to the cylinder B, and from thence to the other cylinders A, and C, by toothed geer shown in *Fig.* 485.

EMBOSSING OF LEATHER. Beautiful ornaments in basso-relievo for decorating the exteriors or interiors of buildings, medallions, picture-frames, cabinet work,

&c., have been recently made by the pressure of metallic blocks and dies, for which invention a patent was obtained in June, 1839, by M. Claude Schroth. The dies are made of type metal, or of the fusible alloy with bismuth, called d'Arcet's. The leather is beaten soft in water, then wrung, pressed, rolled, and fulled as it were, by working it with the hands till it becomes thicker and quite supple. In this state it is laid on the mould, and forced into all its cavities by means of a wooden bone, or copper tool. In other cases, the embossing is performed by the force of a press. The leather, when it has become dry, is easily taken off the mould, however deeply it may be inserted into its crevices, by virtue of its elasticity. A full detail of all the processes is given in *Newton's Journal*, vol. xxii. p. 122.

EMBOSSING WOOD. (*Bossage*, Fr.; *Erhabenes, Arbeit*, Germ.) Raised figures upon wood, such as are employed in picture-frames and other articles of ornamental cabinet work, are usually produced by means of carving, or by casting the pattern in plaster of Paris, or other composition, and cementing, or otherwise fixing it on the surface of the wood. The former mode is expensive; the latter is inapplicable on many occasions. The invention of Mr. Streaker may be used either by itself, or in aid of carving; and depends on the fact, that if a depression be made by a blunt instrument on the surface of the wood, such depressed part will again rise to its original level by subsequent immersion in the water.

The wood to be ornamented having been first worked out to its proposed shape, is in a state to receive the drawing of the pattern; this being put on, a blunt steel tool, or burnisher, or die, is to be applied successively to all those parts of the pattern intended to be in relief, and, at the same time, is to be driven very cautiously, without breaking the grain of the wood, till the depth of the depression is equal to the intended prominence of the figures. The ground is then to be reduced by planing or filing to the level of the depressed part; after which, the piece of wood being placed in water, either hot or cold, the part previously depressed will rise to its former height, and will then form an embossed pattern, which may be finished by the usual operations of carving.

For this invention the Society of Arts voted to Mr. Streaker their silver Isis medal, and ten guineas.

EMBROIDERING MACHINE. (*Machine à broder*, Fr.; *Steckmaschine*, Germ.) This art has been till of late merely a handicraft employment, cultivated on account of its elegance by ladies of rank. But a few years ago M. Heilmann, of Mulhause, invented a machine of a most ingenious kind, which enables a female to embroider any design with 80 or 140 needles as accurately and expeditiously as she formerly could do with one. A brief account of this remarkable invention will therefore be acceptable to many readers. It was displayed at the national exposition of the products of industry in Paris for 1834, and was unquestionably the object which stood highest in public esteem; for whether at rest or in motion, it was always surrounded with a crowd of curious visitors, admiring the figures which it had formed, or inspecting its movements and investigating its mechanism. 130 needles were occupied in copying the same pattern with perfect regularity, all set in motion by one person.

Several of these machines are now mounted in France, Germany, and Switzerland. I have seen one factory in Manchester, where a great many of them are doing beautiful work.

The price of a machine having 130 needles, and of consequence 260 pincers or fingers and thumbs to lay hold of them, is 5000 francs, or 200*l.* sterling; and it is estimated to do daily the work of 15 expert hand embroiderers, employed upon the ordinary frame. It requires merely the labour of one grown-up person, and two assistant children. The operative must be well taught to use the machine, for he has many things to attend to: with the one hand he traces out, or rather follows the design with the point of the pantograph; with the other he turns a handle to plant and pull all the needles, which are seized by pincers and moved along by carriages, approaching to and receding from the web, rolling all the time along an iron railway; lastly, by means of two pedals, upon which he presses alternately with the one foot and the other, he opens the 130 pincers of the first carriage, which ought to give up the needles after planting them in the stuff, and he shuts with the same pressure the 130 pincers of the second carriage, which is to receive the needles, to draw them from the other side, and to bring them back again. The children have nothing else to do than to change the needles when all their threads are used, and to see that no needle misses its pincers.

This machine deserves particular attention, because it is no less remarkable for the happy arrangement of its parts, than for the effects which it produces. It may be described under four heads: 1. the structure of the frame; 2. the disposition of the web; 3. the arrangement of the carriages; and 4. the construction of the pincers.

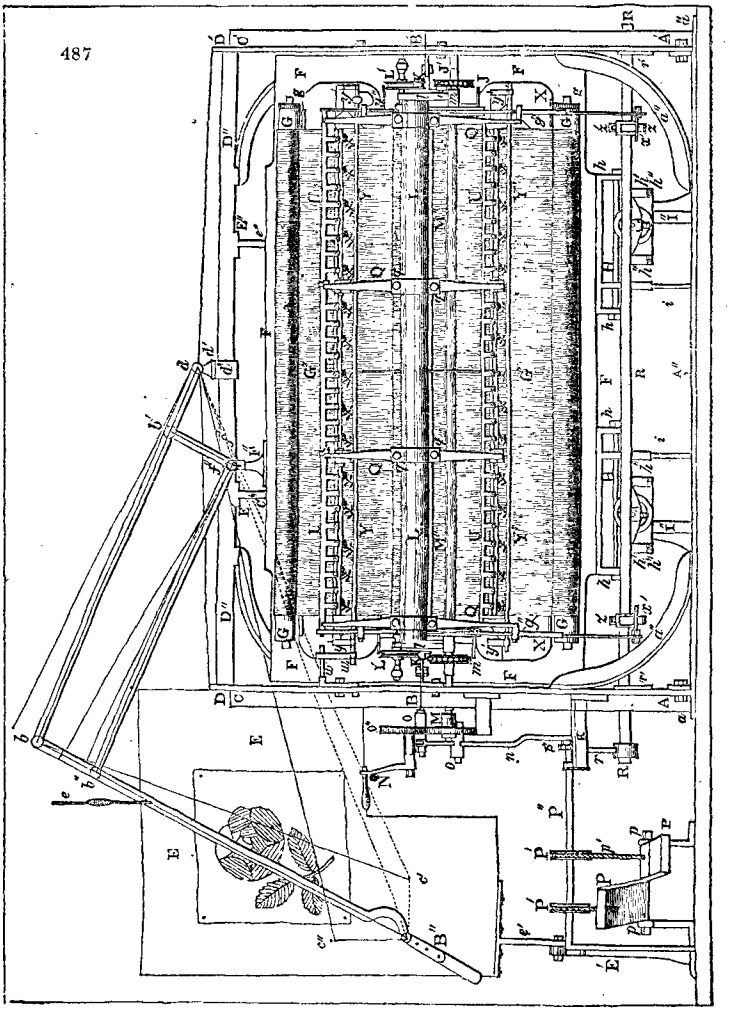
1. The structure of the frame. It is composed of cast-iron, and is very massive. *Fig.* 487. exhibits a front elevation of it. The length of the machine depends upon the number of pincers to be worked. The model at the exposition had 260

pincers, and was 2 metres and a half (about 100 inches or 8 feet 4 inches English) long. The figure here given has been shortened considerably, but the other proportions are not disturbed. The breadth of the frame ought to be the same for every machine, whether it be long or short, for it is the breadth which determines the length of the thread to be put into the needles, and there is an advantage in giving it the full breadth of the model machine, fully 100 inches, so that the needles may carry a thread at least 40 inches long.

Disposition of the piece to be embroidered.—We have already stated that the pincers which hold the needles always present themselves opposite to the same point, and that in consequence they would continually pass backwards and forwards through the same hole, if the piece was not displaced with sufficient precision to bring successively opposite the tips of the needles every point upon which they are to work a design, such as a flower.

The piece is strained perpendicularly upon a large rectangular frame, whose four sides are visible in *fig.* 487.; namely, the two vertical sides at F F, and the two horizontal sides, the upper and lower at F′ F″. We see also in the figure two long wooden rollers

487



G and G, whose ends, mounted with iron studs, are supported upon the sides F of the frame, so as to turn freely. These form a system of beams upon which the piece destined to receive the embroidery, is wound and kept vertically stretched to a proper de-

gree, for each of these beams bears upon its end a small ratchet wheel g, g; the teeth of one of them being inclined in the opposite direction to those of the other. Besides this system of lower beams, there is another of two upper beams, which is however but imperfectly seen in the figure, on account of the interference of other parts in this view of the machine. One of these systems presents the web to the inferior needles, and the other to the upper needles. As the two beams are not in the same vertical plane, the plane of the web would be presented obliquely to the needles were it not for a straight bar of iron, round whose edge the cloth passes, and which renders it vertical. The piece is kept in tension crosswise by small brass templets, to which the strings g'' are attached, and by which it is pulled towards the sides of the frame F. It remains to show by what ingenious means this frame may be shifted in every possible direction. M. Heilmann has employed for this purpose the pantograph which draughtsmen use for reducing or enlarging their plans in determinate proportions.

$b\ b'\ f''\ b''$ (*fig.* 487.) represents a parallelogram of which the four angles b, b', f'', b'' are jointed in such a way that they may become very acute or very obtuse at pleasure, while the sides of course continue of the same length; the sides $b\ b'$ and $b\ b''$ are prolonged, the one to the point d, and the other to the point c, and these points c and d are chosen under the condition that in one of the positions of the parallelogram, the line $c\ d$ which joins them passes through the point f; this condition may be fulfilled in an infinite number of manners, since the position of the parallelogram remaining the same, we see that if we wished to shift the point d further from the point b', it would be sufficient to bring the point c near enough to b'', or *vice versâ*; but when we have once fixed upon the distance $b'\ d$, it is evident that the distance $b''\ c$ is its necessary consequence. Now the principle upon which the construction of the pantograph rests is this; it is sufficient that the three points d, f, and c be in a straight line, in one only of the positions of the parallelogram, in order that they shall remain always in a straight line in every position which can possibly be given to it.

We see in the figure that the side $b\ c$ has a handle B'' with which the workman puts the machine in action. To obtain more precision and solidity in work, the sides of the pantograph are joined, so that the middle of their thickness lies exactly in the vertical plane of the piece of goods, and that the axes of the joints are truly perpendicular to this plane, in which consequently all the displacements are effected. We arrive at this result by making fast to the superior great cross bar D'' an elbow piece d'', having a suitable projection, and to which is adapted in its turn the piece d', which receives in a socket the extremity of the side $b\ d$; this piece d' is made fast to d'' by a bolt, but it carries an oblong hole, and before screwing up the nut, we make the piece advance or recede, till the fulcrum point comes exactly into the plane of the web. This condition being fulfilled, we have merely to attach the frame to the angle f of the parallelogram, which is done by means of the piece F''.

It is now obvious that if the embroiderer takes the handle B'' in his hand and makes the pantograph move in any direction whatever, the point f will describe a figure similar to the figure described by the point c, and six times smaller, but the point f cannot move without the frame, and whatever is upon it, moving also. Thus, in the movement of the pantograph, every point of the web describes a figure equal to that described by the point f, and consequently similar to that described by the point c, but six times smaller; the embroidered object being produced upon the cloth in the position of that of the pattern. It is sufficient therefore to give the embroidering operative who holds the handle B'', a design six times greater than that to be executed by the machine, and to afford him at the same time a sure and easy means of tracing over with the point c, all the outlines of the pattern. For this purpose he adapts to c, perpendicularly to the plane of the parallelogram, a small style terminated by a point c', and he fixes the pattern upon a vertical tablet E, parallel to the plane of the stuff and the parallelogram, and distant from it only by the length of the style $c\ c''$; this tablet is carried by the iron rod e', which is secured to a cast iron foot E', serving also for other purposes, as we shall presently see. The frame loaded with its beams and its cloth forms a pretty heavy mass, and as it must not swerve from its plane, it needs to be lightened, in order that the operative may cause the point of the pantograph to pass along the tablet without straining or uncertainty in its movements. M. Heilmann has accomplished these objects in the following way. A cord e attached to the side $b\ c$ of the pantograph passes over a return pulley, and carries at its extremity a weight which may be graduated at pleasure; this weight equipoises the pantograph, and tends slightly to raise the frame. The lower side of the frame carries two rods H and H, each attached by two arms $h\ h$, a little bent to the left; both of these are engaged in the grooves of a pulley. Through this mechanism a pressure can be exercised upon the frame from below upwards which may be regulated at pleasure, and without preventing the frame from moving in all directions, it hinders it from deviating from the primitive plane to which the pantograph was adjusted. The length of the rods H ought to be equal to the amount of the lateral

movement of the frame. Two guides *i i* carried by two legs of cast iron, present vertical slits in which the lower part of the frame F′ is engaged.

Disposition of the carriages. — The two carriages, which are similar, are placed the one to the right, and the other to the left of the frame. The carriage itself is composed merely of a long hollow cylinder of cast iron L, carrying at either end a system of two grooved castors or pulleys L′, which roll upon the horizontal rails K; the pulleys are mounted upon a forked piece *l′*, with two ends to receive the axes of the pulleys, and the piece *l′* is itself bolted to a projecting ear *l* cast upon the cylinder.

This assemblage constitutes, properly speaking, the carriage, resting in a perfectly stable equilibrium upon the rails K, upon which it may be most easily moved backwards and forwards, carrying its train of needles to be passed or drawn through the cloth.

M. Heilmann has contrived a mechanism by which the operative, without budging from his place, may conduct the carriages, and regulate as he pleases the extent of their course, as well as the rapidity of their movements. By turning the axes M″ in the one direction or the other, the carriage may be made to approach to, or recede from, the web.

When one of the carriages has advanced to prick the needles into the stuff, the other is there to receive them; it lays hold of them with its pincers, pulls them through, performs its course by withdrawing to stretch the thread, and close the stitch, then it goes back with the needles to make its pricks in return. During these movements the first carriage remains at its post waiting the return of the second. Thus the two chariots make in succesSsion an advance and a return, but they never move together.

To effect these movements M. Heilmann has attached to the piece o′ made fast to the two uprights A C and A D of the frame, a bent lever *n o n′ n″* movable round the point *o*; the bend *n′* carries a toothed wheel o′, and the extremity *n″* a toothed wheel o″; the four wheels M, M′, o′, and o″, have the same number of teeth and the same diameter; the two wheels o′ and o″ are fixed in reference to each other, so that it is sufficient to turn the handle N to make the wheel o″ revolve, and consequently the wheel o′; when the lever *n o* is vertical, the wheel o′ touches neither the wheel M nor the wheel M′; but if it be inclined to the one side or the other, it brings the wheel o′ alternately into geer with the wheel M or the wheel M′. As the operative has his two hands occupied, the one with the pantograph, and the other with the handle of impulsion, he has merely his feet for acting upon the lever *n o*, and as he has many other things to do, M. Heilmann has adapted before him a system of two pedals, by which he executes with his feet a series of operations no less delicate than those which he executes with his hands.

The pedals P are movable round the axis *p*, and carry cords *p′* wound in an opposite direction upon the pulleys P′; these pulleys are fixed upon a movable shaft P″, supported upon one side by the prop E′, and on the other in a piece K′ attached to the two great uprights of the frame. In depressing the pedal P (now raised in the figure), the upper part of the shaft P″ will turn from the left to the right, and the lever *n o* will become inclined so as to carry the wheel o′ upon the wheel M′, but at the same time the pedal which is now depressed will be raised, because its cord will be forced to wind itself upon its pulley, as much as the other cord has unwound itself; and thus the apparatus will be ready to act in the opposite direction, when wanted.

Disposition of the pincers. — The shaft L′ carries, at regular intervals of a semidiameter, the appendages *q q* cast upon it, upon which are fixed, by two bolts, the curved branches Q destined to bear the whole mechanism of the pincers. When the pincers are opened by their appropriate leverage, and the half of the needle, which is pointed at each end, with the eye in the middle, enters the opening of its plate, it gets lodged in an angular groove, which is less deep than the needle is thick, so that when the pincers are closed, the upper jaw presses it into the groove. In this way the needle is firmly held, although touched in only three points of its circumference.

Suppose, now, that all the pincers are mounted and adjusted at their proper distances upon their prismatic bar, forming the upper range of the right carriage. For opening all the pincers there is a long plate of iron, U, capable of turning upon its axis, and which extends from the one end of the carriage to the other. This axis is carried by a kind of forks which are bolted to the extremity of the branches Q. By turning that axis the workman can open the pincers at pleasure, and they are again closed by springs. This movement is performed by his feet acting upon the pedals.

The threads get stretched in proportion as the carriage is run out, but as this tension has no elastic play, inconveniences might ensue, which are prevented by adapting to the carriage a mechanism by means of which all the threads are pressed at the same time by a weight susceptible of graduation. A little beneath the prismatic bar, which carries the pincers, we see in the figure a shaft Y, going from one end of the carriage to the other, and even a little beyond it; this shaft is carried by pieces *y* which are fixed to the arms Q, and in which it can turn. At its left end it carries two small bars *y′* and

w', and at its right a single bar y', and a counterweight (not visible in this view); the ends of the two bars y' are joined by an iron wire somewhat stout and perfectly straight. When the carriage approaches the web, and before the iron wire can touch it, the little bar w presses against a pin w', which rests upon it, and tends to raise it more and more. In what has preceded we have kept in view only the upper range of pincers and needles, but there is an inferior range quite similar, as the figure shows, at the lower ends of the arms Q. In conclusion, it should be stated, that the operative does not follow slidingly with the pantograph the trace of the design which is upon the tablet or the picture, but he must stop the point of the style upon the point of the pattern into which the needle should enter, then remove it, and put it down again upon the point by which the needle ought to re-enter in coming from the other side of the piece, and so on in succession. To facilitate this kind of reading off, the pattern upon the tablet is composed of right lines terminated by the points for the entrance and return of the needle, so that the operative (usually a child) has continually under her eyes the series of broken lines which must be followed by the pantograph. If she happens to quit this path an instant, without having left a mark of the point at which she had arrived, she is under the necessity of looking at the piece to see what has been already embroidered, and to find by this comparison the point at which she must resume her work, so as not to leave a blank, or to repeat the same stitch.

Explanation of Figure.

A, lower cross bars, which unite the legs of the two ends of the frame.
a, the six feet of the front end of the frame,
a', the six feet of the posterior end of the frame.
a'', curved pieces which unite the cross bars A'' to the uprights.
B'', handle of the pantograph.
b, b', b'', three of the angles of the pantograph.
c, point of the side $b\,b''$ on which the point is fixed.
c'', point of the pantograph.
D'', cross bar in form of a gutter, which unites the upper parts of the frame.
d, fixed point, round which the pantograph turns.
E, tablet upon which the pattern to be embroidered is put.
E', support of that tablet.
e, cord attached at one end to the side $b\,c$ of the pantograph passing over a guide pulley, and carrying a weight at the other end.
e', iron rod by which the tablet E is joined to its support E'.
F, F, uprights of the cloth-carrying frame.
F', F', horizontal sides of the same frame.
G, four roll beams.
G'', the piece of cloth.
g'', the strings, which serve to stretch the cloth laterally.

EMERALD (*Emeraude*, Fr.; *Smaragd*, Germ.), is a precious stone of a beautiful green colour; valued next to diamond, and in the same rank as oriental ruby and sapphire. It occurs in prisms with a regular hexagonal base; sp. grav. 2·7; scratches quartz with difficulty; is scratched by topaz; fusible at the blowpipe into a frothy bead; the precipitate afforded by ammonia, from its solution, is soluble, in a great measure, in carbonate of ammonia. Its analysis is given very variously by different chemists. It contains about 14 per cent. of glucina, which is its characteristic constituent; along with 68 of silica, 16 of alumina, a very little lime and iron. The beautiful emerald of Peru is found in a clay schist mixed with some calcareous matter. A stone of 4 grains weight is said to be worth from 4*l.* to 5*l.*; one of 8 grains, 10*l.*; one of 15 grains, being fine, is worth 60*l.*; one of 24 grains fetched, at the sale of M. de Drée's cabinet, 2400 francs, or nearly 100*l.*

The beryl is analogous in composition to the emerald, and is employed (when of the common opaque kind, found near Limoges), by chemists, for procuring the earth glucina.

EMERY. This mineral was long regarded as an ore of iron; and was called by Haüy *fer oxidé quartzifère*. It is very abundant in the island of Naxos, at cape *Emeri*, whence it is imported in large quantities. It occurs also in the islands of Jersey and Guernsey, at Almaden, in Poland, Saxony, Sweden, Persia, &c. Its colour varies from red brown to dark brown; its specific gravity is about 4·000; it is so hard as to scratch quartz and many precious stones. By Mr. Tennant's analysis, it consists of alumina, 80; silica, 3; iron, 4. Another inferior kind yielded 32 of iron, and only 50 of alumina.

We have recent accounts of emery discoveries in Minesota, but nearly all that is used at present in the arts comes from Turkey, near ancient Smyrna. Dr. Lawrence Smith, the American geologist, made a discovery of a deposit of emery while residing in Smyrna, and he made an examination of the locality in 1847.

Dr. Smith having reported his discoveries to the Turkish government, a commission of inquiry was instituted, and the business soon assumed a mercantile form. The monopoly of the emery of Turkey was sold to a mercantile house in Smyrna, and since then the price has diminished in the market.

The mining of the emery is of the simplest character. The natural decomposition of the rock in which it occurs facilitates its extraction. The rock decomposes into an earth, in which the emery is found imbedded. The quantity procured under these circumstances is so great that it is rarely necessary to explore the rock. The earth in the neighbourhood of the block is almost always of a red colour, and serves as an indication to those who are in search of the mineral. Sometimes, before beginning to excavate, the spots are sounded by an iron rod with a steel point, and when any resistance is met with, the rod is rubbed in contact with the resisting body, and the effect produced on the point enables a practised eye to decide whether it has been done by emery or not. The blocks which are of a convenient size are transported in their natural state, but are frequently broken by large hammers; when they resist the action of the hammer, they are subjected to the action of fire for several hours, and on cooling they most commonly yield to blows. It sometimes happens that large masses are abandoned, from the impossibility of breaking them into pieces of a convenient size, as the transportation, either on camels or horses, requires that pieces shall not exceed 100 lbs. each in weight.

Emery appears to be a mechanical mixture of corundum and oxide of iron.

When reduced to a powder, it varies in colour from dark grey to black. The colour of its powder affords no indication of its commercial value. The powder examined under the microscope shows the distinct existence of two minerals, corundum and oxide of iron. Emery, when moistened, always affords a very strong argillaceous odour. Its hardness is its most important property in its application to the arts, and was ascertained by Mr. Smith in the following manner: — Fragments were broken from the piece to be examined, and crushed in a diamond mortar with two or three blows of a hammer, then thrown into a sieve with 400 holes to the inch. The powder is then weighed, and the hardness tested with a circular piece of glass, about four inches in diameter, and a small agate mortar. The glass is first weighed, and placed on a piece of glazed paper; the pulverized emery is then thrown upon it at intervals, rubbing it against the glass with the bottom of the agate mortar. The emery is brushed off the glass from time to time with a feather, and when all the emery has been made to pass once over the glass, it was collected, and passed through the same operation three or four times. The glass was then weighed, again subjected to the same operation, the emery by this time being reduced to an impalpable powder. This series of operations is continued until the loss sustained by the glass is exceedingly small. The total loss in the glass is then noted, and when all the specimens of emery are submitted to this operation under the same circumstances, an exact idea of their relative hardness is obtained. The advantages of using glass and agate are, that the latter is sufficiently hard to crush the emery, and in a certain space of time to reduce it to such an inpalpable state, that it has no longer any sensible effect on the glass; and, on the other hand, the glass is soft enough to lose during this time sufficient of its substance to allow of accurate comparative results. By this method, the best emery was found capable of wearing away about half of its weight of common French window-glass. The blue sapphire of Ceylon, pulverized and experimented with in this manner, wears away more than four-fifths of its weight. This furnished the standard of comparison.

In the ordinary process, the lumps of emery ore are broken up in the same manner as stone is for repairing Macadamised roads, and into lumps of similar size. These lumps then crushed under stampers, such as are used for pounding metallic ores, driven by water or by steam power. It is supposed that the stampers leave the fragments more angular than they would be if they were ground under runners, a mode which is sometimes employed. The coarse powder is then sifted through sieves of wire cloth, which are generally cylindrical, like the bolting cylinders of corn-mills; but the sieves are covered with wire cloth, having in general about ninety to sixteen wires to the inch. No. 16. sieve gives emery of about the size of mustard-seed; and coarser fragments, extending nearly to the size of pepper-corns, are also occasionally prepared for the use of engineers. The sieves have sometimes as many as 120 wires in the inch; but the very fine sizes of emery are more commonly sifted through lawn sieves. The finest emery that is obtained from the manufacturers is that which floats in the atmosphere of the stamping-room, and is deposited on the beams and shelves, from which it is occasionally collected. The manufacturers rarely or never wash the emery; this is mostly done by the glass-workers, and such others as require a greater degree of precision than can be obtained by sifting.

Washing emery by hand is far too tedious for those who require very large quantities of emery, such as the manufacturers of plate-glass and some others, who generally adopt the following method: — Twelve or more cylinders of sheet copper, of the common

height of about two feet, and varying from about three, five, eight, to thirty or forty inches in diameter, are placed exactly level, and communicating at their upper edges, each to the next, by small troughs or channels; the largest vessel has also a waste-pipe near the top. At the commencement of the process, the cylinders are all filled to the brim with clean water; the pulverised emery is then churned up with abundance of water in another vessel, and allowed to run into the smallest or the three-inch cylinder, through a tube opposite the gutter leading to the second cylinder. The water during its short passage across the three-inch cylinder, deposits in that vessel such of the coarsest emery as will not bear suspension for that limited time; the particles next finer are deposited in the five-inch cylinder, during the somewhat longer time the mixed steam takes in passing the brim of that vessel; and so on. Eventually the water forms a very languid eddy in the largest cylinder, and deposits therein the very fine particles that have remained in suspension until this period; and the water, lastly, escapes by the waste-pipe nearly or entirely free from emery. In this simple arrangement, time is also the measure of the particles respectively deposited in the manufacture to which the emery is applied. When the vessels are to a certain degree filled with emery, the process is stopped, the vessels are emptied, the emery is carefully dried and laid by, and the process is recommenced.

Emery paper is prepared by brushing the paper over with thin glue, and dusting the emery-powder over it from a sieve. There are about six degrees of coarseness. Sieves with thirty and ninety meshes per linear inch, are in general the coarsest and finest sizes employed. When used by artizans, the emery-paper is commonly wrapped around a file or a slip of wood, and applied just like a file, with or without oil, according to circumstances. The emery-paper cuts more smoothly with oil, but leaves the work dull.

Emery cloth only differs from emery-paper in the use of thin cotton cloth instead of paper, as the material upon which the emery is fixed by means of glue. The emery cloth, when folded around a file, does not ply so readily to it as emery-paper, and is apt to unroll. Hence smiths, engineers, and others, prefer emery-paper and emery-sticks; but for household and other purposes, where the hand alone is used, the greater durability of the cloth is advantageous.

Emery-sticks are rods of board about eight or twelve inches long, planed up square; or with one side rounded like a half-round file. Nails are driven into each end of the stick as temporary handles; they are then brushed over one at a time with thin glue, and dabbed at all parts in a heap of emery-powder, and knocked on one end to shake off the excess. Two coats of glue and emery are generally used. The emery-sticks are much more economical than emery-paper wrapped on a file, which is liable to be torn.

Emery-cake consists of emery mixed with a little beeswax, so as to constitute a solid lump, with which to dress the edges of buff and glaze wheels. The ingredients should be thoroughly incorporated by stirring the mixture whilst fluid, after which it is frequently poured into water, and thoroughly kneaded with the hands, and rolled into lumps before it has time to cool. The emery-cake is sometimes applied to the wheels whilst they are revolving; but the more usual course is, to stop the wheel, and rub in the emery-cake by hand. It is afterwards smoothed down by the thumb.

Emery-paper, or patent razor-strop paper, an article in which fine emery and glass are mixed with paper pulp, and made into sheets as in making ordinary paper; the emery and glass are said to constitute together 60 per cent. of the weight of the paper, which resembles drawing-paper, except that it has a delicate fawn colour. The emery-paper is directed to be pasted or glued upon a piece of wood, and when rubbed with a little oil, to be used as a razor-strop.

In 1842, Mr. Henry Barclay took out a patent for a method of combining powdered emery into *discs* and *laps* of different kinds, suitable to grinding, cutting, and polishing glass, enamels, metals, and other hard substances. The process of manufacture is as follows:—Coarse emery-powder is mixed with about half its weight of pulverized Stourbridge loam and a little water or other liquid, to make a thick paste; this is pressed into a metallic mould by means of a screw-press, and after having been thoroughly dried, is baked or burned in a muffle or close receiver at a temperature considerably above a red heat and below the full white heat. In this case, the clay or alumina serves as a bond, and unites the particles very completely into a solid artificial emery-stone, which cuts very greedily, and yet seems hardly to suffer perceptible wear.

Superfine grinding emery is formed into wheels exactly in the same manner as the above, but the proportion of loam is then only one-fourth instead of one-half that of the emery. Those emery stones, which are of medium fineness, cut less quickly, but more smoothly than the above.

Flour-emery, when manufactured into artificial stones, requires no uniting substance, but the moistened powder is forced into the metal mould and fired; some portions of the alumina being sufficient to unite the whole. These fine wheels render the works

submitted to them exceedingly smooth, but they do not produce a high polish on account of the comparative coarseness of the flour-emery.

The alumina of emery is believed to be aggregated to the same degree of hardness as in corundum or adamantine spar; which is one of the hardest minerals known. Emery is extensively employed for grinding metals, glass, &c.; for which purpose it is reduced to powders of different degrees of fineness by grinding and elutriation.

2,000 tons per annum at from 50 to 70 dollars each, according to quality, are consumed in the United Kingdom.

EMPYREUMA, means the offensive smell produced by fire applied to organic matters, chiefly vegetable, in close vessels. Thus, empyreumatic vinegar is obtained by distilling wood at a red heat, and empyreumatic oil from many animal substances in the same way.

ENAMELS (*Emaux*, Fr.; *Schmelzglas*, Germ.) are varieties of glass, generally opaque or coloured, always formed by the combination of different metallic oxides, to which certain fixed fusible salts are added, such as the borates, fluates, and phosphates.

The simplest enamel, and the one which serves as a basis to most of the others, is obtained by calcining first of all a mixture of lead and tin, in proportions varying from 15 to 50 parts of tin for 100 of lead. The middle term appears to be the most suitable for the greater number of enamels; and this alloy has such an affinity for oxygen, that it may be calcined with the greatest ease in a flat cast-iron pot, and at a temperature not above a cherry red, provided the dose of tin is not too great. The oxide is drawn off to the sides of the melted metal according as it is generated, new pieces of the alloy being thrown in from time to time, till enough of the powder be obtained. Great care ought to be taken that no metallic particles be left in the oxide, and that the calcining heat be as low as is barely sufficient; for a strong fire frits the powder, and obstructs its subsequent comminution. The powder when cold is ground in a proper mill, levigated with water, and elutriated, as will be described under *Red lead*. In this state of fineness and purity, it is called calcine or flux, and it is mixed with siliceous sand and some alkaline matter or sea-salt. The most ordinary proportions are, 4 of sand, 1 of sea-salt, and 4 of *calcine*. Chaptal states, that he has obtained a very fine product from 100 parts of calcine, made by calcining equal parts of lead and tin, 100 parts of ground flint, and 200 parts of pure subcarbonate of potash. In either case, the mixture is put into a crucible, or laid simply on a stratum of sand, quicklime spontaneously slacked, or wood-ashes, placed under a pottery or porcelain kiln. This mass undergoes a semivitrification, or even a complete fusion on its surface. It is this kind of frit which serves as a radical to almost every enamel; and by varying the proportions of the ingredient, more fusible, more opaque, or whiter enamels are obtained. The first of these qualities depends on the quantity of sand or flux, and the other two on that of the tin.

The sea-salt employed as a flux may be replaced either by salt of tartar, by pure potash, or by soda; but each of these fluxes gives peculiar qualities to the enamel.

Most authors who have written on the preparation of enamels, insist a great deal on the necessity of selecting carefully the particular sand that should enter into the composition of the frit, and they even affirm that the purest is not the most suitable. Clouet states, in the 34th volume of the *Annales de Chimie*, that the sand ought to contain at least 1 part of talc for 3 of siliceous matter, otherwise the enamel obtained is never very glassy, and that some wrinkled spots from imperfect fusion are seen on its surface; and yet we find prescribed in some old treatises, to make use of ground flints, fritted by means of salt of tartar or some other flux. It would thence appear that the presence of talc is of no use towards the fusibility of the silica, and that its absence may be supplied by increasing the dose of the flux. In all cases, however, we ought to beware of metallic oxides in the sand, particularly those of iron and manganese, which most frequently occur, and always injure the whiteness of the frit.

The ancients carried the art of enamelling to a very high perfection, and we occasionally find beautiful specimens of their work, of which we know neither the composition, nor the manner of applying it. Then, as at present, each artist made a mystery of the means that succeeded best with him, and thus a multitude of curious processes have been buried with their authors. Another cause contributes powerfully to this sort of declension in the arts. Among the vast number of recipes which have been published for the formation of enamels, there are several in which substances are mentioned that can no longer be procured, whether owing to a change of denomination, or because the substances cannot now be found in commerce, or because they are not of the same nature as of old. Hence, in many cases, we find it impossible to obtain satisfactory results. What we have now said renders it desirable that the operations should be resumed anew, or upon new bases, and availing ourselves of all the known chemical facts, we should employ in the production of enamels, raw materials of the purest kind.

The Venetians are still in possession of the best enamel processes, and they supply the French and other nations with the best kinds of enamel, of every coloured shade.

Enamels are distinguished into transparent and opaque; in the former all the elements have experienced an equal degree of liquefaction, and are thus run into crystal glass, whilst in the others, some of their elements have resisted the action of heat more, so that their particles retain sufficient aggregation to prevent the transmission of light. This effect is produced, particularly by the oxide of tin, as we shall perceive in treating of white enamel.

The frits for enamels that are to be applied to metallic surfaces require greater fusibility, and should therefore contain more flux; and the sand used for these should be calcined beforehand with one-fourth its weight of sea-salt; sometimes, indeed, metallic fluxes are added, as minium or litharge. For some metallic colours, the oxides of lead are very injurious, and in this case recourse must be had to other fluxes. Clouet states that he has derived advantage from the following mixtures, as bases for purples, blues, and some other delicate colours: —

Three parts of siliceous sand, one of chalk, and three of calcined borax; or, three of glass (of broken crystal goblets), one of calcined borax, one-fourth of a part of nitre, and one part of well washed diaphoretic antimony. These compositions afford a very white enamel, which accords perfectly well with blue.

It is obvious that the composition of this primary matter may be greatly varied: but we should never lose sight of the essential quality of a good enamel; which is, to acquire, at a moderate heat, sufficient fluidity to take a shining surface, without running too thin. It is not complete fusion which is wanted; but a pasty state, of such a degree as may give it, after cooling, the aspect of having suffered complete liquefaction.

Dead-white Enamel.—This requires greater nicety in the choice of its materials than any other enamel, as it must be free from every species of tint, and be perfectly white; hence the frit employed in this case should be itself composed of perfectly pure ingredients. But a frit should not be rejected hastily because it may be somewhat discoloured, since this may depend on two causes; either on some metallic oxides, or on fuliginous particles proceeding from vegetable or animal substances. Now the latter impurities may be easily removed by means of a small quantity of peroxide of manganese, which has the property of readily parting with a portion of its oxygen, and of thus facilitating the combustion, that is to say, the destruction of the colouring carbonaceous matter. Manganese indeed possesses a colouring power itself on glass, but only in its highest state of oxidizement, and when reduced to the lower state, as is done by combustible matters, it no longer communicates colour to the enamel combinations. Hence the proportion of manganese should never exceed what is just; for the surplus would cause colour. Sometimes, indeed, it becomes necessary to give a little manganese-colour, in order to obtain a more agreeable shade of white; as a little azure blue is added to linens, to brighten or counteract the dulness of their yellow tint.

A white enamel may be conveniently prepared also with a *calcine* composed of two parts of tin and one of lead calcined together; of this combined oxide, one part is melted with two parts of fine crystal and a very little manganese, all previously ground together. When the fusion is complete, the vitreous matter is to be poured into clear water, and the frit is then dried, and melted anew. The pouring into water and fusion are sometimes repeated four times, in order to secure a very uniform combination. The crucible must be carefully screened from smoke and flame. The smallest portions of oxide of iron or copper admitted into this enamel will destroy its value.

Some practitioners recommend the use of washed diaphoretic antimony (antimoniate of potash, from metallic antimony and nitre deflagrated together) for white enamel; but this product cannot be added to any preparation of lead or other metallic oxides; for it would tend rather to tarnish the colour than to clear it up; and it can be used therefore only with ordinary glass, or with saline fluxes. For three parts of white glass (without lead) one part of washed diaphoretic antimony is to be taken; the substances are well ground together, and fused in the common way.

Blue Enamel.—This fine colour is almost always obtained from the oxide of cobalt or some of its combinations, and it produces it with such intensity that only a very little can be used, lest the shade should pass into black. The cobalt blue is so rich and lively that it predominates in some measure over every other colour, and masks many so that they can hardly be perceived; it is also most easily obtained. To bring it out, however, in all its beauty, the other colours must be removed as much as possible, and the cobalt itself should be tolerably pure. This metal is associated in the best known ores with a considerable number of foreign substances, as iron, arsenic, copper, nickel, and sulphur, and it is difficult to separate them completely; but for enamel blues, the oxide of cobalt does not require to be perfectly free from all foreign metals; the iron, nickel, and copper being most prejudicial, should be carefully eliminated. This object may be most easily attained by dissolving the ore in nitric acid, evaporating this solution to a syrupy consistence, to expel the excess of acid, and separate a portion of arsenic. It is now diluted with water, and solution of carbonate of soda is dropped

slowly into it with brisk agitation, till the precipitate, which is at first of a whitish gray, begins to turn of a rose-red. Whenever this colour appears, the whole must be thrown on a filter, and the liquid which passes through must be treated with more of the carbonate of soda, in order to obtain the arseniate of cobalt, which is nearly pure. Since arsenic acid and its derivatives are not capable of communicating colour themselves, and as they moreover are volatile, they cannot impair the beauty of the blue, and hence this preparation affords it in great perfection.

Metallic fluxes are not the most suitable for this colour; because they always communicate a tint of greater or less force, which never fails to injure the purity of the blue. Nitre is a useful addition, as it keeps the oxide at the maximum of oxidation, in which state it produces the richest colour.

Yellow Enamel. — There are many processes for making this colour in enamel; but it is somewhat difficult to fix, and it is rarely obtained of an uniform and fine tint. It may be produced directly with some preparations of silver, as the phosphate or sulphate; but this method does not always succeed, for too strong a heat or powerful fluxes readily destroy it, and nitre is particularly prejudicial. This uncertainty of success with the salts of silver causes them to be seldom employed; and oxides of lead and antimony are therefore preferred, which afford a fine yellow when combined with some oxides that are refractory enough to prevent their complete vitrification. One part of white oxide of antimony may be taken with from one to three parts of white lead, one of alum, and one of sal-ammoniac. Each of these substances is to be pulverized, and then all are to be exactly mixed, and exposed to a heat adequate to decompose the sal-ammoniac. This operation is judged to be finished when the yellow colour is well brought out. There is produced here a combination quite analogous to that known under the name of Naples yellow.

Other shades of yellow may be procured either with the oxide of lead alone, or by adding to it a little red oxide of iron; the tints varying with the proportion of the latter.

Clouet says, in his Memoir on Enamels, that a fine yellow is obtained with pure oxide of silver, and that it is merely necessary to spread a thin coat of it on the spot to be coloured. The piece is then exposed to a moderate heat, and withdrawn as soon as this has reached the proper point. The thin film of metallic silver revived on the surface being removed, the place under it will be found tinged of a fine yellow, of hardly any thickness. As the pellicle of silver has to be removed which covers the colour, it is requisite to avoid fixing this film with fluxes: and it ought therefore to be applied after the fusion of the rest. The yellows require in general little flux, as they answer better with one of a metallic nature.

Green Enamel. — It is known that a green colour may be produced by a mixture of yellow and blue; but recourse is seldom had to this practice for enamels, as they can be obtained almost always directly with the oxide of copper; or, still better, with the oxide of chrome, which has the advantage of resisting a strong heat.

Chemists describe two oxides of copper, the protoxide, of an orange red colour, which communicates its colour to enamels, but it is difficult to fix; the deutoxide is blue in the state of hydrate, but blackish-brown when dry, and it colours green all the vitreous combinations into which it enters. This oxide requires, at most, one or two proportions of flux, either saline or metallic, to enter into complete fusion; but a much smaller dose is commonly taken, and a little oxide of iron is introduced. To 4 pounds of frit, for instance, 2 ounces of oxide of copper and 48 grains of red oxide of iron are used; and the ordinary measures are pursued for making very homogeneous enamel.

The green produced by the oxide of chrome is much more solid; it is not affected by a powerful fire, but it is not always of a fine shade. It generally inclines too much to the dead-leaf yellow, which depends on the degree of oxygenation of the chrome.

Red Enamel. — We have just stated, that protoxide of copper afforded a fine colour when it could be fixed, a result difficult to obtain on account of the fugitive nature of this oxide; slight variations of temperature enabling it to absorb more oxygen. The proper point of fusion must be seized for taking it from the fire whenever the desired colour is brought out. Indeed, when a high temperature has produced peroxidizement, this may be corrected by adding some combustible matter, as charcoal, tallow, tartar, &c. The copper then returns to its minimum of oxidizement, and the red colour which had vanished, reappears. It is possible, in this way, and by pushing the heat a little, to accomplish the complete reduction of a part of the oxide; and the particles of metallic copper thereby disseminated in a reddish ground, give this enamel the aspect of the stone called *avanturine*. The surest and easiest method of procuring protoxide of copper is to boil a solution of equal parts of sugar, and sulphate or rather acetate of copper, in four parts of water. The sugar takes possession of a portion of the oxygen of the cupreous oxide, and reduces it to the protoxide; when it may be precipitated in the form of a granular powder of a brilliant red. After about two hours of moderate

ebullition, the liquid is set aside to settle, decanted off the precipitate, which is washed and dried.

The protoxide, properly employed by itself, furnishes a red which vies with the finest carmine, and by its means every tint may be obtained from red to orange, by adding a greater or smaller quantity of peroxide of iron.

The preparations of gold, and particularly the oxide and purple of Cassius, are likewise employed, with advantage, to colour enamel red, and this composition resists a powerful fire tolerably well. For some time back, solutions of gold, silver, and platinum have been used with success instead of their oxides; and, in this way, a more intimate mixture may be procured, and, consequently, more homogeneous tints.

Black Enamel. — Black enamels are made with peroxide of manganese or protoxide of iron; to which more depth of colour is given with a little cobalt. Clay alone, melted with about a third of its weight of protoxide of iron, gives, according to Clouet, a fine black enamel.

Violet Enamel. — The peroxide of manganese in small quantity by itself furnishes with saline or alkaline fluxes, an enamel of a very fine violet hue; and variations of shade are easily had, by modifying the proportions of the elements of the coloured frit. The great point is to maintain the manganese in a state of peroxidation, and, consequently, to beware of placing the enamel in contact with any substance attractive of oxygen.

Such are the principal coloured enamels hitherto obtained by means of metallic oxides; but since the number of these oxides is increasing every day, it is to be wished that new trials be made with such as have not yet been employed. From such researches some interesting results would unquestionably be derived.

Of painting on Enamel.—Enamelling is only done on gold and copper; for silver swells up, and causes blisters and holes in the coat of enamel. All enamel paintings are, in fact, done on copper or gold.

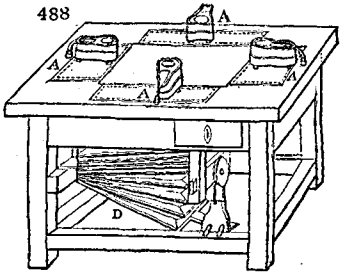
The goldsmith prepares the plate that is to be painted upon. The gold should be 22 carats fine: if purer, it would not be sufficiently stiff; if coarser, it would be subject to melt; and its alloy should be half white and half red, that is, half silver and half copper; whereby the enamel with which it is covered will be less disposed to turn green, than if the alloy were entirely copper.

The workman must reserve for the edge of the plate a small fillet, which he calls the *border*. This ledge serves to retain the enamel, and hinders it from falling off when applied and pressed on with a spatula. When the plate is not to be counter-enamelled, it should be charged with less enamel, as when exposed to heat, the enamel draws up the gold to itself, and makes the piece convex. When the enamel is not to cover the whole plate, it becomes necessary to prepare a lodgement for it. With this view, all the outlines of the figure are traced on the plate with a black-lead pencil, after which recourse is had to the graver.

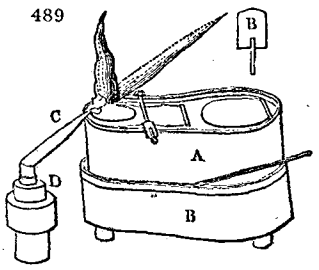
The whole space enclosed by the outlines must be hollowed out in *bas-relief*, of a depth equal to the height of the fillet, had the plate been entirely enamelled. This sinking of the surface must be done with a flat graver as equally as possible; for if there be an eminence, the enamel would be weaker at that point, and the green would appear. Some artists hatch the bottom of the hollow with close lines, which cross each other in all directions; and others make lines or scratches with the edges of a file broken off square. The hatchings or scratches lay hold off the enamel, which might otherwise separate from the plate. After this operation, the plate is cleansed by boiling it in an alkaline lye, and it is washed first with a little weak vinegar, and then with clear water.

The plate thus prepared is to be covered with a coat of white enamel, which is done

488



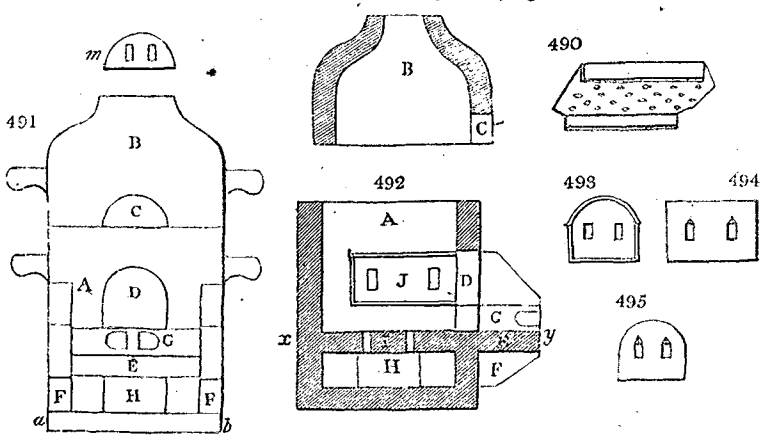
489



by bruising a piece of enamel in an agate or porcelain mortar to a coarse powder like sand, washing it well with water, and applying it in the hollow part in its moist state.

The plate may meanwhile be held in an ordinary forceps. The enamel powder is spread with a spatula. For condensing the enamel powder, the edges of the plate are struck upon with the spatula.

Whenever the piece is dry, it is placed on a slip of sheet iron perforated with several small holes, see *fig.* 490., which is laid on hot cinders; and it is left there until it ceases to steam. It must be kept hot till it goes to the fire; for were it allowed to cool it would become necessary to heat it again very gradually at the mouth of the furnace of fusion, to prevent the enamel from decrepitating and flying off.



Before describing the manner of exposing the piece to the fire, we must explain the construction of the furnace. It is square, and is shown in front elevation in *fig.* 491. It consists of two pieces, the lower part A, or the body of the furnace, and the upper part B, or the capital, which is laid on the lower part, as is shown in *fig.* 492., where these two parts are separately represented. The furnace is made of good fire-clay, moderately baked, and resembles very closely the assay or cupellation furnace. Its inside dimensions are 9 inches in width; 12 inches in height in the body, and 9 in the capital. Its general thickness is 2 inches.

The capital has an aperture or door C, *fig.* 491., which is closed by a fire-brick stopper *m*, when the fire is to be made active. By this door fuel is supplied.

The body of the furnace has likewise a door D, which reaches down to the projecting shelf E, called the bib (*mentonnière*), whose prominence is seen at E, *fig.* 491. This shelf is supported and secured by the two brackets, F, F; the whole being earthenware. The height of the door D, is abridged by a peculiar fire-brick G, which not only covers the whole projection of the shelf E, but enters within the opening of the door D, filling its breadth, and advancing into the same plane with the inner surface of the furnace. This plate is called the hearth; its purpose will appear presently; it may be taken out and replaced at pleasure, by laying hold of the handle in its front.

Below the shelf E, a square hole, H, is seen, which serves for admitting air, and for extracting the ashes. Similar holes are left upon each side of the surface, as is shown in the ground plan of the base, *fig.* 492., at H.

On a level with the shelf, in the interior of the furnace, a thin fire-tile I rests, perforated with numerous small holes. This is the grate represented in a ground view in *fig.* 490. *Figs.* 493, 494, 495. represent, under different aspects, the muffle. *Fig.* 492. shows the elevation of its further end; *fig.* 494. its sides; and *fig.* 495. its front part. At J, *fig.* 492., the muffle is seen in its place in the furnace, resting on two bars of iron, or, still better, on ledges of fire-clay, supported on brackets attached to the lateral sides of the furnace. The muffle is made of earthenware, and as thin as possible. The fuel consists of dry beech-wood, or oaken branches, about an inch in diameter, cut to the length of nine inches, in order to be laid in horizontal strata within the furnace, one row only being placed above the muffle. When the muffle has attained to a white red heat, the sheet iron tray, bearing its enamel plate, is to be introduced with a pair of pincers into the front of the muffle, and gradually advanced towards its further end. The mouth of the muffle is to be then closed with two pieces of charcoal only, between which the artist may see the progress of the operation. Whenever the enamel begins to flow, the tray must be turned round on its base to insure equality of temperature;

and as soon as the whole surface is melted, the tray must be withdrawn with its plate, but slowly, lest the vitreous matter be cracked by sudden refrigeration.

The enamel plate, when cold, is to be washed in very dilute nitric acid, and afterwards in cold water, and a second coat of granular enamel paste is to be applied, with the requisite precautions. This, being passed through the fire, is to be treated in the same way a third time, when the process will be found complete. Should any chinks happen to the enamel coat, they must be widened with a graver, and the space being filled with ground enamel, is to be repaired in the muffle. The plate, covered with a pure white enamel, requires always to be polished and smoothed with sandstone and water, particularly if the article have a plane surface; and it is then finally glazed at the fire.

The painting operation now follows. The artist prepares his enamel colours by pounding them in an agate mortar, with a pestle of agate, and grinding them on an agate slab, with oil of lavender, rendered viscid by exposure to the sun in a shallow vessel, loosely covered with gauze or glass. The grinding of two drachms of enamel pigment into an impalpable powder, will occupy a labourer a whole day. The painter should have alongside of him a stove in which a moderate fire is kept up, for drying his work whenever the figures are finished. It is then passed through the muffle.

Enamelling at the Lamp. — The art of the lamp enameller is one of the most agreeable and amusing that we know. There is hardly a subject in enamel which may not be executed by the lamp-flame in very little time, and more or less perfectly, according to the dexterity of the artist, and his acquaintance with the principles of modelling.

In working at the lamp, tubes and rods of glass and enamel must be provided, of all sizes and colours.

The enamelling table is represented in *fig.* 488., round which several workmen, with their lamps, may be placed, while the large double bellows D below is set a-blowing by a treadle moved with the foot. The flame of the lamp, when thus impelled by a powerful jet of air, acquires surprising intensity. The bent nozzles or tubes A, A, A, A, are made of glass, and are drawn to points modified to the purpose of the enameller.

Fig. 489. shows, in perspective, the lamp A of the enameller standing in its cistern B; the blowpipe C is seen projecting its flame obliquely upwards. The blow-pipe is adjustable in an elastic cork D, which fills up exactly the hole of the table into which it enters. When only one person is to work at a table provided with several lamps, he sits down at the same side with the pedal of the bellows; he takes out the other blowpipes, and plugs the holes in the table with solid corks.

The lamp is made of copper or tin plate, the wick of cotton threads, and either tallow or oil may be used. Between the lamp and the workman a small board or sheet of white iron B, called the screen, is interposed to protect his eyes from the glare of light. The screen is fastened to the table by a wooden stem, and it throws its shadow on his face.

The enamelling workshop ought to admit little or no daylight, otherwise the artist, not perceiving his flame distinctly, would be apt to commit mistakes.

It is impossible to describe all the manipulations of this ingenious art, over which taste and dexterity so entirely preside. But we may give an example. Suppose the enameller wishes to make a swan. He takes a tube of white enamel, seals one of its ends hermetically at his lamp, and while the matter is sufficiently hot, he blows on it a minikin flask, resembling the body of the bird: he draws out, and gracefully bends the neck; he shapes the head, the beak, and the tail; then, with slender enamel rods of a proper colour, he makes the eyes; he next opens up the beak with pointed scissors; he forms the wings and the legs; finally attaching the toes, the bird stands complete.

The enameller also makes artificial eyes for human beings, imitating so perfectly the colours of the sound eye of any individual, as to render it difficult to discover that he has a blind and a seeing one.

It is difficult to make large articles at the blowpipe; those which surpass 5 or 6 inches become nearly unmanageable by the most expert workmen.

Enamelling of Cast Iron and other Hollow Ware for Saucepans, &c.—In December, 1799, a patent was obtained for this process by Dr. Samuel Sandy Hickling. His specification is subdivided into two parts: —

1. The coating or lining of iron vessels, &c., by fusion with a vitrifiable mixture, composed of 6 parts of calcined flints, 2 parts of *composition* or Cornish stone, 9 parts of litharge, 6 parts of borax, 1 part of argillaceous earth, 1 part of nitre, 6 parts of calx of tin, and 1 part of purified potash. Or, 2dly,

8 parts of calcined flints, 8 red lead, 6 borax, 5 calx of tin, and 1 of nitre. Or, 3dly,

12 of potter's composition, 8 borax, 10 white lead, 2 nitre, 1 white marble calcined, 1 argillaceous earth, 2 purified potash, and 5 of calx of tin. Or, 4thly,

4 parts calcined flint, 1 potter's composition, 2 nitre, 8 borax, 1 white marble calcined, ½ argillaceous earth, and 2 calx of tin.

Whichever of the above compositions is taken, must be finely powdered, mixed, fused; the vitreous mass is to be ground when cold, sifted, and levigated with water. It is then made into a pap with water or gum water. This pap is smeared or brushed over the interior of the vessel, dried, and fused with a proper heat in a muffle.

Calcined bones are also proposed as an ingredient of the flux.

The fusibility of the vitreous compounds is to vary according to the heat to be applied to the vessel, by using various proportions of the siliceous and fluxing materials. Colours may be given, and also gilding.

The second part or process in his specification describes certain alloys of iron and nickel, which he casts into vessels, and lines or coats them with copper precipitated from its saline solutions. It also describes a mode of giving the precipitated copper a brassy surface by acting upon it with an amalgam of zinc with the aid of heat.

A factory of such enamelled hollow wares was carried on for some time, but it was given up for want of due encouragement.

A patent was granted to Thomas and Charles Clarke on the 25th of May, 1839, for a method of enamelling or coating the internal surfaces of iron pots and saucepans, in such a way as shall prevent the enamel from cracking or splitting off from the effects of fire. This specification prescribes the vessel to be first cleaned by exposing it to the action of dilute sulphuric acid (sensibly sour to the taste) for three or four hours, then boiling the vessel in pure water for a short time, and next applying the composition. This consists of 100 lbs. of calcined ground flints; 50 lbs. of borax, calcined, and finely ground with the above. That mixture is to be fused and gradually cooled.

40 lbs. weight of the above product is to be taken with 5 lbs. weight of potter's clay; to be ground together in water until the mixture forms a pasty consistenced mass, which will leave or form a coat on the inner surface of the vessel about one-sixth of an inch thick. When this coat is set, by placing the vessel in a warm room, the second composition is to be applied. This consists of 125 lbs. of white glass (without lead), 25 lbs. of borax, 20 lbs. of soda (crystals), all pulverized together and vitrified by fusion, then ground, cooled in water, and dried. To 45 lbs. of that mixture, 1 lb. of soda is to be added, the whole mixed together in hot water, and when dry pounded; then sifted finely and evenly over the internal surface of the vessel previously covered with the first coating or composition whilst this is still moist. This is the glazing. The vessel thus prepared is to be put into a stove, and dried at the temperature of 212° Fahr. It is then heated in a kiln or muffle like that used for glazing china. The kiln being brought to its full heat, the vessel is placed first at its mouth to heat it gradually, and then put into the interior for fusion of the glaze. In practice it has been found advantageous also to dust the glaze powder over the fused glaze, and apply a second fluxing heat in the oven. The enamel, by this double application, becomes much smoother and sounder.

Messrs. Kenrick, of West Bromwich, having produced in their factory and sent into the market some excellent specimens of enamelled saucepans of cast iron, were sued by Messrs. Clarke for an invasion of their patent rights; but after a long litigation in Chancery the patentees were nonsuited in the Court of Exchequer. The previous process of cleansing with dilute sulphuric acid appeared by the evidence on the trial to have been given up by the patentees, and it was also shown by their own principal scientific witness that a good enamelled iron saucepan could be made by Hickling's specification. In fact, the formulæ by which a good enamel may be compounded are almost innumerable; so that a patent for such a purpose seems to be untenable, or at least most easily evaded. I have exposed the finely enamelled saucepans of Messrs. Kenrick to very severe trials, having fused even chloride of calcium in them, and have found them to stand the fire very perfectly without chipping or cracking. I consider such a manufacture to be one of the greatest improvements recently introduced into domestic economy; such vessels being remarkably clean, salubrious, and adapted to the most delicate culinary operations of boiling, stewing, making of jellies, preserves, &c. They are also admirably fitted for preparing pharmaceutical decoctions, and ordinary extracts.

The enamel of the said saucepans is quite free from lead, in consequence of the glass which enters into its composition being quite free from that metal. In several of the saucepans which were at first sent into the market by Messrs. Clarke, their enamel was found on analysis by several chemists to contain a notable proportion of oxide of lead. In consequence of the quantity of borax and soda in the glaze, this oxide was so readily acted upon by acids that sugar of lead was formed by digesting vinegar in them with a gentle heat. The presence of this noxious metal formed, in my opinion, a legitimate ground for contesting the patent, being in direct violation of the terms of the specification. Messrs. Kenrick's wares have been always free from this deleterious metal. Messrs. Clarke, I understand, have for some time been careful to reject from their enamel-com-

position all glass which contains lead; and they now manufacture also wholesome enamelled ware. Thus the public have profited in a most important point by the aforesaid litigation.

Enamelled iron saucepans had been many years ago imported from Germany, and sold in London. I had occasion to analyze their enamel, and found to my surprise that it contained abundance of litharge or oxide of lead. The Prussian government has issued an edict prohibiting the use of lead in the enamelling of saucepans, which are so extensively manufactured in Peiz, Gleiwitz, &c. Probably the German ware sent to England was fabricated for exportation, with an enamel made to flux easily by a dose of litharge. The composition of the said enamel is nearly the same with that which I found upon some of the earlier saucepans of Messrs. Clarke. Had their patent been sustained, the important legal question would have arisen, whether it gave the patentees the power of preventing dealers from continuing to sell what they had been habitually doing for a great many years.

A suitable oven or muffle for lining or coating metals with enamel may have the following dimensions: —

The outside, 8 feet square, with 14-inch walls; the interior muffle, 4 feet square at bottom, rising 6 inches at the sides, and then arched over; the crown may be 18 inches high from the floor; the muffle should be built of fire-brick, 2½ inches thick. Another arch is turned over the first one, which second arch is 7 inches wider at the bottom, and 4 inches higher at the top. A 9-inch wall under the bottom of the muffle at its centre divides the fire-places into two, of 16 inches width each, and 3 feet 3 inches long. The flame of the fire plays between the two arches and up through a 3-inch flue in front, and issues from the top of the arch through three holes, about 4 inches square. These open into a flue, 10 × 9 inches, which runs into the chimney.

The materials for the enamel body (ground flint, potter's clay, and borax) are first mixed together, and then put into a reverberatory furnace, 6 feet 6 inches long, by 3 feet 4 inches wide, and 12 inches high. The flame from an 18-inch fire-place passes over the hearth. The materials are spread over the floor of the oven, about 6 inches thick, and ignited or fritted for 4 or 5 hours, until they begin to heave and work like yeast, when another coating is put on the top, also 6 inches thick, and fired again, and so on the whole day. If it be fired too much, it becomes hard and too refractory to work in the muffles. The glaze is worked in an oven similar to the above. It may be composed of about one-half borax and one-half of Cornish stone in a yellowish powder procured from the potteries. This is fritted for 10 hours, and then fused into a glass which is ground up for the glaze.

Enamelled Cast-Iron. Cast-iron vessels have been exceedingly well enamelled under two different patents within these few years; at first, by Mr. Clark, of Wolverhampton, and in November, 1846, by Messrs. Kenrick, of West Bromwich. Before the enamel is applied, the surface of the iron should be made quite clean and bright. The enamel consists of two coats; the one forming the body, and the other the glaze. The body is made by fusing 100 lbs. of ground flints, and 75 of borax, and grinding 40 lbs. of this frit with 5 lbs. of potter's clay in water till it is brought to the consistence of a pap. A coating of this pap being applied and dried, but not hard, the glaze powder is sifted over it. This consists of 100 parts of Cornish stone, in fine powder, 117 of borax, 35 of soda-ash, 35 of nitre, 35 of sifted slaked lime, 13 of white sand, and 50 of pounded white glass. These are all fused together; the frit obtained is pulverized. Of this powder 45 pounds are mixed with 1 pound of soda-ash, in hot water; and the mixture being dried in a stove is the glaze powder. When this powder has been very finely sifted over the body coat, the cast-iron article is put into a stove, kept at a temperature of about 212°, to dry it hard; after which it is set in a muffle kiln to be fused into a glaze.

The inside of pipes is enamelled (after being cleaned) by pouring the above body composition through them while the pipe is being turned about, to insure its being uniformly coated. After the body has become set, the glaze pap is poured in in a like manner. The pipe is finally fired in the kiln.

Enamelled Leather. Instead of enamelling the grain surface as heretofore, Mr. Nossiter removes that surface by splitting or buffing, and then produces what is called "a finish" upon the surface thus formed, by means of a roller, or glass instrument. Or the flesh side may be thus prepared for enamelling; and it is less liable to crack, and the enamel to become cloudy than the grain side. He also shaves hides and skins by knives set tangentially upon a rotary axis, with a certain degree of obliquity. He squeezes the grease out of the skins by hard pressure between rollers; and he uses a rotary brush to clear away all filth.

Enamelling Metals. In February, 1847, Mr. Walton patented a method of

enamelling copper and other vessels, by coating them (after their surfaces are scaled by heat and cleaned) with powders of a vitrifiable kind applied in a thin pasty state with a brush, then drying and firing them. His formula for the composition is as follows: 6 parts of flint glass, 3 of borax, 1 of red lead, and 1 of oxide of tin; mixed, fritted, ground into powder, made into a thin paste with water, applied, dried, and fused on by the heat of an enamel kiln (See POTTERY). A second and even a third coat is prescribed. Into the second he puts calcined bone in powder, with china clay and carbonate of potash. These materials are fritted, ground, and mixed with certain of the former vitrifiable materials. Being reduced to a creamy consistence with water in a porcelain mill, the mixture is painted on with a brush, or applied by dipping, dried, and fired. One of his formulæ consists of 4 parts of ground felspar, 4 of white sand, 4 of carbonate of potash, 1 of arsenic, 6 of borax, 1 of oxide of tin, 1 of nitre, 1 of whiting—being in my opinion a most injudicious farrago, for which a much better and simpler combination of vitrifiable china-like materials might be substituted. — *Newton's Journal*, XXXI. p. 183.

EPSOM SALTS. Sulphate of Magnesia.

EQUIVALENTS, CHEMICAL. (*Stöchiometrie*, Germ.) This expression was first employed by Dr. Wollaston, to denote the primary proportions in which the various chemical bodies reciprocally combine; the numbers representing these proportions being referred to one standard substance of general interest, such as oxygen or hydrogen reckoned unity, or 1,000. Dr. Dalton, who is the true author of the grand discovery of definite, and multiple chemical ratios, calls these equivalent numbers *atomic weights*, when reduced to their lowest terms, either hydrogen or oxygen being the radix of the scale. Though it belongs to a chemical work, to discuss the principles and develope the applications of the Atomic Theory, I shall be careful, upon all proper occasions, to point out the vast advantages which the chemical manufacturer may derive from it, and to show how much he may economise and improve his actual processes by its means. See ELEMENT.

ESSENCES are either ethereous oils, in which all the fragrance of vegetable products reside, or the same combined and diluted with alcohol. See OILS, ETHEREOUS.

ESSENCE D'ORIENT, the name of a pearly looking matter procured from the blay or bleak, a fish of the genus *cyprinus*. This substance, which is found principally at the base of the scales, is used in the manufacture of artificial pearls. A large quantity of the scales being scraped into water in a tub, are there rubbed between the hands to separate the shining stuff, which subsides on repose. The first water being decanted, more is added with agitation till the essence is thoroughly washed from all impurities, when the whole is thrown upon a sieve; the substance passes through, but the scales are retained. The water being decanted off, the essence is procured in a viscid state, of a bluish-white colour, and a pearly aspect. The intestines of the same fish are also covered with this beautiful glistening matter. Several other fish yield it, but in smaller proportion. When well prepared, it presents exactly the appearance and reflections of the real pearls, or the finest mother of pearl; properties which are probably owing to the interposition of some portions of this same substance, between the laminæ of these shelly concretions. Its chemical nature has not been investigated; it putrefies readily when kept moist, an accident which may however be counteracted by water of ammonia. See PEARLS.

ETCHING VARNISH. (*Aetzgrund-Deckfirniss*, Germ.) Though the practice of this elegant art does not come within the scope of our Dictionary, the preparation of the varnishes, and of the biting menstrua which it employs, legitimately does.

The varnish of Mr. Lawrence, an English artist resident in Paris, is made as follows: Take of virgin wax and asphaltum, each two ounces, of black pitch and burgundy-pitch each half an ounce. Melt the wax and pitch in a new earthenware glazed pot, and add to them, by degrees, the asphaltum, finely powdered. Let the whole boil till such time as that, taking a drop upon a plate, it will break when it is cold, on bending it double two or three times betwixt the fingers. The varnish, being then enough boiled, must be taken off the fire, and after it cools a little, must be poured into warm water, that it may work the more easily with the hands, so as to be formed into balls, which must be kneaded, and put into a piece of taffety for use.

Care must be taken, first, that the fire be not too violent, for fear of burning the ingredients, a slight simmering being sufficient; secondly, that whilst the asphaltum is putting in, and even after it is mixed with the ingredients, they should be stirred continually with the spatula; and, thirdly, that the water into which this composition is thrown should be nearly of the same degree of warmth with it, in order to prevent a kind of cracking that happens when the water is too cold.

The varnish ought always to be made harder in summer than in winter, and it will become so if it be suffered to boil longer, or if a greater proportion of the asphaltum or

brown rosin be used. The experiment above mentioned, of the drop suffered to cool, will determine the degree of hardness or softness that may be suitable to the season when it is used.

Preparation of the hard varnish used by Callot, commonly called the Florence Varnish:—Take four ounces of fat oil very clear, and made of good linseed oil, like that used by painters; heat it in a clean pot of glazed earthenware, and afterwards put to it four ounces of mastick well powdered, and stir the mixture briskly till the whole be well melted, then pass the mass through a piece of fine linen into a glass bottle with a long neck, that can be stopped very securely; and keep it for the use that will be explained below.

Method of applying the soft varnish to the plate, and of blackening it.—The plate being well polished and burnished, as also cleansed from all greasiness by chalk or Spanish white, fix a hand-vice on the edge of the plate where no work is intended to be, to serve as a handle for managing it when warm; then put it upon a chafing dish, in which there is a moderate fire, and cover the whole plate equally with a thin coat of the varnish; and whilst the plate is warm, and the varnish upon it in a fluid state, beat every part of the varnish gently with a small ball or dauber made of cotton tied up in taffety, which operation smooths and distributes the varnish equally over the plate.

When the plate is thus uniformly and thinly covered with the varnish, it must be blackened by a piece of flambeau, or of a large candle which affords a copious smoke; sometimes two or even four such candles are used together for the sake of dispatch, that the varnish may not grow cold, which if it does during the operation, the plate must be heated again, that it may be in a melted state when that operation is performed; but great care must be taken not to burn it, which when it happens may be easily perceived by the varnish appearing burnt and losing its gloss.

The menstruum used and recommended by Turrell, an eminent London artist, for etching upon steel, was prepared as follows:—

Take	Pyrolignous acid	4 parts by measure,
	Alcohol	1 part, mix, and add
	Nitric acid	1 part.

This mixed liquor is to be applied from 1½ to 15 minutes, according to the depth desired. The nitric acid was employed of the strength of 1·28 — the double aquafortis of the shops.

The *eau forte* or menstruum for copper, used by Callot, as also by Piranesi, with a slight modification, is prepared, with 8 parts of strong French vinegar,

4 parts of verdigris,
4 ditto sea salt,
4 ditto sal ammoniac,
1 ditto alum,
16 ditto water.

The solid substances are to be well ground, dissolved in the vinegar, and diluted with the water; the mixture is now to be boiled for a moment, and then set aside to cool. This menstruum is applied to the washed, dried, and varnished plate, after it has suffered the ordinary action of aquafortis, in order to deepen and finish the delicate touches. It is at present called the *eau forte à passer*.

ETHER, is the name of a class of very light, volatile, inflammable, and fragrant spirituous liquids, obtained by distilling in a glass retort, a mixture of alcohol with almost any strong acid. Every acid modifies the result, in a certain degree, whence several varieties of ether are produced. The only one of commercial importance is sulphuric ether, which was first made known under the name of *sweet oil of vitriol*, in 1540, by the receipt of Walterus Cordus. Froberus, 190 years after that date, directed the attention of chemists afresh to this substance, under the new denomination of *ether*.

There are two methods of preparing it; by the first, the whole quantity of acid and alcohol are mixed at once, and directly subjected to distillation; by the second, the alcohol is admitted, in a slender streamlet, into a body of acid previously mixed with a little alcohol, and heated to 220° Fahr.

1. Mix equal weights of alcohol at spec. grav. 0·830, and sulphuric acid at 1·842, by introducing the former into a large tubulated retort, giving it a whirling motion, so that the alcohol may revolve round a central conical cavity. Into this species of whirlpool the acid is to be slowly poured. The mixture, which becomes warm, is to be forthwith distilled by attaching a spacious receiver to the retort, and applying the heat of a sand-bath. The formation of ether takes place only at a certain temperature. If the contents of the retort be allowed to cool, and be then slowly heated in a water bath, alcohol alone will come over for some time without ether, till the mixture acquires the

proper degree of heat. The first receiver should be a globe, with a tube proceeding from its bottom, into a second receiver, of a cylindric shape, surrounded with ice-cold water. The joints must be well secured by lutes, after the expanded air has been allowed to escape. The liquid in the retort should be kept in a steady state of ebullition. The ether, as long as it is produced, condenses in the balloon and neck of the receiver in striæ; when these disappear the process is completed. The retort must now be removed from the sand; otherwise it would become filled with white fumes containing sulphurous acid, and denser striæ would flow over, which would contaminate the light product with a liquid called sweet oil of wine.

The theory of etherification demonstrates that when strong sulphuric acid is mixed with alcohol, there is formed, on the one hand, a more aqueous sulphuric acid, and, on the other, sulphovinic acid. When this mixture is made to boil, the sulphovinic acid is decomposed, its dihydrate of carbon combines with the alcohol, and constitutes ether; while the proportion of sulphovinic acid progressively diminishes. Mr. Hennell, of the Apothecaries' Hall, first explained these phenomena, and he was confirmed in his views by the interesting researches of Serullas. The acid left in the retort is usually of a black colour, and may be employed to convert into ether half as much alcohol again; an experiment which may be repeated several times in succession.

The most profitable way of manufacturing ether has been pointed out by Boullay. It consists in letting the alcohol drop in a slender stream into the acid, previously heated to the etherifying temperature. If the acid in this case were concentrated to 1·846, the reaction would be too violent, and the ether would be transformed into bicarburetted hydrogen (dihydrate of carbon.) It is therefore necessary to dilute the acid down to the density of 1·780; but this dilution may be preferably effected with alcohol instead of water, by mixing three parts of the strongest acid with 2 of alcohol, specific gravity 0·830, and distilling off a portion of the ether thereby generated; after which the stream of alcohol is to be introduced into the tubulure of the retort through a small glass tube plunged into the mixture; this tube being the prolongation of a metallic syphon, whose shorter leg dips into a bottle filled with the alcohol. The longer leg is furnished with a stop-cock, for regulating at pleasure the alcoholic streamlet. The distilled vapours should be transmitted through a worm of pure tin surrounded by cold water, and the condensed fluid received in a glass bottle. The quantity of alcohol which can be thus converted into ether by a given weight of sulphuric acid, has not hitherto been accurately determined; but it is at least double. In operating in this way, neither sulphurous acid, nor sweet oil of wine is generated, while the residuary liquid in the retort continues limpid and of a merely brownish yellow colour. No sulphovinic acid is formed, and according to the experiments of Geiger, the proportion of ether approaches to what theory shows to be the maximum amount. In fact 57 parts of alcohol of 0·83 sp. grav. being equivalent to 46·8 parts of anhydrous alcohol, yield according to Geiger, 33⅓ parts of ether; and by calculation, they should yield 37¼.

The ether of the first distillation is never pure, but always contains a certain quantity of alcohol. The density of that product is usually 0·78, and if prepared by the first of the above methods, contains besides alcohol, pretty frequently sulphurous acid, and sweet oil of wine, impurities from which it must be freed. Being agitated with its bulk of milk of lime, both the acid and the alcohol are removed at the same time; and if it be then decanted and agitated, first with its bulk of water, next decanted into a retort containing chloride of calcium in coarse powder and distilled, one third of perfectly pure ether may be drawn over. Gay Lussac recommends to agitate the ether, first with twice its volume of water, to mix it, and leave it in contact with powdered unslaked lime for 12 or 14 hours, and then to distil off one third of pure ether. The remaining two thirds consist of ether containing a little alcohol. If in preparing ether by Boullay's method, the alcohol be too rapidly introduced, much of this liquid will come over unchanged. If in this state the ether be shaken with water, a notable quantity of it will be absorbed, because weak alcohol dissolves it very copiously. The above product should therefore be re-distilled, and the first half that comes over may be considered as ether, and treated with water and lime. The other half must be exposed afresh to the action of sulphuric acid.

Pure ether possesses the following properties. It is limpid, of spec. grav. 0·713, or 0·715 at 60°; has a peculiar penetrating strong smell; a taste at first acrid, burning, sweetish, and finally cooling. It has neither an acid nor alkaline reaction; is a non-conductor of electricity, and refracts light strongly. It is very volatile, boiling at 96° or 97° F., and produces by its evaporation a great degree of cold. At the temperature of 62·4, the vapour of ether balances a column of mercury 15 inches high, or half the weight of the atmosphere. When ether is cooled to — 24° F. it begins to crystallize in brilliant white plates, and at — 47° it becomes a white crystalline solid. When vapour of ether is made to traverse a red hot porcelain tube, it deposits within it one half per cent. of charcoal, and there are condensed in the receiver one and two thirds

per cent. of a brown oil, partly in crystalline scales, and partly viscid. The crystalline portion is soluble in alcohol, but the viscid only in ether. The remainder of the decomposed ether consists of bi-carburetted hydrogen gas, tetrahydric carburet, carbonic oxide gas, and one per cent. at most of gaseous carbonic acid.

Ether takes fire readily, even at some distance from a flame, and it should not therefore be poured from one vessel to another in the neighbourhood of a lighted candle. It may be likewise set on fire by the electric spark. It burns all away with a bright fuliginous flame. When the vapour of ether is mixed with 10 times its volume of oxygen, it burns with a violent explosion, absorbs 6 times its bulk of oxygen, and produces 4 times its volume of carbonic acid gas.

Ether alters gradually with contact of air; absorbing oxygen, and progressively changing into acetic acid and water. This conversion takes place very rapidly when the ether is boiled in an open vessel, while the acid enters into a new combination forming acetic ether. Ether should be preserved in bottles perfectly full and well corked, and kept in a cool place, otherwise it becomes sour, and is destroyed. It contains in this state 15 per cent. of its bulk of azote, but no oxygen gas, as this has combined with its elements. Ether is composed of oxygen 21·24; hydrogen 13·85; carbon 65·05. This composition may be represented by 1 prime equivalent of water, and 4 primes of bi-carburetted hydrogen gas; in other words, ether contains for 1 prime of water, once as much olefiant gas as alcohol, and its prime equivalent is therefore 468·15 to oxygen 100. By my analysis, as published in the Phil. Trans. for 1822, ether is composed of oxygen 27·10; hydrogen 13·3; and carbon 59·6 in 100 parts. The density of my ether was 0·700. One volume of vapour of ether consists of one volume of aqueous vapour and two volumes of olefiant gas (bi-carburetted hydrogen,) while alcohol consists of two volumes of each.

ETHER, ACETIC, is used to flavour silent corn spirits in making imitation brandy. It may be prepared by mixing 20 parts of acetate of lead, 10 parts of alcohol, and 1½ of concentrated sulphuric acid; or 16 of the anhydrous acetate, 5 of the acid, and 4½ of absolute alcohol; distilling the mixture in a glass retort into a very cold receiver, agitating along with weak potash lye the liquor which comes over, decanting the supernatant ether, and rectifying it by re-distillation over magnesia and ground charcoal.

Acetic ether is a colourless liquid of a fragrant smell and pungent taste, of spec. grav. 0·866 at 45° F., boiling at 166° F., burning with a yellowish flame, and disengaging fumes of acetic acid. It is soluble in 8 parts of water.

Acetic ether may be economically made with 3 parts of acetate of potash, 3 of very strong alcohol, and 2 of the strongest sulphuric acid, distilled together. The first product must be re-distilled along with one fifth of its weight of sulphuric acid; as much ether will be obtained as there was alcohol employed.

ETHIOPS, is the absurd name given by the alchemists to certain black metallic preparations. Martial ethiops was the black oxide of iron; mineral ethiops, the black sulphuret of mercury; and ethiops *per se*, the black oxide of mercury.

EVAPORATION, (Eng. and Fr.; *Abdampfen; Abdunsten*, Germ.) is the process by which any substance is converted into, and carried off in, vapour. Though ice, camphor, and many other solids evaporate readily in dry air, I shall consider, at present, merely the vaporization of water by heat artificially applied.

The vapour of water is an elastic fluid, whose tension and density depend upon the temperature of the water with which it is in contact. Thus the vapour rising from water heated to 165° F. possesses an elastic force capable of supporting a column of mercury 10·8 high; and its density is such that 80 cubic feet of such vapour contain one pound weight of water; whereas 32½ cubic feet of steam of the density corresponding to a temperature of 212° and a pressure of 30 inches of mercury, weigh one pound. When the temperature of the water is given, the elasticity and specific gravity of the vapour emitted by it, may be found.

Since the vapour rises from the water only in virtue of the elasticity due to its gaseous nature, it is obvious that no more can be produced, unless what is already incumbent upon the liquid have its tension abated, or be withdrawn by some means. Suppose the temperature of the water to be midway between freezing and boiling, viz. 122° Fahr., as also that of the air in contact with it, to be the same but replete with moisture, so that its interstitial spaces are filled with vapour of corresponding elasticity and specific gravity with that given off by the water, it is certain that no fresh formation of vapour can take place in these circumstances. But the moment a portion of vapour is allowed to escape, or is drawn off by condensation to another vessel, an equivalent portion of vapour will be immediately exhaled from the water.

The pressure of the air and of other vapours upon the surface of water in an open vessel, does not prevent evaporation of the liquid; it merely retards its progress. Experience shows that the space filled with an elastic fluid, as air or other gaseous body, is capable of receiving as much aqueous vapour as if it were vacuous, only the repletion of that

space with the vapour proceeds more slowly in the former predicament than in the latter, but in both cases it arrives eventually at the same pitch. Dr. Dalton has very ingeniously proved, that the particles of aeriform bodies present no permanent obstacle to the introduction of a gaseous atmosphere of another kind among them, but merely obstruct its diffusion momentarily, as if by a species of friction. Hence, exhalation at atmospheric temperatures is promoted by the mechanical diffusion of the vapours through the air with ventilating fans or chimney draughts; though under brisk ebullition, the force of the steam readily overcomes that mechanical obstruction.

The quantities of water evaporated under different temperatures in like times, are proportional to the elasticities of the steam corresponding to these temperatures. A vessel of boiling water exposing a square foot of surface to the fire, evaporates 725 grains in the minute; the elasticity of the vapour is equivalent to 30 inches of mercury. To find the quantity that would be evaporated from the same surface per minute at a heat of 88° F. At this temperature the steam incumbent upon water is capable of supporting 1·28 inch of mercury; whence the rule of proportion is 30 : 1·28 :: 725 : 30·93; showing that about 31 grains of water would be evaporated in the minute. If the air contains already some aqueous vapour, as it commonly does, then the quantity of evaporation will be proportional to the difference between the elastic force of that vapour, and what rises from the water.

Suppose the air to be in the hygrometric state denoted by 0·38 of an inch of mercury, then the above formula will become: 30 : 1·28 — 0·38 :: 725 : 21·41; showing that not more than 21½ grains would be evaporated per minute under these circumstances.

The elastic tension of the atmospheric vapour is readily ascertained by the old experiment of Le Roi, which consists in filling a glass cylinder (a narrow tumbler for example) with cool spring water, and noting its temperature at the instant it becomes so warm that dew ceases to be deposited upon it. This temperature is that which corresponds to the elastic tension of the atmospheric vapour. See VAPOUR, Table of.

Whenever the elasticity of the vapour, corresponding to the temperature of the water, is greater than the atmospheric pressure, the evaporation will take place not only from its surface, but from every point in its interior; the liquid particles throughout the mass assuming the gaseous form, as rapidly as they are actuated by the caloric, which subverts the hydrostatic equilibrium among them, to constitute the phenomena of ebullition. This turbulent vaporization takes place at any temperature, even down to the freezing point, provided the pneumatic pressure be removed from the liquid by the air pump, or any other means. Ebullition always accelerates evaporation, as it serves to carry off the aqueous particles not simply from the surface, but from the whole body of the water.

The vapours, exhaled from a liquid at any temperature, contain more heat than the fluid from which they spring; and they cease to form whenever the supply of heat into the liquid is stopped. Any volume of water requires for its conversion into vapour *five and a half times* as much heat as is sufficient to heat it from the freezing to the boiling temperature. The heat, in the former case, seems to be absorbed, being inappreciable by the thermometer; for steam is no hotter than the boiling water from which it rises. It has been therefore called *latent heat*; in contradistinction to that perceived by the touch, and measured by the thermometer, which is called *sensible heat*. The quantity of heat absorbed by one volume of water in its conversion into steam, is about 1000° Fahr.; it would be adequate to heat 1000 volumes of water, one degree of the same scale; or to raise one volume of boiling water, confined in a non-conducting vessel, to 1180°. Were the vessel charged with water so heated, opened, it would be instantaneously emptied by vaporization, since the whole caloric equivalent to its constitution as steam, is present. When, upon the other hand, steam is condensed by contact with cold substances, so much heat is set free as is capable of heating five and a half times its weight of water, from 32° to 212° F. If the supply of heat to a copper be uniform, five hours and a half will be required to drive off its water in steam, provided one hour was taken in heating the water, from the freezing to the boiling pitch, under the atmospherical pressure.

Equal weights of vapour of any temperature contain equal quantities of heat; for example, the vapour exhaled from one pound of water, at 77° F., absorbs during its formation, and will give out in its condensation, as much heat as the steam produced by one pound of water, at 212° F. The first portion of vapour with a tension = 30 inches, occupies a space of 27·31 cubic feet; the second, with a tension of 0·92 inch, occupies a space of 890 cubic feet.* Suppose that these 890 volumes were to be compressed into 27·31 in a cylinder capable of confining the heat, the temperature of the vapour would rise from 77° to 212°, in virtue of the condensation, as air becomes so hot by com-

* One pound avoirdupois of water contains 27·72 cubic inches; one cubic inch of water forms 1696 cubic inches of steam at 212° F.: therefore one pound of water will form 27·31 cubic feet of such steam: and 0·92 : 30 :: 27·31 : 890 cubic feet.

pression in a syringe, as to ignite *amadou*. The latent heat of steam at 212° F. is 1180° — 180 = 1000; that of vapour, at 77°, is 1180 — 45 = 1135°; so that, in fact, the lower the temperature at which the vapour is exhaled, the greater is its latent heat, as Joseph Black and James Watt long ago proved by experiments upon distillation and the steam engine.

From the preceding researches it follows, that evaporation may be effected upon two different plans: —

1. Under the ordinary pressure of the atmosphere; and that either,

A, by external application of heat to boilers, with *a*, an open fire; *b*, steam; *c*, hot liquid *media*.

B, by evaporation with air; *a*, at the ordinary temperature of the atmosphere; *b*, by currents of warm air.

2. Under progressively lower degrees of pressure than the atmospheric, down to evaporation in as perfect a vacuum as can be made.

It is generally affirmed, that a thick metallic boiler obstructs the passage of the heat through it so much more than a thin one, as to make a considerable difference in their relative powers of evaporating liquids. Many years ago, I made a series of experiments upon this subject. Two cylindrical copper pans, of equal dimensions, were provided; but the metal of the one was twelve times thicker than that of the other. Each being charged with an equal volume of water, and placed either upon the same hot plate of iron, or immersed, to a certain depth, in a hot solution of muriate of lime, I found that the ebullition was greatly more vigorous in the thick than in the thin vessel, which I ascribed to the conducting substance up the sides, above the contact of the source of heat, being 12 times greater in the former case than in the latter.

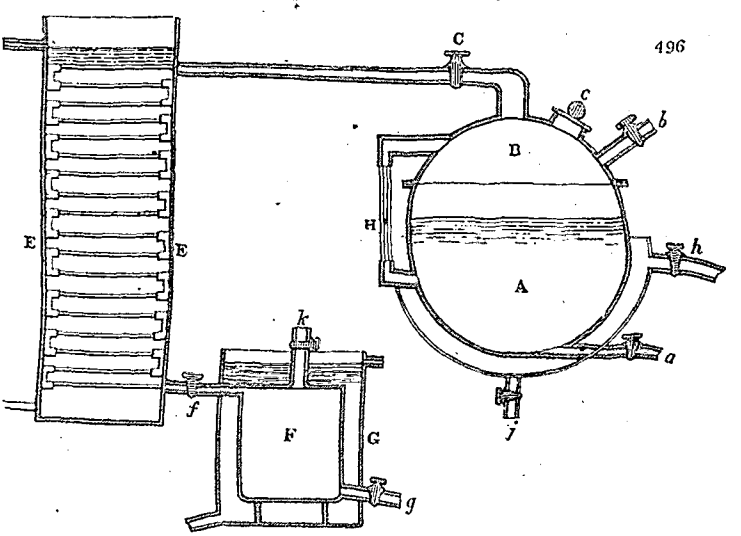
If the bottom of a pan, and the portions of the sides, immersed in a hot fluid medium, solution of caustic potash or muriate of lime, for example, be corrugated, so as to contain a double expanse of metallic surface, that pan will evaporate exactly double the quantity of water, in a given time, which a like pan, with smooth bottom and sides, will do immersed equally deep in the same bath. If the corrugations contain three times the quantity of metallic surface, the evaporation will be threefold in the above circumstances. But if the pan, with the same corrugated bottom and sides, be set over a fire, or in an oblong flue, so that the current of flame may sweep along the corrugations, it will evaporate no more water from its interior than a smooth pan of like shape and dimensions placed alongside in the same flue, or over the same fire. This curious fact I have verified upon models constructed with many modifications. Among others, I caused a cylindrical pan, 10 inches diameter, and 6 inches deep, to be made of tin-plate, with a vertical plate soldered across its diameter; dividing it into two equal semi-cylindrical compartments. One of these was smooth at the bottom, the other corrugated; the former afforded as rapid an evaporation over the naked fire as the latter, but it was far outstripped by its neighbour when plunged into the heated liquid medium.

If a shallow pan of extensive surface be heated by a subjacent fire, by a liquid medium, or a series of steam pipes upon its bottom; it will give off less vapour in the same time when it is left open, than when partially covered. In the former case, the cool incumbent air precipitates by condensation a portion of the steam, and also opposes considerable mechanical resistance to the diffusion of the vaporous particles. In the latter case, as the steam issues with concentrated force and velocity from the contracted orifice, the air must offer less proportional resistance, upon the known hydrostatic principle of the pressure being as the areas of the respective bases, in communicating vessels.

In evaporating by surfaces heated with ordinary steam, it must be borne in mind that a surface of 10 square feet will evaporate fully one pound of water per minute, or $725 \times 10 = 7250$ gr., the same as over a naked fire; consequently the condensing surface must be equally extensive. Suppose that the vessel is to receive of water 2500 libs., which corresponds to a boiler 5 feet long, 4 broad, and 2 deep, being 40 cubic feet by measure, and let there be laid over the bottom of this vessel 8 connected tubes, each 4 inches in diameter and 5 feet long, possessing therefore a surface of 4·8 feet square. If charged with steam, they will cause the evaporation of half a pound of water per minute. The boiler to supply the steam for this purpose must expose a surface of 4·8 square feet to the fire. It has been proved experimentally that 10 square feet surface of thin copper can condense 3 libs. of steam per minute, with a difference of temperature of 90 degrees Fahr. In the above example, 10 square feet evaporate 1 lib. of water per minute; the temperature of the evaporating fluid being 212 °F., consequently $3 : 1 :: 90 : \frac{30}{3}$. During this evaporation the difference of the temperature is therefore = 30°. Consequently the heat of the steam placed in connection with the interior of the boiler, to produce the calculated evaporation, should be, 212 + 30 = 242°, corresponding to an elastic force of 53·6 inches of mercury. Were the temperature of

the steam only 224, the same boiler in the same time would produce a diminished quantity of steam, in the proportion of 12 to 30; or to produce the same quantity the boiler or tubular surface should be enlarged in the proportion of 30 to 12. In general, however, steam boilers employed for this mode of evaporation are of such capacity as to give an unfailing supply of steam.

I shall now illustrate by some peculiar forms of apparatus, different systems of evaporation. *Fig.* 496. explains the principles of evaporating in vacuo. A B represents



496

a pan or kettle charged with the liquor to be evaporated. The somewhat wide orifice *c*, secured with a screw-plug, serves to admit the hand for the purpose of cleaning it thoroughly out when the operation is finished; *h* is the pipe of communication with the steam boiler; *b* is a tube prolonged and then bent down with its end plunged into the liquor to be evaporated, contained in the charging back, (not shown in the figure). H is a glass tube communicating with the vacuum pan at the top and bottom, to shew by the height of the column the quantity of liquid within. The eduction evaporating pipe C is provided with a stop-cock to cut off the communication when required. *i* is a tube for the discharge of the air and the water from the steam-case or jacket; the refrigerator E is best formed of thin copper tubes about 1 inch in diameter, arranged zig-zag or spirally like the worm of a still in a cylinder. The small air-tight condenser F, connected with the efflux pipe *f* of the refrigerator, is furnished below with a discharge cock *g*, and surrounded by a cooling case, for the collection of the water condensed by the refrigerator. In its upper part there is a tube *k*, also furnished with a cock, which communicates with the steam boiler, and through which the pan A B is heated.

The operation of this apparatus is as follows: after opening the cocks c, *f*, *g*, and before admitting the cold water into the condenser F, the cock of the pipe *k* is opened, in order that by injecting steam it may expel the included air; after which the cocks *k* and *g* are to be shut. The water must now be introduced into the condenser, and the cock *b* opened, whereon the liquid to be evaporated rises from the charging back, through the tube *b*, and replenishes the vacuum pan to the proper height, as shown by the register glass tube H. Whenever the desired evaporation or concentration is effected, the cock c must be closed, the pipe *k* opened, so as to fill the pan with steam, and then the efflux cock *a* is opened to discharge the residuary liquor. By shutting the cocks *a* and *k*, and opening the cock *b*, the pan will charge itself afresh with liquor, and the operation will be begun anew, after *b* has been shut and c opened.

The contents of the close water cistern F, may be drawn off during each operation. For this purpose, the cock *f* must first be shut, the cold water is to be then run out of the condenser G, and *k* and *g* are to be opened. The steam entering by *k* makes the water flow, but whenever the steam itself issues from the cock *g*, this orifice must be immediately shut, the cock *f* opened, and the cold water again introduced, whereupon the condensed water that had meanwhile collected in the under part of the refrigerator, flows off into the condenser vessel F. Since some air always enters with the liquor

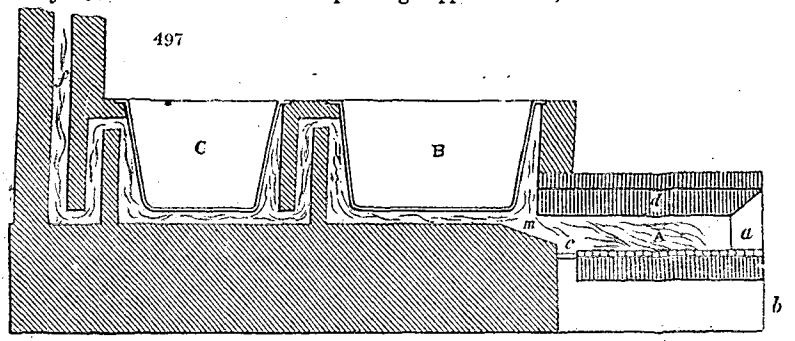
sucked into the pan, it must be removed at the time of drawing off the water from the two condensers, by driving steam through the apparatus. This necessity will be less urgent if the liquor be made to boil before being introduced into the vacuum pan.

Such an apparatus may be modified in size and arrangement to suit the peculiar object in view, when it will be perfectly adapted for the concentration of extracts of every kind, as well as saline solutions containing vegetable acids or alkalis. The interior vessel of A B should be made of tinned or plated copper. For an account of Howard's vacuum pan, made upon the same principle, see SUGAR.

When aboiler is set over a fire, its bottom should not be placed too near the grate lest it refrigerate the flame, and prevent that vivid combustion of the fuel essential to the maximum production of heat by its means. The evil influence of leaving too little room between the grate and the copper may be illustrated by a very simple experiment. If a small copper or porcelain capsule containing water be held over the flame of a candle a little way above its apex, the flame will suffer no abatement of brightness or size, but will continue to keep the water briskly boiling. If the capsule be now lowered into the middle of the flame, this will immediately lose its brightness, becoming dull and smoky covering the bottom of the capsule with soot; and, owing to the imperfect combustion though the water is now surrounded by the flame, its ebullition will cease.

Fig. 497. is a section of two evaporating coppers *en suite*, so mounted as to favour

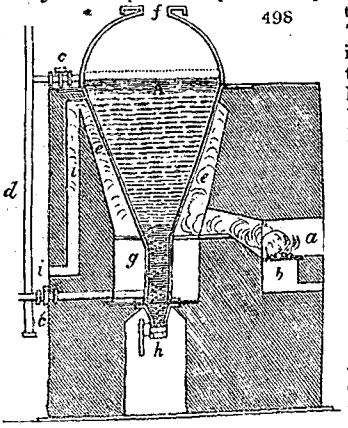
497



the full combustion of the fuel. A is the hearth, in which wood or coal may be burned. For coal, the grate should be set higher and be somewhat smaller. *a* is the door for feeding the fire; *d*, an arch of fire-bricks over the hearth; *c*, a grate through which the ashes fall into the pit beneath, capable of being closed in front to any extent by a sliding door *b*. B and C are two coppers encased in brickwork; *f* the flue. At the end of the hearth near *m*, where the fire plays first upon the copper, the sole is made somewhat lower and wider, to promote the spreading of the flame under the vessel. The second copper, C, receives the benefit of the waste heat; it may be placed upon a higher level, so as to discharge its concentrated liquor by a stop-cock or syphon into the first. When coals are burned for heating such boilers, the grate should be constructed as shown in the figure of the brewing copper, page 116.

Fig. 498. represents a pan for evaporating liquids, which are apt, during concentration, to let fall crystals or other sediment. These would be injured either by the fire playing upon the bottom of the pan, or, by adhesion to it, they would allow the metal to get red hot, and in that state run every risk of being burnt or rent on the sudden intrusion of a little liquor through the incrustation. When large coppers have their bottoms planted in loam, so that the flame circulates in flues round their sides, they are said to be *cold-set*.

498



A is a pear-shaped pan, charged with the liquid to be evaporated; it is furnished with a dome cover, in which there is an opening with a flange *f*, for attaching a tube, to conduct the steam wherever it may be required. *a* is the fire-place; *b*, the ash-pit. The conical part terminates below in the tube *g*, furnished with a stop-cock at its nozzle *h*. Through the tube *c d c'*, furnished above and below with the stop-cocks *c* and *c'*, the liquid is run from the

charging back or reservoir. During the operation, the upper cock *c* is kept partially open, to replace the fluid as it evaporates; but the under cock *c'* is shut. The flame from the fire-place plays round the kettle in the space *e*, and the smoke escapes downwards through the flue *i* into the chimney. The lower cylindrical part *g* remains thus comparatively cool, and collects the crystalline or other solid matter. After some time, the under stop-cock *c'*, upon the supply-pipe, is to be opened to admit some of the cold liquor into the cylindrical neck. That cock being again shut, the sediment settled, and the large stop-cock (a horizontal slide-valve would be preferable) *h* opened, the crystals are suffered to descend into the subjacent receiver; after which the stop-cock *h* is shut, and the operation is continued. A construction upon this principle is well adapted for heating dyeing coppers, in which the sediment should not be disturbed, or exposed to the action of the fire. The fire-place should be built as for the brewing copper.

499

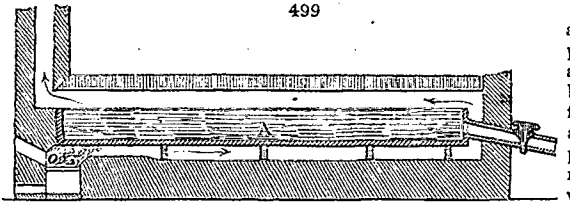


Fig. 499. represents an oblong evaporating pan, in which the flame, after beating along its bottom, turns-up at its further end, plays back along its surface, and passes off into the chimney. A is a rectangular vessel, from 10 to 15 feet long, 4 to 6 feet broad, and 1 or 1½ feet deep. The fire-bricks, upon which the pan rests, are so arranged as to distribute the flame equally along its bottom.

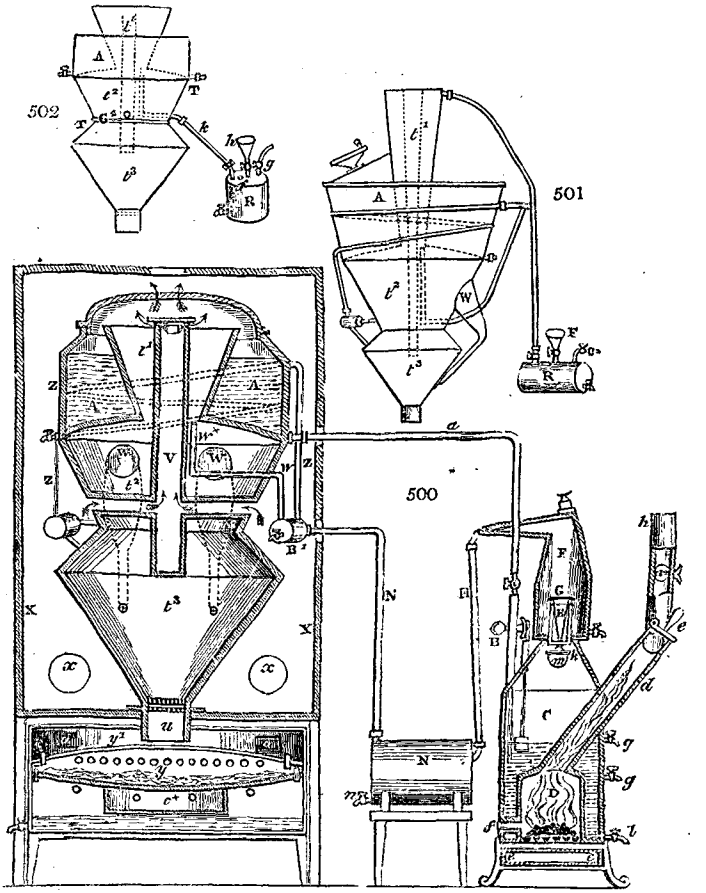
EVAPORATION. For the following scheme of generating, purifying, and condensing steam, Mr. Charles Clarke, merchant, London, obtained a patent in January, 1843. His apparatus for converting sea-water, &c., economically into good fresh water, is represented in *figs.* 500, 501, 502. A is the supply cistern, which communicates with a pipe *a*, with a self-regulating eduction apparatus B. C is a strong wrought iron cylinder, fitted at bottom into a flanged ring-place *c*, and covered with a conical top; it is about two-thirds filled with the water to be operated upon. D is a cylindrical furnace concentric with the water cylinder C; *d* is an upwards air and water-tight tube, which serves both as a feed-pipe, through which the fuel is supplied to the furnace, and as a passage for the escape of the smoke and other gaseous products of combustion; *e* is a hinged trap-door through which the fuel is passed into the tube *d*; *h* is a chimney into which the pipe *d* terminates; and *i*, a damper, by which the degree of activity given to the furnace can be regulated at pleasure; *f* is an open air-pipe, which leads from the outside, through the boiler, into the furnace, a little way above the fire-bars, and assists in securing a good draught through the furnace into the chimney. To the water cylinder C there are attached gauge-cocks, *g g*, for ascertaining from time to time the height of the water; *l* is a cock or tap for drawing off the brine, and other residual matters which collect at the bottom of the boiler; *m* is a screw-cap and hole, through which access may be had to the interior of the water cylinder C, when it needs to be cleaned; E is a short pipe fitted into the conical top of the water cylinder C, which conveys the steam generated in it into the steam-head or receiver F; G is a concave plate, resting upon the top of the pipe E, a little larger than that pipe, and kept steady by a weight, *k*, of one or more pounds, suspended from it by wires. This plate prevents, in a great measure, the escape-water escaping into the steam-head (an accident commonly called *priming* in steam engines); because, till the steam has acquired a pressure exceeding that of the counterweight *k*, it cannot raise the weight G, so as to escape freely into the steam-head F, since any particle of water must, during the rising of the cap G, strike against it, and drop back, either into the water cylinder C, through the pipe E, or into the space round that pipe at the bottom of the steam-head H; whence it may be withdrawn by the cock shown in the drawing. H is a pipe which conveys the steam from the steam-head F to the rectifier R. This consists simply of a cylinder (about one-third the size of the cylinder *c*) laid horizontally, in the lower part of which a body of water speedily collects, and serves to retain any particle of undecomposed matter, which may come over with the steam, as it continues to flow in from the boiler; whereby only its purer portions may pass off from the rectifier R, by the pipe N. *n* is a cock or tap, at the bottom of the cylinder R for drawing off its water occasionally; R' is a second steam-rectifier, like R, into which the steam passes from the pipe N, and is thereby still further purified; but when the proportion of saline matter is small, R' may be dispensed with, and for very foul water, two or three more such rectifiers may be added.

The condenser for liquefying the purified steam, and *aërating* the resulting water, is shown at t^1, t^2, t^3. It is composed of conical upright compartments communicating with each other; the chamber t^1 is surrounded by the water in the cistern A (slightly

heated by the steam in that chambers), while the chamber t^2 and t^3 are exposed freely to the air. The lowest of these, t^3, terminates at bottom in a tube, *u*, containing at the mouth of the cone two or three plates of perforated zinc, for admission of the atmo-



sphere. An upright steam-tight tube of zinc, at about the middle of the lowest chamber, t^3, and is continued to the top of the uppermost chamber, t^1, having two internal branches. This tube is closed at its lower end, but open at top, and at the ends of the two branches, to give a draught of cool air into the tube, and a rapid flow of heated air from the top of the tube. w, w, are pipes which pass externally from about the middle of the chamber t^2, to near the bottom of the chamber t^3. At their tops they are of large dimensions, as represented, but diminish gradually to small pipes at bottom. Of these pipes, there should be as many as can be conveniently applied, in order that the process of condensation may be effectually promoted.

From the second rectifier, R^1, the steam is conveyed by a pipe, *w*, of gradually increasing dimensions, to near the top of the middle chamber, *t*, whence it diffuses itself through the three chambers, where it gets condensed. The hottest steam passes into t^1, and is there most powerfully condensed. The main body of the water produced therefrom, either drops directly into the bottom of the chamber t^3, or runs down the inclined sides of the chambers, t^1 t^2, t^3, thence through the outer pipes w, w, and out at the bottom of the tube, getting partially aerated in its progress, by means of the air ascending constantly through the tube *u*.

z, *z*, is an auxiliary steam-pipe from the rectifier R^1, passing twice or thrice close round the water supplying the cistern, A, and terminating in a cylinder which communicates by pipes with the chambers t^2 and t^3; whereby all the water thus condensed

may fall through the perforated zinc plates, into the general discharge tube, *u*. x is an outer casing of wood or metal, leaving a small space round the condenser, with draught-holes, *x*, *x*, for the admission of air. The refrigerator is made of protected metal "(tinned copper?)," and divided into three compartments, y^1, y^2, y^3.

In the top of y^1, the end of the discharged tube *u* is inserted; and at a little distance from this tube there are air apertures, *a*, *a*, furnished with shutters in the inside, slanting from the top downwards, to prevent as much as possible the escape outwards of any vapour which may occasionally be carried down with the water from the condenser. The middle compartment, y^2, is perforated, convex at top, and concave at bottom; so that the water that drops from the tube *u*, in the convex top of y^2, falls off laterally through small pipes into the chamber y^2, while its concave bottom turns the water into a central filtering-box, *c*, that projects a little into y^3, set to receive it. For aërating this water, the bottom of y^2 is covered about an inch deep with small pebbles. y^3, which is the reservoir of the purified cool water, is perforated with small holes. c^1, c^1, are small pipes for promoting a continual upwards flow of cold air. y^3 is furnished with a tap to draw off its water, as required.

For re-distilling or rectifying spirituous liquids, the apparatus *fig.* 501. is employed; in which the supply cistern A is much larger, and close at top; the upper condensing chambers, t^1, t^2, are also larger, but the lowest, t^3, is narrowed. The second rectifier of *fig.* 500. is removed. The feints collect in the bottom of the rectifier R, to be drawn off by a cock; while the rectified spirit passes off at top into the condenser. The refrigerator has only two compartments, and no pebbles. F is a funnel into which the spirits may be returned for re-distillation.

For extracting the soluble matter of vegetable infusions, the apparatus, shown in *fig.* 502., is used. The rectifier is vertical, has a screw-capped hand-hole *f*, for admitting the vegetables. *g* is a steam pipe; and *h* is a funnel for returning portions of the liquid extract. R is connected by a pipe, *k*, with the condenser, T, made in two portions, fitted water-tight together, but separable for the purpose of cleansing. The steam which passes from the boiler into the rectifier R disengages the soluble portion of the vegetable substances, and if they be volatile, carries them off to the condenser; if not, it combines and falls with them to the bottom of the vessel, whence this portion of the extract is drawn off by the cock, and a fresh charge may be introduced. The steam is shut off from the rectifier R by a cock on the pipe *g*. When the steam is afterwards admitted to assist the process of maceration, the supply of it is regulated by the stop-cocks in the pipes *g* and *k*.—*Newton's Journal*, xxiii. p. 247. C. S.

In each experiment 1,840 lbs. weight were burnt, and the relative quantities of water evaporated show the relative economic effect. Two kinds of coal were used: Knowles's Clifton coal, a free burning kind which does not cake, and produces a considerable quantity of ashes; Barker and Evan's Oldham coal, a slow burning rich caking coal, yielding little ashes. The boiler was a 24 horse power, of Watt's waggon shape.

Mr. H. Houldsworth's Economy of Evaporation.

Effect as furnaces are usually worked, being assumed 100.

The average heat given in the first flue, as ascertained by a pyrometer and deduced from pyrometric diagrams. The air was admitted partly at the door and partly at the bridge; at the latter point through one of Mr. Williams's diffusion boxes, except in the last experiment with Clifton coal. They showed the effect of admitting air in greater or less quantity permanently or periodically by a uniform or varying aperture; and the general result arrived at is, that by the simple and inexpensive plan of admitting air into the furnaces both at the door and bridge by permanent apertures always open, varying in aggregate area from $1\frac{1}{2}$ to 3 square inches (according to the quality of the coals) for every square foot of area of grate, an important saving in fuel is effected, and $\frac{9}{10}$ of the dense smoke prevented, without any special care of the fireman.

Deductions from the experiments on Clifton coal:—

Gain in evaporation by regulated admission of air	35 per cent.
Do. by 45 square inches constant aperture	34 „
Do. by charges of 460 lbs. instead of 230 lbs.	4 „

Steam produced in a given time: —

No air	230 lbs.	charges	100
No air	460 lbs.	do.	109
53 square inches air	230 lbs.	do.	132
Air regulated	230 lbs.	do.	134
53 square inches	460 lbs.	do.	140

showing that the admission of air increases the production of steam in a given time from 30 to 40 per cent.

EUDIOMETER, is the name of any apparatus subservient to the chemical examination of the atmospheric air. It means a *measure of purity*, but it is employed merely to determine the proportion of oxygen which it may contain. The explosive eudiometer, in which about two measures of hydrogen are introduced into a graduated glass tube, containing five measures of atmospheric air, and an electric spark is passed across the mixture, is the best of all eudiometers; and of these the syphon form, proposed by me in a paper published by the Royal Society of Edinburgh in 1819, is probably the surest and most convenient. Volta's explosive eudiometer as made in Paris, costs 3 guineas; mine may be had nicely graduated for 6 or 8 shillings.

EXPANSION (Eng. and Fr.; *Ausdehnung*, Germ.), is the increase of bulk experienced by all bodies when heated, unless a change of chemical texture takes place, as in the case of clays in the potter's kiln.

Table I. exhibits the linear expansion of several solids by an increase of temperature from 32° to 212° Fahr.; Table II. exhibits the expansion in bulk of certain liquids.

Water, saturated with common salt	do.	0·0500	$\frac{1}{20}$
Sulphuric ether (to its boiling point)?	do.	0·0700	$\frac{1}{14}$
Fixed oils	do.	0·0800	$\frac{1}{12\cdot5}$
Oil of turpentine	do.	0·0700	$\frac{1}{14}$

If the density of water at 39° be called 1·00000,
at 212° it becomes 0·9548,
and its volume has increased to 1·04734;
at 77° it becomes 0·9973587,
and its volume has increased to only 1·00265,
which, though one fourth of the whole range of temperature, is only $\frac{1}{18}$ of the total expansion. Water at 60° F. has a specific gravity of 0·9991953,
and has increased in volume from 39° to 1·00008,
which is only about $\frac{1}{38}$ of the total expansion to 212°, with $\frac{1}{6\cdot4}$ of the total range of temperature.

All gases expand the same quantity by the same increase of temperature, which from 32° to 212° Fahr. $= \frac{180}{480} = \frac{3}{8}$, or 100 volumes become 1·375. For each degree of Fahr. the expansion is $\frac{1}{480}$.

When dry air is saturated with moisture, its bulk increases, and its specific gravity diminishes, because aqueous vapour is less dense than air, at like temperatures.

The following Table gives the multipliers to be employed for converting one volume of moist gas at the several temperatures, into a volume of dry gas.

Temperature.	Multiplier.	Temperature.	Multiplier.
53° F.	0·9870	64°	0·9799
54	0·9864	65	0·9793
55	0·9858	66	0·9786
56	0·9852	67	0·9779
57	0·9846	68	0·9772
58	0·9839	69	0·9765
59	0·9833	70	0·9758
60	0·9827	71	0·9751
61	0·9820	72	0·9743
62	0·9813	73	0·9735

EXTRACTS. (*Extraits*, Fr.; *Extracten*, Germ.) The older apothecaries used this term to designate the product of the evaporation of any vegetable juice, infusion, or decoction; whether the latter two were made with water, alcohol, or ether; whence arose the distinction of aqueous, alcoholic, and etherous extracts.

Fourcroy made many researches upon these preparations, and supposed that they had all a common basis, which he called the *extractive* principle. But Chevreul and other chemists have since proved that this pretended principle is a heterogeneous and very variable compound. By the term *extract* therefore is now meant merely the whole of the soluble matters obtained from vegetables, reduced by careful evaporation to either a pasty or solid consistence. The watery extracts, which are those most commonly made, are as various as the vegetables which yield them; some containing chiefly sugar or gum in great abundance, and are therefore innocent or inert; while others contain very energetic impregnations. The conduct of the evaporating heat is the capital point in the preparation of extracts. They should be always prepared if possible from the juice of the fresh plant, by subjecting its leaves or other succulent part, to the action of a powerful screw or hydraulic press; and the evaporation should be effected by the warmth of a water bath, heated not beyond 100° or 120° F. Steam heat may perhaps be applied advantageously in some cases, where it is not likely to decompose any of the principles of the plant. But by far the best process for making extracts is in vacuo, upon the principles explained in the article Evaporation. It is much easier to fit up a proper apparatus of this kind, than most practical men imagine. The vacuum may either be made through the agency of steam, as there pointed out, or by means of an air-pump. One powerful air-pump may form and maintain a good vacuum under several receivers, placed upon the flat-ground flanges of so many basins, each provided with a stop-cock at its side for exhaustion. The air-less basin containing the juice being set on the shelf of a water-bath, and exposed to a proper temperature, will furnish in a short time a large quantity of medicinal extract, possessing the properties of the plant unimpaired.

For exceedingly delicate purposes, the concentration may be performed in the cold, by placing saucers filled with the expressed juice over a basin containing sulphuric acid, putting a glass receiver over them, and exhausting its air.

These preparations of vegetables for medicinal use are made either by evaporating the infusions of the dried plant in water, or in alcohol, or the expressed juice of the fresh plant; and this evaporation may be effected by a naked fire, a sand bath, an air bath, a steam heat, or a liquid *balneum* of any nature, all of which may be carried on either in the open air, or *in vacuo*. Of late years, since the vacuum-pan has been so successfully employed in concentrating syrups in sugar-houses, the same system has been adopted for making pharmaceutical extracts. An elegant apparatus of this kind invented by Mr. Barry, of Plough Court, was made the subject of a patent about 35 years ago. The use of the air-pump for evaporating such chemical substances as are readily injured by heat, has been very common since Professor Leslie's discovery of the efficacy of the combined influence of rarified air and an absorbing surface of sulphuric acid in evaporating water at low temperatures. It has been supposed that the virtues of narcotic plants in particular might be better obtained and preserved by evaporation in vacuo than otherwise, as the decomposing agency of heat and atmospheric oxygen would be thereby excluded. There is no doubt that extracts thus made from the expressed juices of fresh vegetables possess, for some time at least, the green aspect and odour of the plants in far greater perfection than those usually made in the air, with the aid of artificial heat. Dr. Meurer, in the *Archiv. der Pharmacie* for April, 1843, has endeavoured to show that the colour and odour are of no use in determining the value of extracts of narcotics, that the albumen left unchanged in the extracts made in vacuo tends to cause their spontaneous decompositon, and that the extracts made with the aid of alcohol, as is the practice in Germany, are more efficacious at first, and much less apt to be injured by keeping. M. Baldenius has, in the same number of the *Archiv.*, detailed experiments to prove that the juices of recent plants mixed with alcohol, in the homœopathic fashion, are very liable to spontaneous decomposition. To the above expressed juice, the Germans add the alcoholic tincture of the residuary vegetable matter, and evaporating both together, with filtration, prepare very powerful extracts.

F.

FAHLERZ. Gray copper-ore, called also Panabase, from the many oxides it contains.

FAINTS is the name of the impure spirit which comes over first and last in the

distillation of whiskey; the former being called the *strong*, and the latter, which is much more abundant, the *weak* faints. This crude spirit is much impregnated with fœtid essential oil, is therefore very unwholesome, and must be purified by rectification.

FAIRBAIRN'S TUBULAR BRIDGES. Of the tubular bridge system, the Conway and Menai are the first, and will probably for ever remain the most remarkable specimens, to attest the scientific genius of Mr. W. Fairbairn, their inventor and constructor. His claims, indeed, are exclusive and palpable. Mr. Robert Stephenson, however, has, unfortunately for himself, claimed the entire merit of having not only first conceived the idea of constructing a tubular bridge of such huge dimensions as to allow the passage of locomotive engines and railway trains through the interior of it, and of such length as to span distances of from 400 to 500 feet, but of having assured himself by laborious investigation and calculation of "the perfect feasibility of the work," without consulting any one else on the subject; and he has assigned to Mr. Fairbairn, in a very slighting fashion, the place of a mere after adviser, of one who, in common with two other gentlemen (Mr. Eaton Hodgkinson and Mr. Edwin Clarke), but not more than either of them, assisted him in working out the construction which he "first broached." Mr. Fairbairn maintains, on the contrary, that the idea of a tubular bridge, though it unquestionably originated with Mr. Stephenson, was in his hands nothing more than a crude conception, very hesitatingly entertained, until he (Mr. Fairbairn) was called in to work it out, and that it has been wholly owing to his determined perseverance in the execution of the task confided to him, and to his numerous and elaborate experiments, that "the true principle on which tubular bridges should be constructed has been established, and thereby Mr. Stephenson's vague idea successfully carried into execution."

"At the period of the consultation in April, 1845, there were no drawings illustrative of the original idea of the bridge, nor had any calculations been made as to the strength, form, or proportions of the tube. I was asked whether such a design was practicable, and whether I could accomplish it: it was ultimately arranged that the subject should be investigated experimentally, to determine not only the value of Mr. Stephenson's original conception, but that of any other tubular form of bridge which might present itself in the prosecution of my researches. The matter was placed unreservedly in my hands; the entire conduct of the investigation was entrusted to me; and, as an experimenter, I was to be left free to exercise my own discretion in the investigation of whatever forms or conditions of the structure might appear to me best calculated to secure a safe passage across the Straits." (*W. Fairbairn's Correspondence.*)

In commenting on the treatise of Mr. Fairbairn "on the Construction of the Britannia and Conway Bridges," the editor of the Mechanics' Magazine says, "We have read it carefully, and not without strong prepossessions in favour of the inculpated party, but we feel honestly bound, however, to say, that the perusal has left us convinced, in spite of all leanings, that Mr. Fairbairn has not received at Mr. Stephenson's hands that justice to which he was entitled, but, on the contrary, has been treated most ungenerously and ungratefully. We will not say, that but for Mr. Fairbairn the tubular bridge idea would never have been carried out into practice, for that would be to assume that he engrossed in his single person all the practical skill of the country; but, looking into the facts of the case as they stand, and as we see them established in the volume before us beyond all possibility of dispute, we hesitate not to affirm, that it is more owing to Mr. Fairbairn than to any one other individual whatever, not excepting Mr. Stephenson himself, that it is now the triumphant reality which it is. Another might possibly have done the part which fell to the lot of Mr. Fairbairn as well, but none could possibly have done it better. He conceived and directed all the preliminary experiments,—all at least with an exception or two, which were of any practical value, exhibiting therein a combination of philosophical painstaking with mechanical skill and ingenuity, such as is not often witnessed; he finally settled the form which it was best to give to the tube, and arranged the whole of the executive details; he personally superintended the construction of the Conway Bridge, which our readers are aware is but the Menai or Britannia Bridge on a smaller scale; and he only retired from further co-operation with Mr. Stephenson in the affair, when nothing new was left to be discovered or achieved. The motives for his retirement are thus very fairly and temperately stated.

"'I have now brought down this correspondence to the period when my official connection with the Chester and Holyhead Railway Company as engineer, for the construction of the tubular bridges, may be said to have virtually ceased, and I should willingly have passed over in silence the remainder of the events which transpired, were it not that the completeness of the narrative, as well as the justification of my conduct, demand some explanation, independently of the regret which I experienced in withdrawing from an undertaking to which I had devoted so much time and thought,—an

undertaking fraught with the greatest interest, and which had, as it were, grown up in all its magnificent proportions under my own directions. I can truly say that the disagreement which took place with Mr. Stephenson is on my part much deplored. But I trust that the reader of the foregoing pages will at least have arrived at the conclusion, that I had taken the most important part in developing, and giving a practical form to Mr. Stephenson's idea, and also in the superintending the construction and erection of the first Conway tube. The fact is, I laboured almost incessantly in devising plans, or in watching over the practical details of the work, from the day in which Mr. Stephenson's suggestion was communicated to me until the close of my engagement; and I can sincerely say that I was always actuated by the principle of leaving nothing undone which could in any way contribute to the successful accomplishment of the undertaking. Regardless of the prognostications of failure with which the scheme was assailed, and in despite of the opposition of those whose assistance I had solicited, I uniformly advocated the peculiar principle on which the Conway Bridge has been constructed.

"'Such being my position, and viewing the extent of services I had rendered, it will, I think, be generally allowed that it was very natural that I should desire to have my name publicly associated with Mr. Stephenson's as joint engineer for these bridges. Indeed, it may very fairly be said that I might have ventured to claim this distinction, since it had been conferred upon me by the Board of Directors on Mr. Stephenson's own recommendation. If, instead of success having crowned our efforts, failure had unfortunately ensued, would not my reputation have suffered as well as Mr. Stephenson's? The working plans having gone forth with my name alone attached to them, and from my being recognised as the acting engineer, might not the whole blame have been conveniently thrown on me in case of failure?

"'It was not, however on any of these grounds that I was induced to resign my appointment, for there had not then occurred any opportunity where I conceived it necessary to have my position publicly recognised; and I had always believed that, when the proper time came, Mr. Stephenson would be the first to establish that position, and acknowledge the services I had rendered. The recognition was, however, very shortly afterwards denied me. The first Conway tube having been completed, and the success of the principle established, I conceived that the construction of the remaining tubes simply required a close attention to the system of construction already adopted, and therefore might safely be entrusted to those gentlemen whose constant presence during the building of the first tube had rendered them thoroughly acquainted with the whole details of the work. By such an arrangement, moreover, the Company would save the amount which had hitherto been paid for my services, and I should be enabled to devote my time to other pursuits which I had neglected for this work, and which now urgently demanded my attention. This was one reason for my retirement; but what chiefly led me to this decision, was the position assumed by Mr. Stephenson, his public misrepresentation of the position I held under the Company, and his endeavour to recognise my services as the labours of an assistant under his control, and acting entirely under his direction. Had Mr. Stephenson in his public address done me the justice to state my independent claim to some of the most important principles observed in the construction of the tubes, I might, perhaps, have continued my services until the final completion of the whole undertaking; and, most assuredly, this work would never have come before the public. I now appeal to the preceding pages of this narrative, whether Mr. Stephenson's assertions are borne out by the simple statement of facts? I have overstated nothing, concealed nothing; and the reader is left to draw his own conclusions from these facts, after having become acquainted with the course pursued by Mr. Stephenson, which I will in conclusion concisely relate.' (p. 171.)

"Mr. Fairbairn proceeds then to give an account of a public dinner to celebrate the completion of the Conway Bridge, which took place on the 17th of May, 1848; on which occasion it was, Mr. Stephenson first openly assumed that position in regard to Mr. Fairbairn and the undertaking, which has made the present appeal to public justice necessary. Mr. Stephenson's speech was confessedly a studied affair — he had announced beforehand that he would avail himself of the opportunity of 'setting the question at rest;' but for all that it does not take Mr. Fairbairn many words to demolish it utterly.

"'The inaccuracies, both as to facts and dates, in the statements of Mr. Stephenson, are very numerous. It simply requires a reference to the short description of the Ware Bridge, and to the drawings, to disprove the assertion, that it is a thin tubular bridge, although not precisely the same as the present, yet in principle precisely the same; and it can easily be shown too, that considering the Ware Bridge as a simple girder bridge, it is exceedingly defective in design. Is there anything new in this application of wrought-iron plate girders? As well might it be said that the combination

of wrought-iron deck beams, so many years applied in iron ships for the support of the decks, is a 'counterpart of the proposed cellular top for the Britannia tubes." I really cannot but regret that Mr. Stephenson, whose name will be always associated with the grandest bridge that has ever been constructed, should have committed himself in making such an erroneous assertion as that it was by reviving and extending his original conception of this imperfect structure at Ware, that he was led to originate the bridges crossing the Conway and Menai Straits.

"'Mr. Stephenson's remarks further admit of the disingenuous construction that his scheme was matured before the Bill for the Chester and Holyhead Railway was passed by Parliament, and before I was consulted, and that he was at that early period acquainted with the present design of the bridge. He refers to the incredulous glances which were directed towards him when the description of the bridge was explained to the Committee; and intimates, "that it was not until the Bill had been obtained, and it became necessary to commence, that he requested my assistance." Now, my advice was asked by Mr. Stephenson before his evidence to the Parliamentary Committee was given, and he announced his idea to that Committee strengthened by more than one opinion of its feasibility. Let the reader turn again to the earlier letters of the correspondence, and he will find of what a crude and dangerous scheme that idea consisted; how totally dissimilar in form and principle it was to the present tubular structures, and how slowly Mr. Stephenson was persuaded to give up his earliest conceptions. Again; Mr. Stephenson states that he called in the aid of Mr. Hodgkinson and myself at the same time; now it is essential to the proof of my claims that this assertion should be explicitly contradicted. It was I, and not Mr. Stephenson, who solicited Mr. Hodgkinson's co-operation, and this was not done until I had been actively engaged for several months in my experimental researches, and after I had discovered the principle of strength which was offered in the cellular top, and not only proved the impracticability of Mr. Stephenson's original conceptions, but had given the outline of that form of tube which was ultimately carried into execution.

"'When Mr. Stephenson had made up his mind to claim in the manner he did the whole merit of the undertaking, it is not difficult to understand his reason for giving Mr. Clarke, his own assistant, so prominent a position. I willingly bear my testimony to the great value of the services rendered by Mr. Clarke, to his talents, and to the great energy which he displayed in working out his several duties, but these had no reference whatever to the designing of the structures.' (p. 178.)

"There is one part of the case on which we think Mr. Fairbairn does not insist enough, though, in our judgment, it is of itself decisive of the inordinateness of Mr. Stephenson's pretensions. Mr. Stephenson and his friends, for obvious reasons, slur it over altogether. We refer to Mr. Fairbairn's appointment to be joint engineer along with Mr. Stephenson to the Conway and Britannia Bridges. The evidence of this is a Minute of the Board of Directors of the Chester and Holyhead Railway, dated 13th May, 1846, which we here quote at length from the work before us.

"'Resolved — 1st. That Mr. Fairbairn be appointed to superintend the construction and erection of the Conway and Britannia Bridges, in conjunction with Mr. Stephenson.

"'2nd. That Mr. Fairbairn have, with Mr. Stephenson, the appointment of such persons as are necessary, subject to the powers of their dismissal by the Directors.

"'3rd. That Mr. Fairbairn furnish a list of the persons he requires, with the salaries he proposes for all foremen or others above the class of workmen.

"'4th. That advances of money be made on Mr. Fairbairn's requisition and certificates, which, with the accounts, or vouchers, are to be furnished monthly.

"'5th. That the Directors appoint a bookkeeper at each spot, the Conway and the Menai.'

"To talk, after this, of Mr. Fairbairn's being only entitled to a secondary and subordinate place in the affair, is to outrage all truth and propriety.

"We can but regard with profound pity the hallucination which has betrayed a man of Mr. Stephenson's genius and worth (this unfortunate episode notwithstanding) into so false a position.

"We do not overlook that we have as yet Mr. Fairbairn's statement of the case only, and that we may expect to see, ere long, something of a very opposite complexion from Mr. Stephenson or some of his friends. We shall give all due consideration to any such counter-statement when it comes before us; but so well is all Mr. Fairbairn says borne out by written, and therefore unalterable proofs, that we do not, in the meanwhile, hesitate to avow our firm belief, that nothing which can possibly be adduced in the way of either evidence or argument, can ever alter materially the conclusion at which we have already arrived."— (*Mechanics' Magazine.*)

FAIRBAIRN'S TUBULAR GIRDER BRIDGES. — William Fairbairn, Esq., of Manchester, F. R. S., and Member of the Institute of France, has been long recognised as the most accomplished of our factory engineers and the most skilful of our millwrights, by his

admirable fire-proof buildings and his magnificent hydraulic machines. Having a few years ago directed his constructive genius to the building of iron steam ships, he became thereby well acquainted with the prodigious stiffness and strength of which hollow girders of thin sheet iron were susceptible. He was naturally pitched upon by Mr. Stephenson, the engineer of the Chester and Holyhead Railway, as the fittest person to execute the tubular bridge which was regarded by him as the only means of carrying ponderous railway trains over the tremendous sea-gulf of Menai's Straits or Conway's roaring flood. The tidal torrents at these two places being deep and rapid required to be crossed by bridges of extraordinary span and strength. No centerings or other substructures usually resorted to for mounting such huge pontitectures could be erected. In such a dilemma, the most obvious resource of the engineer was a suspension bridge; but the failure of more than one attempt of that kind had proved the impossibility of running railway trains over such bridges with safety.

Under Mr. Stephenson's direction, numerous other schemes had been devised. Both timber and cast-iron arches had been thought of; and a model of a very handsome bridge for crossing the Menai Straits on the latter principle had been constructed, and submitted to the consideration of a parliamentary committee. The possibility of throwing cast-iron arches over so great a span as 450 ft. was however questionable; and the security of such a bridge must have been endangered by the great changes which the material would have been subjected to from atmospheric influences, and from vibrations produced by the passage of heavy trains. But a more important objection even than these caused the withdrawal of this design. The Lords Commissioners of the Admiralty, as conservators of the navigation, opposed the erection of any structure which should offer a hindrance to the free passage of vessels under it, and insisted on a clear headway of 105 ft. from the level of high water. Mr. Stephenson then conceived the original idea of a huge tubular bridge, to be constructed of riveted plates, and supported by chains*, and of such dimensions as to allow of the passage of locomotive engines and railway trains through the interior of it. The illustrious Galileo, in demonstrating the strength of tubular structures, adverted to the quills of birds and the stalks of corn; but in our days we see that idea amplified into colossal dimensions.

It was with reference to this expedient, after all others had been found inapplicable, that Mr. Fairbairn was consulted by him, and requested to give his opinion,—first, as to the practicability of the scheme; and secondly, as to the means necessary for carrying it out. The consultation took place early in April, 1845. Mr. Stephenson conceived that the tube should be either of a circular or egg-shaped sectional form; and he was strongly impressed with the primary importance of the use of chains, placing his reliance in them as the principal support of the bridge. He never for a moment entertained the idea of making the tube self-supporting. The wrought-iron tube, according to his idea, was indeed entirely subservient to the chains, and intended to operate from its rigidity and weight as a stiffener, and to prevent, or at least to some extent counteract, the catenary principle of construction.

"February 23rd, 1846.

† "My dear Sir,

"I have been considering the principle on which you purpose attaching the chain for the support of the tube; and with every deference to your judgment, I am almost inclined to differ with you upon that point.

"It appears to me that the great and important consideration is to relieve the strain upon the tube. It is quite clear that a series of chains on each side of the plates, well fitted and tightly screwed up, would tend to stiffen the sides, and give greater rigidity to these parts. This is, however, not what is wanted. *The rigidity is required on the top side;* as in all the experiments, the sides seldom get out of form unless distorted by the crushing of the top side. Under these circumstances, the stiffening should in my opinion be on the top platform of the tube."—*William Fairbairn to Mr. Robert Stephenson.*

For many months afterwards, and even up to the time of the experiments on the model tube in December, 1846, Mr. Stephenson insisted on the application of such chains. "I always felt," says Mr. Fairbairn, "that in a combination of two bodies, the one of a perfectly rigid, and the other of a flexible nature, there was a principle of weakness; for the vibrations to which the one would be subjected, would call into operation forces whose constant action upon the rivets and fastenings of the other could not but tend to loosen them, and thus, by a slow but sure agency, to break up the bridge."

In consequence of the favourable opinion entertained by Mr. Stephenson on the cylin-

* These chains, not only superfluous but dangerous, would have cost 150,000*l.*
† Conway and Menai Bridges, by W. Fairbairn, C. E., p. 48.

drical tubes, it was deemed expedient to commence experiments upon models of that kind, and to extend them subsequently to elliptical tubes. Experiments carefully made, demonstrated the weakness of these two forms, and the vastly greater strength of the rectangular tubes, which were accordingly adopted with cellular top and bottom.

In Mr. Stephenson's examination before the Select Committee of Railways of the House of Commons, 5th and 6th of May, 1845, he says: "I am instituting a series of experiments in conjunction with Mr. Fairbairn of Manchester, who is already in possession of experiments on iron ships, which place the thing beyond a doubt. He has ascertained that a vessel of 250 ft. in length supported at the ends will not yield with all the machinery in the middle.

"Have your calculations been submitted to any other engineers?

"*I have made them, in conjunction with Mr. Fairbairn of Manchester, whose experience is greater than any other man's in England.* There is an iron vessel now building by Mr. Fairbairn 220 ft. in length; and he says that he will engage, that when it is finished, it shall be put down on the stocks at each end, and shall have 1000 tons of machinery in the middle of it, and it will not affect it. But that is not so strong as a tube, and therefore, any experiment that this would carry out, the tube would fully bear."

The floating of the first Conway tube. — "The transport of a huge mass of iron 412 ft. long, 25 ft. 6 in. high, 15 ft. wide, and weighing not less than 1300 tons, was a task of no ordinary difficulty. No former effort with which we are acquainted can, I think, be said to have equalled it, when the unwieldiness of its form, and the extraordinary natural difficulties to be encountered, are taken into consideration. Many of the works of the ancients are stupendous in conception and colossal in dimensions; and it has been a constant matter of inquiry, in what manner a people, ignorant of the mechanical appliances which we possess, could raise structures which have resisted all the inroads of time, and which are to the present generation objects of awe and admiration. In more recent times, the transport of the immense granite block which forms the base of the statue of Peter the Great at St. Petersburg, was looked upon as a most extraordinary achievement; but it cannot be said to have been so formidable an undertaking as the moving of the Conway tube. The granite block was a compact mass, being 42 ft. at the base, 21 ft. thick, and 17 ft. high, and capable of being moved on rollers, &c. to the raft which carried it down the Neva to the site of the city; but in the case of the Conway tube, after the most anxious consideration, and when numerous schemes and proposals had been weighed, examined, and rejected, that of floating the mass on pontoons or barges was decided upon as the most feasible and most secure, the centre of gravity being, in this case, necessarily raised several feet. In addition to this disadvantage, the whole had to be handled and manœuvred in probably the most difficult tideway in Europe, where the current rushes through a narrow gorge of great depth to fill the broad expanse of the inland bay, at a rate of 6 or 7 miles an hour; and the utmost nicety had moreover to be observed in bringing the tube to its place, as there was only a clearance of 12 inches; that is, the distance between the opposite masses of masonry was only 12 inches greater than the length of the tube. All these obstacles may well be termed formidable; and I therefore conceive that the utmost praise is due to Mr. Stephenson for the admirable arrangements and contrivances which rendered the first attempt at so gigantic an operation perfectly successful."

I have quoted these liberal remarks of Mr. Fairbairn in proof of his good feeling towards the engineer associated with him conformably to the Minute of the directors of the Chester and Holyhead Railway, of date May 13. 1846, already quoted.

How defective, and even erroneous, Mr. Stephenson's conceptions were of the tubular girder construction so late as the 26th October, 1846, appears, from his stating in a letter of that date addressed to Mr. Fairbairn, "that this was not the first time he had the idea of employing wrought-iron tubular bridges; for three years ago, or thereabouts, I had erected at Ware, on the Northern and Eastern Railway, a cellular platform of wrought-iron. It was, in fact, I believe, a counterpart of the proposed top of the Britannia bridge."

"As this statement," says Mr. Fairbairn, "has been frequently repeated since the letter was written, I feel myself called upon to show that Mr. Stephenson has no claim to originality in this bridge, and that it has no resemblance whatever, either in principle or construction, to the Conway or Britannia tubes. On the contrary, the bridge in question is constructed upon the principle of the common cast-iron girder bridge, each separate beam being formed of wrought-iron plates connected together by angle irons. This form of wrought-iron girder had been long in use before the erection of the Ware Bridge; and it is defective as well in principle as in construction; the great body of the material is not in the top flanches, as it ought to be, in order to attain the section of greatest strength. In Experiments 14, 15, and 16 (see Appendix and p. 10. in the Report), it is clearly shown that the top flanche of a wrought-iron girder, if made solid,

should be more than twice the area of the bottom flanche. Now it appears that the top flanche in the said bridge at Ware is to the bottom flanche as 4 to 15 nearly; an exceedingly defective structure. If this beam were turned upside down it would carry more than double the weight. From the defective principle upon which the bridge is constructed, it is evident that Mr. Stephenson was not then acquainted with the proper form of wrought-iron girder bridges. Nor is this surprising, as no experimental facts were at that time in existence to show the difference between the two resisting forces of compression and extension of wrought-iron beams." — *Conway and Britannia Bridges, by Mr. Fairbairn*, pp. 113, 114.

"It is impossible to trace any analogy between a combination of this form of beam and a tubular girder with a *cellular top*. The beams in the Ware Bridge do not offer a united resistance to strain in the manner which beams with a cellular structure do; on the contrary, each beam has its distinct part of the load to carry, and that imperfectly, for want of a due proportion in the top and bottom flanches." — *Ibidem.*

A striking proof of the accuracy of Mr. Fairbairn is afforded by the fact, that it was not till the latter part of 1846, that Mr. Stephenson finally made up his mind to abandon the use of the chains, for in the engravings of both the Conway and Britannia Bridges, which were published in that year, there is attached to them the name of Robert Stephenson, Esq., engineer. These drawings represent, with tolerable accuracy, the proportions and forms of the tubes of both bridges as they now exist, — viz., the long, low, rectangular galleries, which Mr. Fairbairn's experiments had shown to be much better adapted to the purpose than the elliptical tubes proposed by Mr. Stephenson. But mark, *in both cases the chains are absolutely shown attached to the tubes.* They are a prominent feature in the drawing, and therefore conclusive evidence that up to that time at least, and notwithstanding the discovery of the increased strength and security to be derived from the adoption of the tube with a rectangular section, and the distribution of the material on the top side in the form of cells, Mr. Stephenson still thought the auxiliary support indispensable.

From the moment that Mr. Fairbairn commenced this experimental investigation, the whole matter, as regarded the development of the best form of the tubes, was unreservedly in his own hands. Mr. Stephenson was not present at the experiments, he neither superintended nor directed them, but was simply made acquainted with results, and approved, when completed, what Mr. Fairbairn did. And now what did Mr. Fairbairn's experiments show? They first of all confirmed his own early opinion, that the security of the bridge, if built at all, must depend solely upon the self-contained strength of the tube, and that the application of any form of catenary would introduce into the structure an agent of a destructive tendency. They proved the weakness and total inadequacy of either of the sectional forms of tubes (cylindrical or elliptical), thought of by Mr. Stephenson. They led Mr. Fairbairn, after carefully observing all the signs and symptoms of weakness shown by the models when under strain, to recommend as a stronger form of tube one having a rectangular section. They brought to light some curious and anomalous appearances exhibited by wrought-iron when subjected to a crushing force. They showed that tubes of a uniform distribution of material, when loaded with an increasing weight, first yielded on the upper side; and this *fact*, therefore, induced Mr. Fairbairn, first, to thicken the material in that part, and, subsequently, led him to suggest that distribution of the material in the form of hollow cells or tubes, wherein lies the secret of the strength of this system of tubular construction.

Mr. Fairbairn therefore, reasoning from his experiments,—1st, suggested the rectangular sections for the tubes; 2nd, discovered that important and beautiful element of strength and lightness, the cellular arrangement of the top; and 3rd, was mainly instrumental in causing the final abandonment of chains.

Beyond this, after he was appointed engineer with Mr. Stephenson for the structure, he worked out the detail of the tubes, had the whole of the *working drawings* for the tubes of both bridges made at his own office, and under his constant supervision, proportioned the different parts, and (again the result of reasoning from experiment) suggested that admirable system of chain riveting, which is adopted in those parts of the tubes liable to a tensile strain, and which adds in a material degree to the strength of the structure.

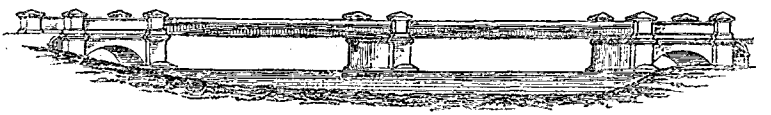
A bridge with several spans of nearly 500 feet each was wanted, which should not only be unyielding with its own necessarily enormous weight, but which should possess within itself such an excess of strength as would satisfy an incredulous public that it would be abundantly safe when subjected to the shocks and vibrations of a heavy locomotive engine with its accompanying train passing across it at a speed of forty miles an hour. The situations both at Conway and the Straits offered obstacles of extraordinary magnitude; at both places the estuaries were of great depth, defying the use of scaffold-

ing to assist in the erection of the bridges, and the tides washed through with appalling impetuosity. The Menai or Britannia Bridge was moreover to stretch from shore to shore at a giddy height of more than 100 feet from the level of high water, and, as if to render insuperable the obstacles which Nature had raised to the progress of the engineer's work, an arbitrary but absolute order was issued from the controllers of the navigation that the whole was to be accomplished without hindrance or obstruction to the rights which they guarded. The manner in which all these necessities were complied with is well known. The Britannia and Conway Bridges exist, the pride of the country which possesses them, triumphs of the constructive arts, and immortal monuments to the men who were associated in their contrivance and execution. It is to be deplored in every respect that jealousies and rivalries should have arisen under circumstances where so much renown and merit was to be divided. The grandeur and boldness of the conception was Robert Stephenson's, but the merits of the existing structure, the ingenuity of the arrangement, and proportions of the material, — the discovery, in fact, of the tubular principles of construction, — are William Fairbairn's.

As an outgrowth of the remarkable introductory experiments made in connection with these wonders of North Wales, we must regard the equally important, though less imposing tubular girder system; the new and scientific discovery of great advantages to be derived from a peculiar combination of material, applied to the simple and generally used beam or girder. A tubular girder, as the name implies, is a hollow beam constructed of metal plates firmly riveted or fastened together. When subjected to a transverse strain or load tending to break it, the law, which is applicable to every body, be it solid or hollow, is observable. The parts of the girder above the neutral axis have to arrange themselves to a resistance of a compressive strain, while those below that line are violently subjected to a force tending to draw them asunder. The extreme ductility of wrought-iron, and its great power to resist tension, were well known, and in the earlier stages of the inquiry it was considered feasible, and frequent efforts were made to arrange the parts in such manner that these known properties might be taken advantage of in both the upper and lower sides of the girder, but every experiment baffled the ingenuity of the contrivance, and nature soon taught the constructor that her unerring laws were not to be disregarded. This point being established, viz., that no distribution of the metal in a tubular girder could change the character of the forces which would act upon it, Mr. Fairbairn's great merit lies in the ingenuity with which he adapted his new material to those strains. In the top or upper side of the girder he distributed it, in that beautiful cellular form which imparts the real strength and security to the structure, and in the bottom he connected the parts by an ingenious system of fastening which assimilated the strength of the joints with that of the solid plate.

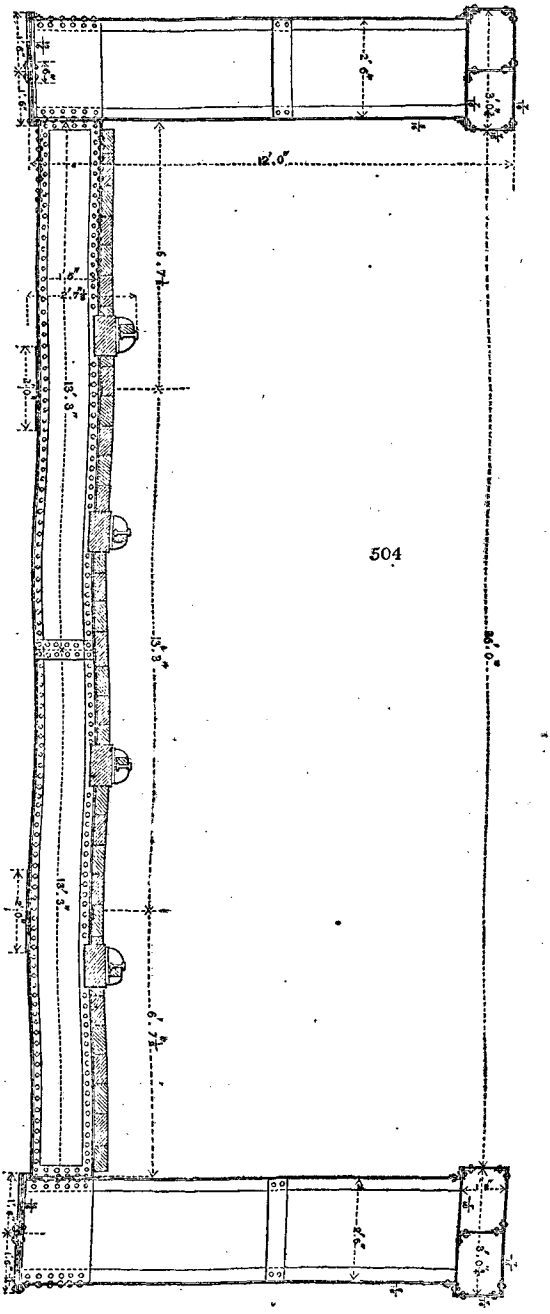
The description of one of the best constructed tubular girders will give the most correct idea of their power and peculiarity. We select for illustration the beautiful

503



bridge erected across the Trent at Gainsborough. *Fig.* 503. represents a general elevation of the bridge which carries the Lincolnshire railway across the Trent. Its total length is 332 feet, the two main spans being 154 feet each. The width of roadway between the two main girders is 26 feet, giving ample room for double lines of railway. The width of the centre pier is 12 feet, and the tubular girders have a bearing on each land abutment of 6 feet. *Fig.* 504. represents a cross section form of the main girders, and to this we must direct especial attention in order to make the peculiarities of the system well understood. The height of each girder from end to end is 12 feet; this parallelism is not the best form to give a maximum resistance with a minimum amount of material; but from the greater facilities of construction is preferable to the parabolic form, and practically the proportions of the strength may be adjusted by varying the thicknesses, instead of the linear dimensions of the parts.

The Bottom of the Girder. — The bottom is framed of double thicknesses of long rolled plates, connected together in the manner hereafter described. Being subjected solely to a tensile strain, the material is condensed as much as possible, so as to assimilate that part of the structure to one unbroken solid sheet, which, if practicable, would be the best distribution or form. Each plate is 12 feet long by 18 inches wide, varying in thickness according to its position from the centre line of each span, where the greatest

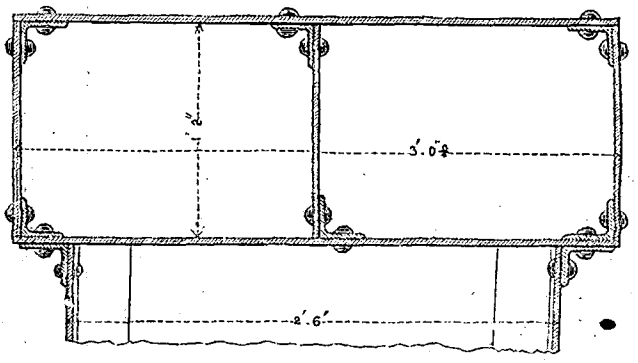


amount of material is accumulated. The bottom is necessarily connected to the sides of the girder by long bars of heavy L or angle iron, firmly riveted to both.

The Sides of the Girder.—The side plates are 2 feet wide throughout, and of uniform thickness, excepting in the immediate neighbourhood of the piers and abutments, where they are strengthened and stiffened by pillars of strong T iron, to offer a due resistance to the dead weight of the girder itself. The joints are made with external covering plates 4½ inches wide, and internal ribs of T iron, which suffice to keep the side plates rigid, and enable them to accomplish their duty of separating the top and bottom of the girder.

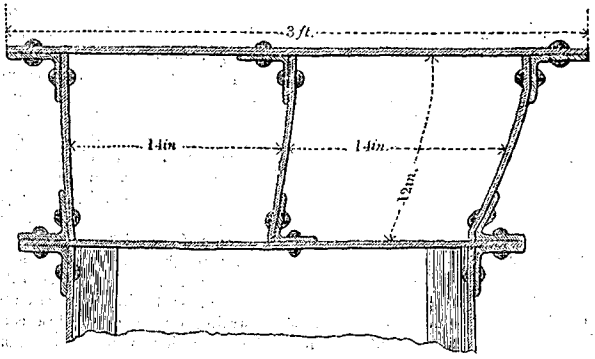
The Top of the Girder.—In this part the principal novelty and ingenuity are observable. A single sheet of iron, like a sheet of paper, is easily put out of shape by a compressive strain. It crumples up, and at once loses all power of resistance. A sheet of common writing paper, which when placed on edge will merely support itself, when rolled into a cylinder, say of 1 inch diameter, will carry a considerable weight. In the same manner a given sectional area of plate, if placed in that simple form in the top of the Trent girder, would crumple up with a comparatively small weight, but when distributed according to Mr. Fairbairn's tubular arrangement it offers extraordinary resistance to compression.

505



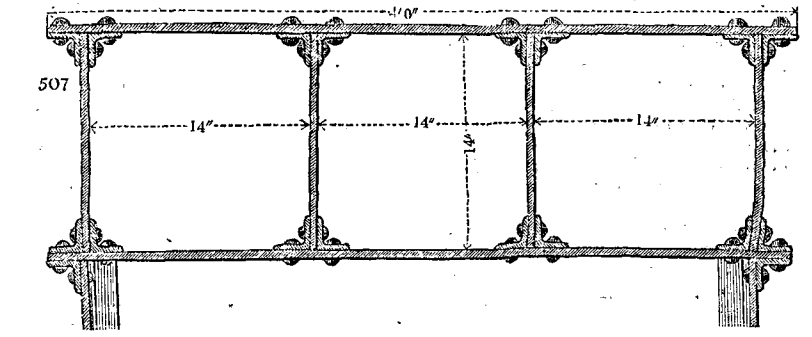
The value of this arrangement will be understood when it is stated that notwithstanding the superior tenacity of wrought-iron, a well constructed tubular girder only requires an excess of sectional area in the top over the bottom of $\frac{1}{15}$. In the Trent girder (see *fig.* 504.) the top compartment is 3 feet ¾ inches wide, and 15 inches deep, divided by a vertical plate into two rectangular cells, and all firmly connected by rivets, and L iron. Those angle irons constitute important elements in its strength. Since the construction of the Trent bridge, the cost of construction of tubular girders has been much diminished by a different arrangement of the parts of the top compartment, as shown in the following, *fig.* 506. This form is equally powerful in its resistance. When the span of the bridge

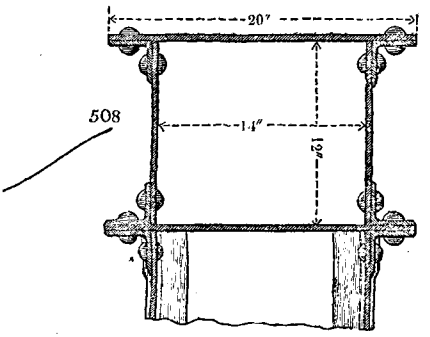
506

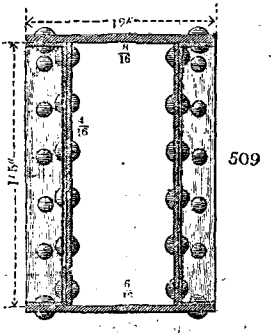


reaches 180 or 200 feet, the top compartment is arranged as shown in *fig.* 507., and when it is under 60 feet as shown in *fig.* 508. It will be noticed that in every case the

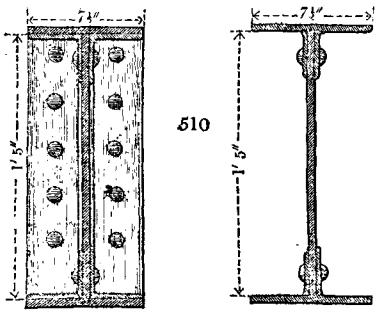
cells are proportioned, so as to admit of the entrance of a man for the purposes of painting or repairs.







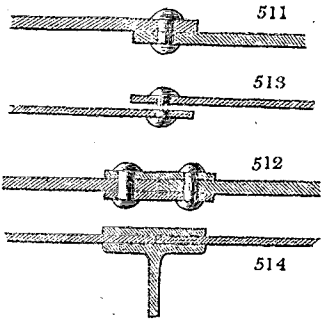
The Cross Beams or Supports of the Roadway. — These are generally, and ought to be universally, made of iron. In the Trent bridge they are made hollow or box beams, as shown in the annexed figure, *fig.* 509. Their construction is now much simpler and equally good, thus, *fig.* 510.



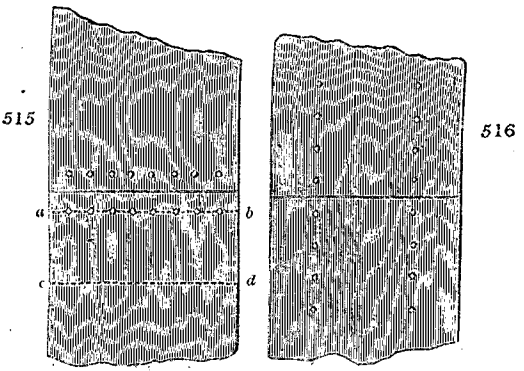
The Riveting. — Upon the judicious fastenings of the plates together depends in great measure the safety of a tubular girder bridge. The system of riveting followed in the several parts should have reference to the strains which occur in those parts. What are technically called "lap joints," where the ends of the plate overlap each other, and are connected by a single row of rivets, (vide *fig.* 511.) should be avoided in every part of the structure, as they have been proved to be weak and insufficient. Mr. Fairbairn (*Phil. Trans.* part ii. 1852) gives the value of single and double riveted joints, as 70 and 56 respectively, the solid plate being assumed to be 100.

"Butt joints" and covering plates are used throughout the girder, the length and substance of these covering plates and the number of rivets varying according to situation. In the top compartment the ends of the plates having been carefully fitted to each other, so as to take their portion of the strain the moment the load is applied, are covered by strips of sufficient width to receive a double row of rivets, one on each side of the joint, thus, as shown in *fig.* 512. This arrangement effectually prevents some such effect as indicated in *fig.* 513., which would occur were the lap joint used, and the load very great. In the tops the rivets are generally spaced 3 inches apart from centre to centre.

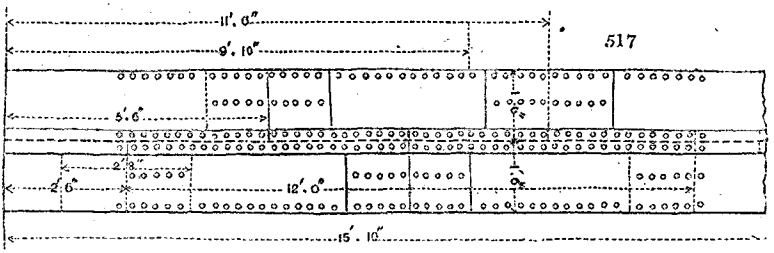
As before mentioned, instead of simple strips covering the vertical joints of the side plates, inside T iron bars are used to afford stiffness, and prevent the approach of the top and bottom (vide *fig.* 514.) Thus, the rivets being spaced 3 inches, the strips give to the external elevation of the girder the appearance of a series of panels.



In the bottom an exceedingly ingenious and beautiful arrangement of riveting has been introduced by Mr. Fairbairn. It is evident that to join two plates together (these two plates having to resist a force tending constantly to separate them) a certain number of rivets or pins are required, and according to the old system of jointing, these rivets were placed in single rows along the edge of the plates, being in fact either single lap joints, or single butt joints. Suppose the plates in *fig.* 515. to be each 2 feet wide, and $\frac{1}{2}$ inch thick, and that to connect them there were wanted 16 rivets, each 1 inch diameter. It is evident the resisting powers of the plates are weakened exactly by the amount of material punched out, in this case one-third, the section of resistance being through the line *a b*, and not through the line *c d*. But if these 16 rivets, instead of being placed all parallel with the joint, are arranged as shown in *fig.* 516. and covered with long "covering plates" instead

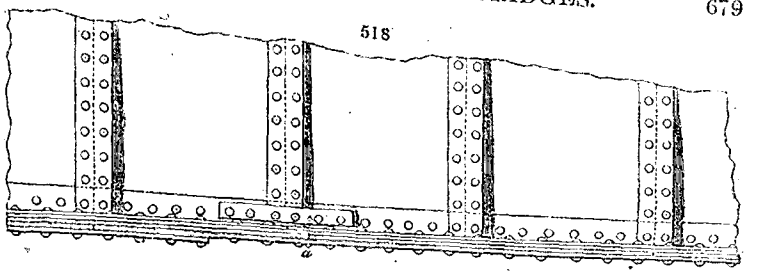


of "strips," it is equally evident that they are in this position equally fitted to their duty of joining the plates, and that the punching has weakened the resisting powers of the plates only $\frac{1}{12}$ instead of $\frac{1}{3}$. These proportions will readily explain the saving in material and weight which Mr. Fairbairn's "chain riveting" has effected, and the following figure of the "bottom" of the Trent bridge will show how it is practically applied, (*fig.* 517.). The joints of the angle irons in the bottom are also jointed by

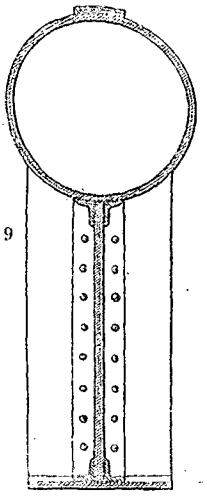


long corner pieces, as may be noticed at *a* in *fig.* 518., which is a view of a short length of the bottom of the main Trent girder. Having thus described the tubular girder bridge in its best and most generally adopted form, a glance at the following figures (*figs.* 519, 520.) will indicate modifications of the system which have gained favour in some quarters.

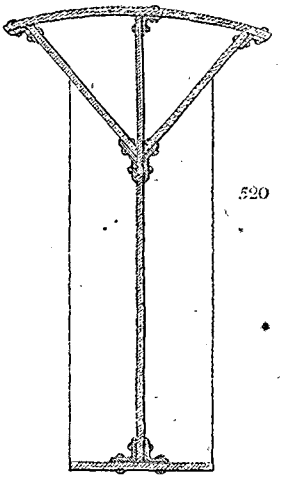
518



519



520



The Proportions and Strength of Tubular Girders.—The limits of this article will not admit of a lengthened examination of these interesting topics. A well proportioned beam or girder should have such a sectional distribution of its material, that when subjected to a transverse strain, the top should yield to compression and the bottom to extension at one and the same time; and as nearly all materials offer unequal resistances to the two forces, direct experiment can alone determine the exact relative proportions of the two parts. Thus, the resisting power of cast-iron to compression is nearly six times greater than that which it offers to extension; but Mr. Fairbairn's ingenious distribution of the wrought-iron plates in the "cellular top" has enabled him to fix the relative sectional areas of the tops and bottoms of tubular beams in the ratio of 12 to 11.

The tables in the following page show the proportions for tubular girder bridges of spans from 30 up to 300 feet.

Mr. Fairbairn's formula for calculating the strength of tubular girder bridges has been much disputed, but at the same time it has had many able defenders, and may be followed with perfect reliance and safety. If it errs, it errs on the right side—that of understating the real strength; it is

$$w = \frac{a\,d\,c}{l}$$

where w = the centre breaking weight in tons irrespective of the weight of the girder
a = sectional area of bottom in inches
d = depth of beam in inches
c = a constant derived from experiment for the particular form of girder, and
l = length of girder between the supports in inches.

The formula always assumes a well made and well proportioned girder, having the relative areas of 12 to 11 in the top and bottom and the chain riveting.

The constant c for the tubular girders we have described was ascertained to be 80. Let us now find by this formula the strength of one of the spans of the Trent bridge

TABLE showing the Proportions of Tubular Girder Bridges, from 30 to 150 Feet Span.

Span.	Centre Breaking Weight of Bridge.	Sec. Area of Bottom of one Girder.	Sec. Area of Top of one Girder.	Depth at the Girder in the Middle.
Feet. In.	Tons.	Inches.	Inches.	Feet. In.

270 0	1620	151·88	177·19	18 0
280 0	1680	157·50	183·75	18 8
290 0	1740	163·13	190·31	19 4
300 0	1800	168·75	196·88	20 0

which we have described. By reference to *fig.* 504. it will be observed that here $a = 58{\cdot}5$, $d = 144$, and $l = 1848$.

$$w = \frac{a\,d\,c}{l} = \frac{58 \times 144 \times 80}{1848} = 364{\cdot}6 \text{ tons}$$

as the weight which a tubular girder 154 feet between the supports will carry suspended from one point in the centre before fracture. Now the actual weight of this girder itself is under 70 tons, and it may safely be asserted that no other form of construction would give so favourable a result. The centre breaking weight of one girder being 364½ tons, it would carry 729 tons equally distributed along its entire length, and there being two main girders to the bridge, the ultimate strength of the structure is in round numbers 1,500 tons. It would be possible, by both lines of railway being covered with

heavy goods train, to have a load on the bridge of about 250 tons at one and the same time, and we thus see there is a margin of strength of six times the greatest possible load. Engineers differ in opinion as to the excess of strength which it is desirable that railway structures should possess: some are satisfied with even as low an ultimate breaking strength as three times the load; but with a comparatively untried material, and one moreover liable to deterioration from atmospheric influences, the larger excess is the better.

On the discovery of Mr. Fairbairn's cellular arrangement for the top compartment of the Conway and Britannia Bridges, several able mathematicians advocated the introduction of iron cylindrical instead of rectangular cells, as being a better distribution of the material to resist the compressive strain. Mr. Fairbairn's original views were in the same direction, but were abandoned on account of the complexity of construction and the difficulties of manufacture, and it is curious to notice now that subsequent scientific investigations have confirmed the practical engineer's views, and shown that the rectangular cells are superior in strength. Mr. Tate especially thus ingeniously argues:—"The cells in a transverse strain undergo a different kind of strain to what they are subjected to in a simple crushing force equally distributed over the section of the tube. In this case, all the parts of the section are equally compressed, and it is reasonable to conclude that the best form of cell will be that in which the material is equally distant from the axis of pressure; but the case of transverse strain is very different, *the upper edge undergoes the greatest strain*, and of the other parts that which is nearest the neutral axis of the beam undergoes the least; in this case therefore the material in the square cells is symmetrically distributed with respect to the axis of pressures, the neutral axis of the beam."

The Durability of Tubular Girders.—On this head there is as yet but a very limited experience as a basis for positive assertion. There can be no doubt that if neglected, the effects of oxidation upon the wrought-iron plates and rivets would speedily be productive of very disastrous results. On the other hand, there are many existing examples of wrought-iron structures, such as iron ships and other vessels, suspension bridges, &c., which with proper care and attention have withstood the wear and tear of constant exposure and use without any serious impairment of their powers of resistance, for periods of upwards of thirty years. It will be noticed too that tubular bridges have been designed with an especial view to the easiest access to every part for the purposes of painting and repairs, and it is not therefore improbable that with attention these structures will prove to be more durable than either cast-iron, timber, or other structures similarly situated.

Their Cost.—In estimating the cost of a tubular girder bridge, one of their most important recommendations must not be overlooked, viz., the saving which they afford in the construction of the masonry, abutments, and piers. For example, in the formation of a bridge of 150 feet span, if cast-iron or stone be the material employed, vast sums of money would have to be expended in the formation of ponderous and solid abutments to receive the thrust of the arch and its load, whereas with the girder bridge two simple well constructed walls giving a bearing of 5 or 6 feet to the ends of the girders is all that is necessary, the girders themselves receiving and maintaining the strain due to the load. The mere iron superstructure may thus in some cases appear costly, but when the whole of the adjuncts of a bridge are taken into consideration there is perhaps no other form of *pontitecture* which can compete with the wrought-iron girder when the clear space exceeds 70 feet. In estimating the cost of the iron superstructure it may be assumed, when the value of manufactured iron is at an average rate, at 20*l.* per ton weight fixed and erected.

General Advantages.—The more prominent advantages of these ingenious structures, viz. lightness, strength, security, and economy, have been referred to in the foregoing remarks. In addition they are a ready resource to the engineer in localities where he is limited for space. Thus, in crossing at a low level a road, river, or canal, a height of 15 inches from the bottom of the bridge to the level of the roadway will suffice for a width of bridge which will admit of a double line of railway or ordinary turnpike road.

Again, the structures are inexpensively fixed. The Trent girders, for example, were constructed on the railway embankment close to the west abutment of the bridge, and drawn across to their permanent places without the expense of scaffolding, &c. in the river. The main girders themselves, in addition to forming the main strength of the bridge, form parapets and protection to the traffic.

In conclusion, it may be stated that, although devoid of the massive but imposing elegance of the stone arch or the fairy lightness of the suspension roadway, the beauty of a tubular girder bridge consists in its usefulness and its evident fitness for the work it has to perform.

THE BRIDGE OVER THE RHINE AT COLOGNE.—"During the course of autumn 1849,

Mr. Fairbairn, of Manchester, was induced by representations made to him through a high official functionary, to propose to the Prussian Government a plan for an iron bridge across the Rhine at Cologne on the tubular principle. This plan met with the entire approbation of the scientific world at Berlin, was sanctioned by the King, and was all but adopted by the Prussian Cabinet. It happened, however, that simultaneously with the proposal of Mr. Fairbairn, one Oberbaurath Lentze had become convinced that a suspension bridge was the true means of communication across the Rhine. He had arrived at this conclusion after years of patient investigation, and so far worthy of all praise, though it somewhat unfortunately chanced that his discovery was some thirty years too late, so that his labours, which would have been at the height of science in 1820, have only served to illustrate a job in 1850. Here, in England, we have some little notion of the nature of jobs, but we question whether any more colossal in this kind has ever been perpetrated in our palmiest days of corruption than the attempt of our worthy friend Herr Van der Heydt, in whose paper, if we are not mistaken, the celebrated figment of the payment of 6,000*l.* to the editors of the 'Times' by the Danish Government first appeared, to bolster up the scheme of M. Lentze, and to throw cold water upon that of Mr. Fairbairn. What mattered it that Baron Humboldt, the Nestor of physical science, sided with Mr. Fairbairn, or that the King of Prussia, in one of his happy moments, had graciously extended his royal protection to the English engineer? Was not M. Van Heydt, and the whole army of the Prussian bureaucracy, whose name is Legion, arrayed on the other side? Still the English scheme must be burked officially; it was to be smothered in due form with the cushion of bureaucracy; so a commission was appointed to enquire into the English tubular bridges; and of whom do our readers suppose that it consisted? Why of Herr Oberbaurath Lentze himself and another person, who, after due deliberation, set off for England on their scientific mission. Why need we detail at length the wanderings of these duumviri of bureaucracy? how they landed in England—how they were received with marked courtesy by Mr. Fairbairn—how they saw the Conway Bridge, the Britannia Bridge, and other structures of minor dimensions in Lancashire? Suffice it to say, that they were quite blind to the merits of tubular bridges, and made their report dead against tubular bridges and strongly in favour of suspension bridges — a report which was adopted by the government, that is to say, by Herr Van der Heydt, who forthwith issued his famous notice, calling upon the engineers of the whole world to compete for the honour of contributing to the glorification of Herr Oberbaurath Lentze, whose plans have been long since in the bureau of M. Van der Heydt, and in all probability will be ultimately carried out." — *Times.*

W. Fairbairn, Esq., to Baron Humboldt.

"My dear Baron Humboldt, — I gather from an article which has recently appeared in the 'Times' newspaper, and from a communication which his Excellency M. Van der Heydt has honoured me with, that a most unfortunate decision has been come to by the authorities at Berlin, with reference to the important structure by which it is intended to connect the opposite banks of the Rhine at Cologne. It having been my good fortune to have been consulted, many months ago, on the subject of this important bridge, and to have visited Berlin for the purpose of submitting my proposals, I hold it due to the warm recommendation which emanated from our excellent friend in London, the Chevalier Bunsen — to the lively interest you manifested in favour of the object of my journey, and also to the gracious approval expressed by His Majesty the King of Prussia in person — to make known as widely as possible the insuperable objections which, in my opinion, attach to the limited programme which has recently been issued from the bureau of the Minister of Public Works.

"So far as words can be allowed to convey an intimation of a genuine conviction, M. Van der Heydt acknowledged at the palace, on the 1st of November last, that no structure should ever be allowed to cross the Rhine which was not calculated to meet, with perfect security, the utmost requirements of the most extended traffic, and the possible contingencies of great military operations. Your own enlarged conceptions at once prompted you to acknowledge that the design (which at that time had received the sanction of the authorities) was totally unfit for these purposes, and to admit that a suspension bridge, owing its strength to a flexible catenary, was inadequate to the transport of heavy weights. But when I submitted the results which had been accomplished in this country by the judicious application of a material until recently untried in such structures — when I announced the successful realization of one of the boldest conceptions of modern times — when I stated that tidal streams, such as the river Conway and the Menai Straits, had been crossed by solid and unyielding bridges of enormous span, which were capable nevertheless of sustaining ten times the greatest possible strain that the heaviest railway traffic could, in practice, subject them to — when I had shown that this new principle of construction was peculiarly adapted

to surmount the numerous difficulties which the passage of the Rhine offers, by requiring very few and comparatively small piers in the stream, and thus allowing of the passage of large timber rafts in the summer, and offering the least possible resistance in times of floods and breaking up of ice in the winter; and, above all, when I had proved that a structure so much superior could be erected and fixed at an outlay considerably below that which had been demanded for a very imperfect one — I confess I was not prepared to find the Minister of an enlightened and powerful people asking for the assistance of the world at large to perpetuate a scheme unworthy of Prussia, unworthy of the practical scientific knowledge of the age, and in opposition to the deliberate and carefully weighed opinion of Science's greatest ornament.

"Pardon me for the warmth with which I address to you this remonstrance; but I feel that your unwearied exertions, and the friendship which you unreservedly testified to me, call upon me to urge, as forcibly as I can, the retracing of the unfortunate steps already taken. We live in times of progress. A scientific discovery, or a practical improvement of any kind, cannot be confined to a particular locality or to one country, it becomes at once the property of all. This community of Knowledge — the most powerful destroyer of national prejudices and antipathies, as it is the surest foundation for general and permanent peace and good will — must ride over and bear down individual ignorance and petty bureaucratic objections. Punctuality and rapidity in our inter-communications have become almost essentials of our existence; and in this manner all Europe may be said to be interested in the completion of that railway system which will traverse the Prussian dominions from one extremity to the other.

"And now let me point out the lamentable imperfections which characterise the Minister's programme, and the limitations and requirements which will effectually trammel the efforts of men of genius, and deter those of experience and reputation from entering at all upon the competition.

"It is an express condition of the scheme that the railway communication is not to be continuous, and the public will therefore continue to suffer the annoyance and inconvenience of considerable delays; for it may be safely said that the proposal of disintegrating a train at one terminus and drawing it across to the other by men or horses, bit by bit, and hour by hour, will offer equal, if not greater, obstacles to a rapid journey than the existing system does. How much better would it be that the bridge should embody within itself such elements of strength and durability as would afford at all times and in all seasons a safe transit to those means of locomotion which constitute the wonder and glory of the age? Instead of such a permanent and substantial structure, will the Prussian Government sanction the erection of one, the feeble and rickety constitution of which would shudder at the very sight of a locomotive? Surely not! Public opinion must step in and forbid it. What is wanted is a bridge to connect the existing railways, not one that will permanently separate them.

"But again; it is stated that the difference between the levels of the existing railways and that required for the roadway of the intended bridge is too great to be overcome by the locomotive within a short distance of length. This objection is purely imaginary; for I can state from personal examination, that the necessary gradient would not be so heavy as several which are worked with great ease in this country. Besides, on the left bank of the Rhine the terminus of the Aix-la-Chapelle line is at the right level; and that on the side of Deutz may without difficulty be reached by any easy gradient of less than 1 in 100.

"Without meaning the slightest disrespect to the author of the design for the chain bridge, I must repeat my firm and deliberate conviction, that it would prove an incomplete and unsatisfactory structure. A permanent, inflexible, durable, and handsome bridge, of enormous strength, (the breaking weight of the bridge I proposed, with the span of 310 feet, was equal to 6,000 tons or 120,000 cwt., equally distributed over each span, giving as the ultimate strength of the bridge, with four spans, 24,000 tons, or 480,000 cwts.) adapted, by arrangements which I have now in progress of execution for similar purposes in this country, to give every possible facility to the navigation of the river — calculated to carry across the heaviest railway train at any speed, and which you might cover with the most powerful ordnance from end to end, may be erected at Cologne within the sum which has been demanded for the chain bridge. These statements are not the imaginings of a sanguine mind; but their accuracy may be corroborated by numerous examples of a similar character which have been erected in this country.

"If, therefore, the determination of the Minister of Public Works to erect a chain bridge cannot be shaken, I confidently anticipate that such an event will not be allowed to pass by without a strong protest on the part of those who are in advance of the

knowledge and judgment displayed by the authors of the invitation which has been issued to the engineering world.

"My letter has attained a much greater length than I at first anticipated. My anxiety to forward your own forcibly expressed views on the subject of a fixed bridge must be my apology for it.

"With an expression of my profound esteem, and with best wishes for your continued good health,

"Believe me to remain, my dear Baron Humboldt, your very faithful and very obedient servant,

"WILLIAM FAIRBAIRN."

"Manchester, April 15."

FAIRBAIRN'S WROUGHT-IRON GIRDER BRIDGE. *Report on the Strength, Elasticity, and other Properties of Wrought-Iron Girder Bridges, as applicable to Railways and other Structures. By* W. Fairbairn, Esq., C.E. (From the Appendix to Report of the Commissioners appointed to inquire into the application of Iron to Railway Structures.) — "The idea of crossing the River Conway and the Menai Straits on the line of the Chester and Holyhead Railway (two of the most formidable barriers ever presented to the engineer), properly belongs to Mr. R. Stephenson.

"To carry this into practice, required the united skill of the mechanical as well as the civil engineer; and it is highly gratifying to find that the successful completion of the first of the Conway tubes has not only attained that object, but it has established a new era in the history of bridges, by the development of the properties of a hitherto untried material, and enables the engineer of the present day to conquer obstacles which, at no very distant date, were considered insurmountable.

"An undertaking of such importance to the scientific world, to the public, and to those more immediately interested, involving heavy responsibilities on the engineer; before anything definite could be accomplished, it became absolutely necessary to institute a series of experiments to determine the practicability of such a structure, including other inquiries into the proportions and other properties of the tube. At the request of Mr. Stephenson, I had the honour of being selected to conduct this inquiry.

"Experiments on circular, elliptical, and rectangular tubes were accordingly undertaken; but it soon became evident from the results obtained that those of a rectangular form were best calculated for the purpose. It was not, however, until I had adopted the tube with the corrugated top that the real value of the tubular form became apparent, and, in fact, absolutely requisite in that part to offer sufficient resistance to the crushing force.

"I will not trouble the Commissioners with the details of the experiments, but simply state that it evidently became necessary to adopt some other shape than those of the circular and elliptical kind, and so to proportion the top and bottom sides of the tube as to effect a balance of the resisting forces of extension and compression, and thus to ensure the maximum force of resistance in every part. These proportions were clearly indicated by the rectangular form; and the formation of cells on the top side gave more effective powers of resistance to the crushing force than had been heretofore accomplished by the single plate.

"This discovery of the cellular top, and the greatly increased value which a tube thus constructed gave to the experiments, at once suggested a modified form of tubular girder adapted to shorter spans. This description of bridge is now becoming general; and from its superior powers of resistance, greater security, and its adaptation to almost every description of span, we may reasonably infer that wrought iron is cheaper and safer, if not equally durable with any other description of materials. It may, and I have no doubt it will be urged, that wrought-iron is much more subject to oxidation and decay than cast iron or stone; a circumstance which cannot be disputed; but that can only arise from gross negligence on the part of those having charge of the structure, as two coats of good oil paint every three years will effectually protect it, and render it durable for almost any length of time. Besides, the girders, as now constructed, are accessible in every part, and, by careful attention, I can see no reason why they should not last 500 instead of 50 or 100 years. Another objection brought against this description of bridge is, the risk of the rivets becoming loose; and from the number of joints, the whole is considered by some as dangerous and insecure. Now, as regards this objection, no real weight can be attached to it; as the parties raising it cannot be acquainted with the nature and solidity of the work. It is next to impossible for a single rivet to get loose (unless the work is improperly executed); and in the whole of my experience, I am not acquainted with any description of jointing so certainly secure, and so well adapted to resist any description of strain, as that of riveted plates. I speak practically and unhesitatingly on this subject; and I have only to instance steam boilers, iron ships, and other vessels subjected to severe strain, as examples of

the strength and tenacity of riveted plates; in fact, rivets seldom or never get loose, but retain their position under every species of strain, and become, as it were, integral parts of the structure in common with the plates themselves.

"In submitting these remarks to the consideration of the Commissioners, and in order to bear them out, it may not be uninteresting briefly to notice a few of the results of the experiments illustrative of this subject, and to show, with a greater degree of exactitude, the nature and value of this description of structure. For these objects, I beg to insert a few of the earlier experiments on different descriptions of tubes, as recorded in a report addressed to Mr. Stephenson and the directors of the Chester and Holyhead Railway, the particulars of which have already been before the public."

(Here follow the details of the experiments referred to.)

The experiments, of which the above is a brief notice, have led to other improvements of great utility in practical science, and probably of equal value with those for which they were originally undertaken.

"I have already stated that the difficulty which the weakness of the material to resist a crushing force occasioned, was overcome by the adoption of the cellular form of top; but another, and, to my mind, very serious difficulty, presented itself, in the reduction in the strength of the plates at the joints by the ordinary method of riveting, in the bottom and those parts where the tensile strain came into operation. This led to a new system of riveting, which, without weakening the body of the plate to so great an extent as formerly, gives a joint of almost equal strength with the plate itself, and thus adds in a most material manner to the security of the structure.

"Consequent upon the experiments and the results obtained therefrom, numerous advantages presented themselves in the construction of wrought iron girders. The strength, ductility, and comparative lightness of the material are the important elements of these girders; and their elasticity, retention of form, and other properties, render them infinitely more secure than those composed of cast-iron, which, from the brittle nature of the material and imperfections in the castings, are liable to break without notice, and to which the wrought-iron girder is not subject. This is, however, probably of less importance, as the wrought-iron girder will be found not only cheaper, but (when well constructed, and upon the right principle) upwards of three times the strength of cast-iron. I have elsewhere stated to the Commissioners that the experiments attracted the notice generally of railway engineers, and, amongst others, that of Mr. Vignoles, who immediately gave an order for two wrought-iron girder bridges for the Blackburn and Bolton Railway Company: — one to cross the Liverpool and Leeds Canal, and the other over the turnpike road, both in the vicinity of Blackburn. These bridges were constructed simultaneously with another of similar form (with a cast-iron top), executed by Mr. Dockray, under the direction of Mr. Robert Stephenson, for carrying the turnpike road over the London and North-Western Railway at Camden Town. Those for the Blackburn and Bolton Railway were, however, the first adapted for railway traffic; and although they are probably not so well proportioned as others since constructed, they nevertheless exhibit extraordinary powers of resistance; and conceiving that a description of these bridges, with the tests to which they were subjected, might be useful, I have great pleasure in submitting the same, with the necessary drawings, to the consideration of the Commissioners.

Explanation of the Engravings, descriptive of the Hollow Girder Bridge over the Turnpike Road near Blackburn.

"*Fig.* 521. is an elevation or side view of the girder, each 66 ft. long, and bedded on cast-iron base plates.

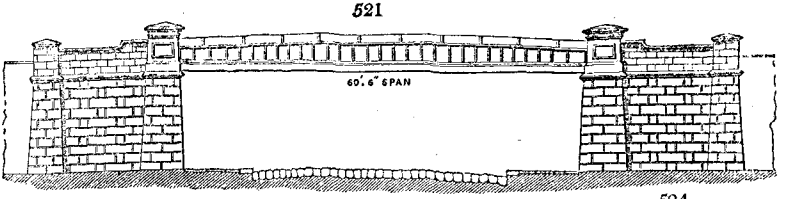
"*Fig.* 522. is a transverse section of the bridge, showing the sides of the cross-beams, and the cross sections of the outside and middle girders.

"*Fig.* 523. is an enlarged transverse section of the outside girder, showing the attachment of the cross-beams, which are riveted to the bottom of the girder, exclusive of two bolts A A, which extend through the bottom plates and angle iron of the girder, and the top and bottom plates of the cross-beam.

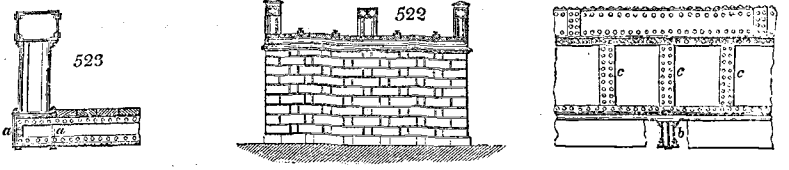
"*Fig.* 524. is an enlarged view of a part of the side of the large girder, exhibiting a transverse section of the cross-beam at B, which is made of wrought-iron, with the top and bottom plates so proportioned as to equalise its powers of resistance to the force of compression on the top, and that of tension on the bottom. It also exhibits the mode of riveting up the joints of the side plates with the covering strip *c c c*, and the additional strength as obtained by the attachment of T iron in the interior of the tube.

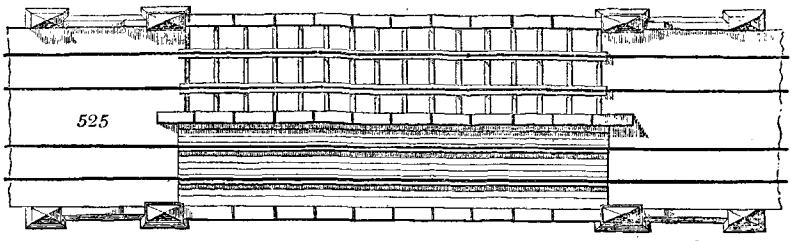
"*Fig.* 525. is a plan of the bridge, showing on one side the platform and the rails, and on the other the cross-beams, which in this bridge are placed 6 ft. asunder; but in those more recently constructed, I have placed them at distances of only 4 ft., and consider this arrangement preferable.

521



524





"From the above description it will be seen that the whole is a strong and perfectly rigid structure. With three longitudinal girders, a bridge of this description will support a load equally distributed of 760 tons; and in order to render it safe, under every species of strain, the middle girder is made nearly double the strength of those on the outside. This is essential, as two trains may be passing the bridge at the same moment; in which case the middle girder would be subjected to a pressure equal to double the load on the outside girders.

"In the construction of bridges of larger span, I generally prefer only two large longitudinal girders with strong cross-beams every three feet, of sufficient length to admit two lines of rails, and sufficient room for two trains to pass at the same time. This mode of construction is preferable to the three girders, as it effects greater simplicity in the structure, and, from every appearance, renders the bridge equally effective and secure.

"Having thus described the advantages peculiar to this description of bridge, I will now direct the attention of the Commissioners to the tests to which the Blackburn Bridge was subjected, previous to its opening for public traffic. The experiments were made in the presence of Captain Coddington, the Government Inspector of Railways, and Mr. Flannagan, engineer of the line, as follows: —

"Three locomotive engines, weighing 60 tons, were coupled together, and passed over the bridge at velocities varying from 5 to 15, and 25 miles an hour. This load (60 tons) produced a deflection of ·025 of a foot, or about $\frac{3}{10}$ths of an inch, and that without any perceptible increase in the deflection arising from the different rates of speed. In fact, the deflection was found to be the same at all velocities.

"After these tests were made, two wedges or inclined plates were fitted to the rails, *fig.* 526., at the middle of the bridge, and the engines run over them at

526

the rate of 1 to 10 miles an hour. The shock of the engines, as they respectively fell upon the girders, from a height of one inch, the thickness of the wedge at *d*, gave an increased deflection from ·025 to ·035 of a foot, and another set of wedges, $1\frac{1}{2}$ feet in height, gave a further increase of deflection (at the same velocity) of ·035 to ·045 of a foot.

"From the above experiments it appears evident that wrought-iron girders are well

calculated to resist not only a heavy dead weight, but the force of impact administered with an unsparing hand; for, in fact, the girders were not injured by the blows inflicted by the engines falling a height of 1½ inches upon them, but restored themselves to their original position from which they were deflected by the shock.

"On the whole we may, therefore, reasonably conclude that the present structure is not only the strongest, but the best calculated to resist strain when applied to large spans, and particularly in situations where bridges, with a perfectly horizontal soffit, are alone admissible.

(Signed) "WILLIAM FAIRBAIRN."

"Manchester, April 26th, 1848."

FAN (*Eventail*, Fr.; *Fächer*, Germ.); is usually a semi-circular piece of silk or paper, pasted double, enclosing slender slips of wood, ivory, tortoise-shell, whale-bone, &c., arranged like the tail of a peacock in a radiating form, and susceptible of being folded together, and expanded at pleasure. This well-known hand ornament is used by ladies to cool their faces by agitating the air. Fans made of feathers, like the wing of a bird, have been employed from time immemorial by the natives of tropical countries.

Fan is also the name of the apparatus for winnowing corn. For an account of the powerful blowing and ventilating fan machine, see FOUNDRY and VENTILATOR.

FARINA (*Farine*, Fr.; *Mehl*, Germ.); is the flour of any species of corn, or starchy root, such as potato, arrow-root, &c. See BREAD and STARCH.

FATS (*Graisses*, Fr.; *Fette*, Germ.) occur in a great number of the animal tissues, being abundant under the skin in what is called the cellular membrane, round the kidneys, in the folds of the omentum, at the base of the heart, in the mediastinum, the mesenteric web, as well as upon the surface of the intestines, and among many of the muscles. They vary in consistence, colour, and smell, according to the animals from which they are obtained; thus, they are generally fluid in the cetaceous tribes, soft and rank-flavoured in the carnivorous, solid and nearly scentless in the ruminants, usually white and copious in well-fed young animals; yellowish and more scanty in the old. Their consistence varies also according to the organ of their production; being firmer under the skin, and in the neighbourhood of the kidneys, than among the movable viscera. Fat forms about one-twentieth of the weight of a healthy animal. But as taken out by the butcher it is not pure; for being of a vesicular structure it is always enclosed in membranes, mixed with blood, blood-vessels, lymphatics, &c. These foreign matters must first be separated in some measure mechanically, after the fat is minced small, and then more completely by melting it along with hot water, passing it through a sieve, and letting the whole cool very slowly. By this means a cake of cleansed fat will be obtained. Many plans of purifying fats have been proposed; one of the best is to mix two per cent. of strong sulphuric acid with a quantity of water, in which the tallow is heated for some time with much stirring; to allow the materials to cool, to take off the supernatant fat, and to re-melt it with abundance of hot water. More tallow will thus be obtained, and that considerably whiter and harder than is usually procured by the melters.

I have found that chlorine, and chloride of lime do not improve, but rather deteriorate the appearances of oils and other fatty bodies. According to Appert, minced suet subjected to the action of high-pressure steam in a digester, at 250° or 260° F., becomes so hard as to be sonorous when struck, whiter, and capable, when made into candles, of giving a superior light. A convenient mode of *rendering* minced tallow, or melting it, is to put it in a tub, and drive steam through it from numerous orifices in ramifying pipes placed near the bottom. Mr. Watt assures me that his plan of purifying fats, patented in March, 1836, has been quite successful. He employs dilute sulphuric acid, to which he adds a little nitric acid, with a very small quantity of bichromate of potash, to "supply oxygen;" and some oxalic acid. These are mixed with the fat in the steaming tub. When the lumps of it are nearly dissolved, he takes for every ton of fat, one pound of strong nitric acid, diluted with one quart of water; to which he adds two ounces of alcohol, naphtha, sulphuric ether, or spirits of turpentine; and after introducing this mixture, he continues the boiling for half an hour. The fat is finally washed. — As I do not comprehend the *modus operandi* of these ingredients, I shall abstain from any comment upon the recipe.

Others have proposed to use vegetable or animal charcoal first, especially for rancid oils, then to heat them with a solution of sulphate of copper and common salt, which is supposed to precipitate the fetid albuminous matter. Milk of lime has been also prescribed; but it is, I believe, always detrimental.

Davidson treats whale oil with infusion of tan, in order to separate the gelatine and albumine in flocks; next with water and chloride of lime, to destroy the smell; and lastly, with dilute sulphuric acid, to precipitate all the lime in the state of a sulphate. This is certainly one of the cheapest and most effective methods of purifying that substance.

Braconnot and Raspail have shown that solid animal fats are composed of very small microscopic, partly polygonal, partly reniform particles, which are connected together by very thin membranes. These may be ruptured by mechanical means, then separated by triturating the fresh fats with cold water, and passing the unctuous matter through a sieve. The particles float in the water, but eventually collect in a white granular crystalline appearance, like starch. Each of them consists of a vesicular integument, of the nature of stearine, and an interior fluid like elaine, which afterwards exudes. The granules float in the water, but subside in spirits of wine. When digested in strong alcohol, the liquid part dissolves, but the solid remains. These particles differ in shape and size, as obtained from different animals; those of the calf, ox, sheep, are polygonal, from $\frac{1}{50}$ to $\frac{1}{350}$ of an inch in diameter; those of the sow are kidney-shaped, and from $\frac{1}{50}$ to $\frac{1}{100}$; those of man are polygonal, and from $\frac{1}{50}$ to $\frac{1}{600}$; those of insects are spherical, and at most $\frac{1}{500}$ of an inch.

Fats all melt at a temperature much under 212° F. When strongly heated with contact of air, they diffuse white pungent fumes, then blacken, and take fire. When subjected to distillation, they afford a changed fluid oil, carburetted hydrogen, and the other products of oily bodies. Exposed for a certain time to the atmosphere, they become rancid, and generate the same fat acids as they do by saponification. In their fresh state they are all composed principally of stearine, margarine, and oleine, with a little colouring and odorous matter; and, in some species, hircine, from the goat; phocenine, from the dolphin; and butyrine, from butter. By subjecting them to a great degree of cold, and compressing them between folds of blotting paper, a residuum is obtained, consisting chiefly of stearine and margarine; the latter of which may be dissolved out by oil of turpentine.

Beef and Mutton Suet. — When fresh, this is an insipid, nearly inodorous fat, of a firm consistence, almost insoluble in alcohol, entirely so if taken from the kidneys and mesenteric web of the ox, the sheep, the goat, and the stag. It varies in its whiteness, consistence, and combustibility, with the species and health of the animals. That of the sheep is very white, and very solid. They may all be purified in the manner above described. Strong sulphuric acid develops readily the acid fats by stirring it through melted suet. Alkalis, by saponification, give rise at once to the three acids, — the stearic, margaric, and oleic. Beef suet consists of stearine, margarine, and oleine; mutton and goat suet contain a little hircine. The specific gravity of the tallow of which common candles are made is, by my experiments, 0·936. The melting point of suet is from 98° to 104° F. The proportion of solid and fluid fat in it is somewhat variable, but the former is in much larger proportion. Mutton suet is soluble in 44 parts of boiling alcohol, of 0·820; beef suet in 44 parts. Marrow fat consists of 76 of stearine, and 24 of oleine; it melts at 115° F.

Hog's-lard is soft, fusible at 81° F., convertible, by an alkaline solution, into a stearate, margarate, oleate, and glycerine. Its sp. grav. is 0·938, at 50° F. It consists of 62 of oleine, and 38 of stearine, in 100 parts.

Goose-fat consisis of 68 oleine and 32 stearine.

Butter, in summer, consists of 60 of oleine and 40 of stearine; in winter, of 35 of oleine, and 65 of stearine; the former substance being yellow and the latter white. It differs, however, as produced from the milk of different cows, and also according to their pasture.

The ultimate constituents of stearine, according to Chevreul, are, 79 carbon; 11·7 hydrogen; and 9·3 oxygen, in 100 parts.

See MARGARINE, OLEINE, SOAP, STEARINE.

The following statement is given on the authority of Braconnot: —

	Oleine.	Stearine.
Fresh Butter in summer	60	40
——— in winter	37	63
Hog's Lard	62	38
Ox Marrow	24	76
Goose Fat	68	32
Duck Fat	72	28
Ox Tallow	25	75
Mutton Suet	26	74

M. Dumas says that butter contains no stearine. The purification and decoloration of fats has been the object of many patents. Under CANDLE, Hempel's process for refining palm-oil and extracting its margarine is described.

About 30 years ago, palm-oil was deprived of colour to a certain degree by mixing with the melted oil, previously freed from its impurities by filtration, some dilute nitric

acid, wooden vessels being used, and the oil being in a melted state. This process was both expensive and imperfect. More lately whitening has been prescribed by means of chromic acid, which, in the act of decomposition into chromic oxide, gives out oxygen, and thereby destroys vegetable colours. One pound of bichromate of potash in solution is to be mixed with two pounds of *strong* sulphuric acid, diluted beforehand with about two gallons of water; and this mixture is to be incorporated by diligent stirring with 2 cwt. of the filtered palm-oil, at a temperature of about 100 F., contained in a wooden vessel. The palm-oil is afterwards to be washed in warm lime-water, to which some solution of chloride of lime may be advantageously added. By this process, well managed, a fat may be obtained from palm-oil fit for making white soap. Tallow may be also blanched to a considerable degree by a like operation.

Instead of sulphuric acid, the muriatic may be used to convert the chromic acid into chromic oxide in the above process, and thereby to liberate the blanching oxygen. The resulting solution of green muriate of chrome being freed from some adhering oil, is to be mixed with so much milk of lime as just to neutralize the excess of acid that may be present. The clear green muriate is then to be decomposed in a separate vessel, by the addition of well-slaked and sifted lime, in some excess. The green mixture of lime and chrome-oxide is now to be dried, and gently ignited, whereby it is converted into yellow chromate of lime, with some unsaturated lime. This compound being decomposed by dilute sulphuric acid, affords chromic acid, to be applied again in the decolouring of palm-oil, on the principles above explained.

Mr. Prynne obtained a patent in March, 1840, for purifying tallow for the candle-maker, by heating it along with a solution of carbonate of potash or soda for 8 hours, letting the whole cool, removing the tallow to another vessel, heating it by means of steam up to 206° F., along with dry carbonate of potash (pearlash): letting this mixture cool very slowly; and finally removing the tallow to a vessel inclosed in steam, so as to expel any subsidiary moisture.—*Newton's Journal*, xxi. 258.

A patent for a like purpose was obtained in June, 1842, by Mr. H. H. Watson. He avails himself of the blanching power of oxygen, as evolved from manganate of potash (chameleon mineral), in the act of its decomposition by acids, while in contact with the melted fat. He prescribes a leaden vessel (a well-joined wooden tub will also serve) for operating upon the melted tallow with one-twentieth of its weight of the manganate, dissolved in water, and acidulated to the taste. The whole are to be well mixed, and gradually heated from 150° up to 212° F., and maintained at that temperature for an hour. On account of the tendency of the dissolved manganate to spontaneous decomposition, it should be added to the dilute acid, mixed with the fat previously melted at the lowest temperature consistent with its fluidity.

Palm-oil may be well blanched in the course of 12 hours by heat alone; if it be exposed in a layer of one or two inches to the air and sunshine, upon the surface of water kept up at nearly the boiling point by a coil of steam-pipes laid in the bottom of a square cistern of lead or wood, well jointed.

Mr. Wilson, of Vauxhall, has applied centrifugal action to the separation of the more liquid from the more solid parts of fatty matters, using in preference the *hydro-extractors* used by Seyrig and Co. for drying textile fabrics. Mr. Wilson employs a stout cotton twill in addition to the wire grating; and in order to avoid the necessity of digging the concrete parts, and to prevent them from clogging the interstices for the discharge of the oily matter, he places the whole in a bag 8 inches in diameter, and of such length that when laid on the rotating machine against the grating the two ends will meet. The speed of the machine must be kept below that at which stearic acid or stearine would pass; which is known by the limpidity of the expressed fluid. To take advantage of the liquefying influence of heat, he keeps the temperature of his room about 2° F. above that of the substances under treatment.

The improved fat and candle factory, called *Price's*, of which Mr. Wilson, of Belmont, Vauxhall, seems to be the main conductor and schemer, is mounted upon a colossal scale. It has five separate works near London, great plantations of cocoa-nut trees in Ceylon, with a capital of about half a million sterling, an annual division of profits to the amount of 50,000*l.*, and it employs about 800 work-people, whose physical and moral well-being is well looked after by the benevolent manager of the whole concern. See CANDLES.

Tallow imported for home consumption in 1850, 1,219,101 cwt.; in 1851, 1,085,660 cwt. Gross amount of duty received, 78,270*l.* and 68,035*l.* respectively; the duty being 1*d.* per cwt. from British possessions, and 1*s.* 6*d.* per cwt. from foreign countries.

FAT BLEACHING. By transmitting streams of atmospheric air through heated palm-oil and other coloured and odorous fatty matters, they are deprived so far of their colour and smell as to be capable of forming white soaps. Mr. A. Dunn obtained a patent for this object in 1843.

FAULTS (*Failles*, Fr.), in mining, are disturbances of the strata which interrupt the miner's operations, and put him at *fault*, to discover where the vein of ore or bed of coal has been thrown by the convulsions of nature. Many examples of faults are exhibited under PITCOAL.

FEATHERS (*Plumes*, Fr.; *Federn*, Germ.), constitute the subject of the manufacture of the *Plumassier*, a name given by the French (and also the English) to the artisan who prepares the feathers of certain birds for ornaments to the toilette of ladies and for military men, and to him also who combines the feathers in various forms. We shall content ourselves with describing the method of preparing ostrich feathers, as most others are prepared in the same way.

Several qualities are distinguished in the feathers of the ostrich; those of the male, in particular, are whiter and more beautiful. Those upon the back and above the wings are preferred; next those of the wings, and lastly, of the tail. The down is merely the feathers of the other parts of the body, which vary in length from 4 to 14 inches. This down is black in the males, and gray in the females. The finest white feathers of the female have always their ends a little grayish, which lessens their lustre, and lowers their price. These feathers are imported from Algiers, Tunis, Alexandria, Madagascar, and Senegal; this being the order of their value.

The *scouring process* is thus performed: — 4 ounces of white soap, cut small, are dissolved in 4 pounds of water, moderately hot, in a large basin; and the solution is made into a lather by beating with rods. Two bundles of the feathers, tied with packthread, are then introduced, and are rubbed well with the hands for five or six minutes. After this soaping they are washed in clear water, as hot as the hand can bear.

The whitening or bleaching is performed by three successive operations.

1. They are immersed in hot water mixed with Spanish white, and well agitated in it; after which they are washed in three waters in succession.

2. The feathers are azured in cold water containing a little indigo tied up in a fine cloth. They should be passed quickly through this bath.

3. They are sulphured in the same way as straw hats are (see SULPHURING); they are then dried by hanging upon cords, when they must be well shaken from time to time to open the fibres.

The ribs are scraped with a bit of glass cut circularly, in order to render them very pliant. By drawing the edge of a blunt knife over the filaments they assume the curly form so much admired. The hairs of a dingy colour are dyed black. For 20 pounds of feathers, a strong decoction is made of 25 pounds of logwood in a proper quantity of water. After boiling it for 6 hours, the wood is taken out, 3 pounds of copperas are thrown in; and, after continuing the ebullition for 15 or 20 minutes, the copper is taken from the fire. The feathers are then immersed by handfuls, thoroughly soaked, and worked about; and left in for two or three days. They are next cleansed in a very weak alkaline lye, and soaped three several times. When they feel very soft to the touch, they must be rinsed in cold water, and afterwards dried. White feathers are very difficult to dye a beautiful black. The acetate of iron is said to answer better than the sulphate, as a mordant.

For dyeing other colours, the feathers should be previously well bleached by the action of the sun and the dew; the end of the tube being cut sharp like a toothpick, and the feathers being planted singly in the grass. After fifteen days' exposure, they are cleared with soap as above described.

Rose colour or *pink*, is given with safflower and lemon juice.

Deep red, by a boiling hot bath of Brazil wood, after aluming.

Crimson. The above deep red feathers are passed through a bath of cudbear.

Prune de Monsieur. The deep red is passed through an alkaline bath.

Blues of every shade, are dyed with the indigo vat.

Yellow; after aluming, with a bath of turmeric or weld.

Other tints may be obtained by a mixture of the above dyes.

Feathers have some more useful employments than the decoration of the heads of women and soldiers. In one case, they supply us with a soft elastic down on which we can repose our wearied frames, and enjoy sweet slumbers. Such are called *bed* feathers. Others are employed for writing, and these are called *quills*.

Goose feathers are most esteemed for beds, and they are best when plucked from the living bird, which is done thrice a year, in spring, midsummer, and the beginning of harvest. The qualities sought for in bed feathers are softness, elasticity, lightness, and warmth. Their only preparation when cleanly gathered are a slight beating to clear away the loose matter, but for this purpose they must be first well dried either by the sun or a stove. Bleaching with lime water is a bad thing, as they can never be freed from white dust afterwards.

The feathers of the eider duck, *anas mollissima*, called eider down, possess in a superior degree all the good qualities of goose down. It is used only as a covering to beds, and never should be slept upon, as it thereby loses its elasticity.

Quills for writing. These consist usually of the feathers plucked out of the wings of geese. Dutch quills have been highly esteemed, as the Dutch were the first who hit upon the art of preparing them well, by clearing them both inside and outside from a fatty humour with which they are naturally impregnated, and which prevents the ink from flowing freely along the pens made with them. The Dutch for a long time employed hot cinders or ashes to attain this end; and their secret was preserved very carefully, but it at length transpired, and the process was then improved. A bath of very fine sand must be kept constantly at a suitable temperature, which is about 140° F.; into this the quill end of the feather must be plunged, and left in it a few instants. On taking them out they must be strongly rubbed with a piece of flannel, after which they are found to be white and transparent. Both carbonate of potash in solution and dilute sulphuric acid have been tried to effect the same end, but without success. The yellow tint which gives quills the air of age, is produced by dipping them for a little in dilute muriatic acid, and then making them perfectly dry. But this process must be preceded by the sand-bath operation. The above is the French process.

Quills are dressed by the London dealers in two ways; by the one, they remain of their natural colour; by the other, they acquire a yellow tint. The former is called the Dutch method, and the principal workman is called a Dutcher. He sits before a small stove fire, into which he thrusts the barrel of the quill for about a second, then lays its root quickly below his blunt-edged knife called a hook, and, pressing this firmly with the left hand, draws the quill briskly through with his right. The bed on which the quill is laid to receive this pressure is called the plate. It is a rectangular smooth lump of iron, about 3 inches long, 1½ broad, and 2½ thick, which is heated on his stove to about the 350th degree Fahr. The hook is a ruler of about 15 inches in length, somewhat like the patten-maker's knife, its fulcrum being formed at the one end by a hook and staple, and the power of pressure being applied by the hand at the other end. The quill, rendered soft and elastic by the heat, endures the strong scraping action of the tool, and thus gets stripped of its opaque outer membrane, without hazard of being split. A skilful workman can pass 2,000 quills through his hands in a day of 10 hours.

They are next cleaned by being scrubbed by a woman with a piece of rough dog-fish skin, and finally tied up by a man in quarter hundred bundles.

In another mode of dressing quills, they are steeped a night in decoction of turmeric, to stain them yellow; taken out and dried in warm sand contained in a pot, then scraped by the Dutcher as above described. The first are reckoned to make the best pens, though the second may appear more beautiful.

Crow quills for draughtsmen, as well as swan quills, are prepared in the same way. The quills plucked from well-fed living birds have most elasticity, and are least subject to be moth-eaten. The best are those plucked, or which are spontaneously cast in the month of May or June, because they are then fully ripe. In the goose's wing the five exterior feathers only are valuable for writing. The first is the hardest and roundest of all, but the shortest. The next two are the best of the five. They are sorted into those of the right and the left wing, which are differently bent. The heaviest quills are, generally speaking, the best. Lately, steaming for four hours has been proposed as a good preparation.

FECULA (*Fecule*, Fr.; *Stärkemehl*, Germ.); sometimes signifies corn flour, sometimes starch, from whatever source obtained.

FELSPAR (*Orthose*, Fr.; *Feldspath*, Germ.) is a mineral crystallizing in oblique rhomboidal prisms, susceptible of two clivages; lustre more pearly than vitreous; spec. grav. 2·39 to 2·58; scratches glass; yields no water when calcined; fusible at the blowpipe into a white enamel; not affected by acids. The liquid left from its analytical treatment with nitrate of baryta, nitric acid, and carbonate of ammonia, affords on evaporation an alkaline residuum which precipitates platina from its chloride, and appears from this, as well as other tests, to be potash. Felspar consists of silica 66·75; alumina, 17·50; potash, 12; lime, 1·25; oxide of iron, 0·75. (*Rose.*) This mineral is a leading constituent of granite; and in its decomposed state furnishes the petuntse or Cornish stone, so much used in the porcelain and best pottery manufactures.

FELTED CLOTH. This woollen fabric, made without spinning and weaving, was made the subject of a patent by Mr. T. R. Williams in February, 1850. A copious description of the process is given in *Newton's Journal*, xxii. 1.

Varnished or Japanned Felt is made by imbuing the stuff of coarse hat bodies with drying oil, prepared by boiling 50 lbs. of linseed oil with white lead, litharge, and umber, of each one pound. The felt is to be dried in a stove, and then polished by pumice-stone. Five or six coats of oil are required. The surface is at last varnished. When the object is intended to be stiff, like visors, the fabric is to be impregnated first

of all with flour-paste, then stove-dried, cut into the desired shape, next imbued with the drying-oil, and pumiced repeatedly; lastly placed, to the number of 20, in a hot iron mould, and exposed to strong pressure. Japanned hats, made in this way, are sold in France at 1*s.* 3*d.* a piece; and they will stand several years' wear.

FELTING (*Feutrage*, Fr.; *Filzen*, Germ.) is the process by which loose flocks of wool, and hairs of various animals, as the beaver, rabbit, hare, &c., are mutually interlaced into a compact textile fabric. The first step towards making felt is to mix, in the proper proportions, the different kinds of fibres intended to form the stuff; and then, by the vibratory strokes of the bowstring, to toss them up in the air, and to cause them to fall as irregularly as possible, upon the table, opened, spread, and scattered. The workman covers this layer of loose flocks with a piece of thick blanket stuff slightly moistened; he presses it with his hands, moving the hairs backwards and forwards in all directions. Thus the different fibres get interlaced, by their ends pursuing ever tortuous paths; their vermicular motion being always, however, *root foremost*. As the matting gets denser, the hand pressure should be increased in order to overcome the increasing resistance to the decussation.

A first thin sheet of soft spongy felt being now formed, a second is condensed upon it in like manner, and then a third, till the requisite strength and thickness be obtained. These different pieces are successively brought together, disposed in a way suitable to the wished-for article, and united by continued dexterous pressure. The stuff must be next subjected to the fulling mill. See HAT MANUFACTURE.

FERMENT (Eng. and Fr.; *Hefe*, Germ.) is the substance which, when added in a small quantity to vegetable or animal fluids, tends to excite those intestine motions and changes which accompany fermentation. It seems to be the result of an alteration which vegetable albumen and gluten undergo with contact of air amidst a fermenting mass. The precipitate or lees which fall down when fermentation is finished consist of a mixture of the fermenting principle with the insoluble matters contained in the fermented liquor, some of which, like hordeine, existed in the worts, and others are probably generated at the time.

To prepare a pure ferment, or at least a compound rich in that principle, the precipitate separated during the fermentation of a clear infusion of malt, commonly called yeast or barm, is made use of. This pasty matter must be washed in cold distilled water, drained and squeezed between the folds of blotting paper. By this treatment it becomes a pulverulent mass, composed of small transparent grains, yellowish gray when viewed in the compound microscope. It contains much water, and is therefore soft, like moist gluten and albumen. When dried it becomes, like these bodies, translucid, yellowish brown, horny, hard, and brittle. In the soft humid state it is insipid, inodorous, insoluble in water and alcohol. If, in this state, the *ferment* be left to itself at a temperature of from 60° to 70° F., but not in too dry a situation, it putrefies with the same phenomena as vegetable gluten and albumen, and leaves, like them, a residuum resembling old cheese.

At the beginning of this change, particularly if the ferment be enclosed in a limited portion of air, there is an absorption of oxygen gas with a five-fold disengagement of carbonic acid gas; while acetic acid makes its appearance in the substance. When distilled by itself it affords the same products as gluten. Dilute acids dissolve it very readily; and so does potash with the production of ammonia, a peculiar circumstance, for in dissolving gluten the alkali causes no such evolution.

The property possessed by yeast of determining the fermentation of a properly diluted solution of sugar is very fleeting, and is lost by very trifling alterations. It is destroyed by complete desiccation, and cannot be restored by moistening it again. The attempts made in London to squeeze out the liquid part of yeast in bags placed in a powerful press, and to obtain a solid cake, in order to transport ferment to India, have had but a very partial success; for its virtue is so impaired that it will rarely excite a perfect fermentation in the best prepared worts. The same method is adopted in Germany, to send yeast to only moderate distances; and therefore with more advantage.

If yeast be boiled for ten minutes, it loses the greater part of its fermenting power, and by longer boiling it becomes inert.

When alcohol is poured upon yeast, it immediately destroys its fermenting faculties, though, on filtering it off, it seems to carry no remarkable principle with it. One thousandth part of sulphuric acid equally deprives yeast of its peculiar property, and so does a little strong acetic acid. All the acids and the salts, especially those which part readily with their oxygen, produce the same effect. A very small quantity of sulphurous acid, or sulphites, mustard powder, particularly the volatile oil of mustard, and in general the volatile oils that contain sulphur, as well as the vegetables which yield them, such as horse-radish and garlic, all kill the fermenting agent. Lastly, fermentation is completely stopped by a moderate depression of temperature.

During fermentation the yeast undergoes a change; it loses the property of causing another wort to ferment. This change probably depends upon the chemical reaction between the ferment and the sugar that is decomposed; for a certain quantity of yeast can effect the fermentation of only a certain quantity of sugar, and all the sugar exceeding this quantity remains unaltered in the liquor. It has been concluded from some rather loose experiments, that one part and a half of yeast (supposed to be in the dry state), is adequate to the fermentation of a solution of 100 parts of pure sugar. When such a solution is fermented by the precise proportion of yeast, the fermenting principle is exhausted, for no new yeast is formed in it. There is a deposit indeed to about half the weight of the yeast employed, of a white matter insoluble in water, which affords no ammonia by dry distillation, and is incapable of acting as a ferment upon a fresh saccharine solution.

Of all the bodies convertible into yeast during fermentation, vegetable gluten and albumen possess the most rapid and energetic powers. But ordinary glue, isinglass, animal fibrine, curd or *caseum*, albumine, urine and other azotized substances, all enjoy the property of causing a solution of sugar to ferment; with this difference, that whilst yeast can establish a complete fermentation in less than an hour, at a temperature of about 68°, the above substances require several days, with a heat of from 77° to 87° F., for becoming ferments, and for occasioning fermentation. Substances devoid of nitrogen do not produce a ferment.

FERMENTATION. (Eng. and Fr.; *Gährung*, Germ.) When organic substances, under the influence of water, air, and warmth, are abandoned to the reciprocal operation of their proximate principles (sugar, starch, gluten, &c.), they are entirely changed and decomposed, so that their ultimate principles (oxygen, hydrogen, carbon, and in some cases azote,) combine in new proportions, and thus give birth to various new compounds. To this process, the general name of fermentation has been given. These operations and their products differ according to the differences of the substances, and of the circumstances in which they are placed. The following may be enumerated as sufficiently distinct species of fermentation. 1. The *saccharine* fermentation, in which starch and gum are changed into sugar. 2. The *vinous* fermentation, in which sugar is converted into alcohol. 3. The *mucilaginous* fermentation, in which sugar is converted into slime, instead of alcohol. 4. The *acetous* fermentation, in which alcohol and other substances are converted into vinegar. 5. The putrid fermentation or putrefaction, which characterizes particularly the decomposition of azotized organic substances.

1. *The Saccharine Fermentation.*—When a paste made by boiling one part of starch with twelve parts of water is left entirely to itself, water merely being stirred in as it evaporates, at the end of a month or two in summer weather it is changed into sugar, equal in weight to from one-third to one-half of the starch, and into gum, equal to from one-fifth to one-tenth, with a residuum of starch paste somewhat altered. This saccharifying process advances much quicker through the co-operation of vegetable albumine or gluten, acting as a ferment. If we boil two parts of potato starch into a paste with twenty parts of water, mix this paste with one part of the gluten of wheat flour, and set the mixture for eight hours in a temperature of from 122° to 167° F., the mixture soon loses its pasty character, and becomes by degrees limpid, transparent and sweet, passing at the same time first into gum, and then into sugar. The remainder consists of the unchanged starch with the altered gluten, which has become sour, and has lost the faculty of acting upon fresh portions of starch. It is probable, however, that the sugar formation in the first case, when the starch undergoes a spontaneous change, may be due to the action of a small portion of gluten and albumine left in the starch, since a putrefactive smell is eventually evolved indicative of that azotized matter. The gum into which during this process the starch is first converted, and which becomes afterwards sugar, is of the same nature as British gum, formed by the roasting of starch.

This production of sugar takes place in the germination and kiln-drying of malt; and the mashing of the brewer, as well as the sweetening of bread in baking, rests upon the same principles. In many cases the vinous fermentation precedes the saccharification, or accompanies it; the starchy parts of the fermenting mass changing into sugar, while the previously formed sugar becomes wine or beer. In the sweetening of fruits by keeping, a similar process occurs; the gummy and starchy fibres become sugar from the action of the glutinous ferment which they contain; as happens also to the juices of many fruits which sweeten for a little while after they have been expressed.

The nature of this sugar formation through the influence of gluten upon starch, is undoubtedly the same as the conversion of starch into sugar, by boiling it with sulphuric acid: though the whole theory of this change is not entirely developed.

The most energetic substance for the conversion of starch into sugar, is the malt of barley. According to the researches of Payen and Persoz, the gum which by this

process is first formed, may be prevented from going into sugar, by merely exposing it to a boiling heat, and hence we have it in our power either to make sugar or gum at pleasure. Of finely ground malt from 10 to 25 parts must be taken for 100 parts of starch. Into a pan placed in a water bath, 400 parts of water being warmed to from 77° to 86° F., the ground malt must be stirred in, and the temperature must be raised to 140°. The 100 parts of starch must now be added, and well mixed. The heat is then to be increased to 158° F.; and be so regulated that it shall not fall below 149°, nor rise above 167°. In the course of 20 or 30 minutes the originally milky and pasty liquid will become gradually more attenuated, and eventually it will turn as fluid nearly as water. This is the point of time in which the starch has passed into gum, or into the substance lately denominated *dextrine* by the chemists. Should this mucilaginous matter, which appears to be a mixture of gum and a little starchy sugar, be wished for in that state, the temperature of the liquid must be suddenly raised to the boiling point, whereby the further action of the malt upon it is stopped. But on the other hand, if sugar be desired, then the temperature must be steadily maintained at from 158° to 167° for three quarters of an hour, in which time the greater part of the starch will have become sugar, and from the evaporation of the fluid a starchy syrup will be obtained, entirely similar to that procurable by the action of very dilute sulphuric acid upon starch.

The substance which operates this saccharine change, or the appropriate yeast of the sugar fermentation, which had been previously imagined to be a residuum of gluten or vegetable albumen in the germinated grain, has been traced by Payen and Persoz to a peculiar proximate vegetable principle, called by them *diastase*. This substance is generated during the germination of barley, oats, and wheat, and may be obtained separately by infusing the ground malt in a small quantity of cold water, straining off the liquor, then filtering it, and heating the clear solution in a water-bath to the temperature of 158° F. The greater part of the vegetable albumen is thus coagulated, and must be separated by a fresh filtration; the liquid is afterwards treated with alcohol as long as the flocculent precipitate of diastase falls. In order to purify it still more completely from the azotized matter, it may be once more dissolved in water, and again precipitated by alcohol. When dried at a low temperature, it appears as a white solid, which contains no azote, is insoluble in strong alcohol, but dissolves in weak alcohol and water. Its solution is neutral and tasteless; and if left to itself, it changes spontaneously sooner or later, according to the degree of warmth, and becomes sour. At the temperature of from 149° to 168°, it has the property of converting starch into gum or dextrine and sugar; and, when sufficiently pure, it does this with such energy, that one part of it is capable of saccharifying 2,000 parts of dry starch. It acts the more rapidly the larger its proportion. Whenever the solution of diastase with starch or dextrine has been heated to the boiling point, it loses the property of transforming these substances. One hundred parts of well malted barley appear to contain about one part of this new body.

2. *The Vinous Fermentation.*—In this fermentation the sugar existing in watery solution is, by the operation of the ferment or yeast, converted into alcohol, with disengagement of carbonic acid gas. If we dissolve one part of pure sugar in ten parts of water, and leave the solution in a temperature of from 68° to 77° F., which is that most favourable to fermentation, it will remain unaltered. But if we stir into that solution some beer yeast, the phenomena of fermentation soon appear in the above circumstances; for carbonic acid gas is evolved, with intestine movements of the liquid, and an increase of its temperature. A body of yeast rises to the surface, and exhibits a continual formation and rupture of air bubbles. At length the sugar being in a great measure decomposed, the motions cease, the liquor becomes clear, and instead of being a syrup, it is now a dilute alcohol. The yeast has by this time fallen to the bottom in a somewhat compact form, and of a whitish colour, deprived of the property of exciting fermentation in fresh syrup, provided no undue excess of it was added at first, for that alone would remain effective. Experience shows that for the conversion of a determinate quantity of sugar by fermentation, a determinate quantity of yeast is necessary, which has been estimated at about 1½ per cent. in the dry state. When the yeast has been decomposed by fermenting its definite proportion of sugar, it loses its fermentable property, and leaves the excess of sugar unaffected, forming a sweet vinous solution. The same thing happens if the yeast be separated from the wort by a filter in the progress of the fermentation, for then all intestine motion speedily stops, although much saccharine matter remains.

In the juices of sweet fruits, of grapes, for example, the ferment is intimately associated with the sugar. It is at first soluble and inactive, till it absorbs oxygen from the atmosphere, whereby it becomes an operative ferment, but, at the same time, insoluble, so as to precipitate at the end of the process. When the expressed juice of the grape, or *must*, is inclosed in a vessel out of contact of air, and there subjected to the heat of

boiling water, the small portion of oxygen present is rendered inactive, and the liquor experiences no fermentative change. If the grapes be squeezed in an atmosphere deprived of oxygen, and confined in the same, the juice will also remain unaltered. Recently expressed grape juice is limpid, and manifests the commencement of fermentation by the separation of the yeasty substance, which can take place only with access of air. The solution becomes turbid after a certain time, gas begins to be evolved, and the separated ferment decomposes the sugar. At the end of the process the yeast collects at the bottom of the vessel, usually in larger quantity than was sufficient to complete the fermentation; and hence a considerable portion of it possesses still the fermentative faculty. The fermentation itself, when once begun, that is, whenever the yeasty particles are evolved, and float in the liquid, for which evolution a very minute quantity of oxygen is sufficient, is thenceforth independent of the contact of air, and goes on as well in close as in open vessels; so that the production of alcohol and carbonic acid depends solely upon the mutual reaction of the ferment and the sugar.

The yeast, which may be obtained tolerably pure from a fine infusion of malt in a state of fermentation, after being washed with cold water to separate the soluble, gummy, and saccharine matter, and after being pressed between folds of blotting paper, constitutes a pulverulent, grayish yellow, granular substance, destitute of both taste and smell, insoluble both in water and alcohol. Cold water dissolves, indeed, only $\frac{1}{100}$, and boiling water very little more.

The essentially operative constituent of yeast is a peculiar azotized matter, which in the wine vat is mixed with some tartar and other salts, and in the beer tun with gum, starch, &c. This animalized substance may be obtained in a separate state, according to Braconnot, by acting upon the washed yeast powder with a weak lye of carbonate of potash, and by decomposing the solution with vinegar, whereby the matter is thrown down in a gelatinous form. The substance thus obtained is insoluble in cold water and alcohol, but dissolves readily in very dilute alkaline lyes, and even in lime water. When diffused through water, it assumes a homogeneous aspect, as if it were really dissolved; but when this mixture is heated, the animalized matter congulates, and separates in thick flocks. In this state it has lost its former properties, being no longer soluble in alkaline lyes, even when concentrated. Acids exercise no solvent power over this peculiar matter; they precipitate it from its solutions, as do also the earthy and metallic salts, which, moreover, combine with it. This is also the case with tannin. The combination of the ferment stuff with acids increases the stability of its constitution, and counteracts its tendency to influence solutions of sugar. These properties of the operative principle of yeast explain many of the phenomena of fermentation, as we shall presently see.

The animalized matter of yeast resembles gluten, albumen, caseum, and other azotized substances; if any one of these be put into a saccharine solution ready for fermentation, it will begin to operate a change, when aided by warmth and time, if it be previously decomposed in some measure to facilitate its influence; or if these substances be brought into a slightly putrescent state beforehand, they will cause more speedy fermentation. Thus, white of egg, when added to saccharine liquors, requires a period of three weeks, with a temperature of 26° F., before it will excite fermentation; afterwards the excess of the albumen forms a precipitate which may be used instead of yeast upon other sweet worts. The rapidity with which such azotized substances are capable of being converted into ferments of more or less purity and power is very variable; vegetable gluten and albumen being best fitted for this purpose. This conversion is accelerated when the sweet liquor in which the substance is diffused or dissolved has already begun to ferment; whence it appears that the presence of carbonic acid gas, combined with the liquor, is here of singular influence. Upon it, in fact, the formation and elimination of the yeast in fermenting liquors depend.

A solution of pure sugar, which has been made to ferment by the addition of yeast, furnishes no new yeast; but there remains after the process a portion of the yeast originally mixed, in an altered inoperative condition, should its quantity have been exactly adequate to the decomposition of the sugar, or in an operative state, should the quantity have been originally excessive.

But if the fermentable liquor contains vegetable albumen and gluten, as is commonly the case with the sweet juices of fruits and beer worts, these substances become changed into ferments in the course of the fermentation induced by the yeast, and, being superfluous, so to speak, for that particular process, they remain entire at the end, and may be collected for use in other operations.

Upon this principle is founded the increased production of yeast, and the manufacture of what has been called *artificial barm*, in which the fermentation is conducted chiefly with a view to the formation of yeast. To the fermenting mass, those kinds of meal are added which abound in albumen and gluten, as barley, beans, or wheat, for instance;

and the process is similar to the production of a great lump of leaven, from the action of a small piece of it upon dough. The following prescription will illustrate this subject. Take 3 ounces of bean flour, add to it 5 quarts of boiling water, and boil the mixture for half an hour. Pour the decoction into a vessel, and stir into it, while hot, 56 ounces of wheaten flour. After the mixture cools to the temperature of 54° F., add to it about 2 quarts of beer barm, stirring the whole well together. About 24 hours after the commencement of the fermentation, incorporate with the mixture 112 ounces of barley or bean flour, till it becomes a uniform dough, which must be thoroughly kneaded, rolled out into cakes about an inch thick, and cut into pieces of the size of a dollar. These cakelets must be dried upon laths in the sun in favourable weather, and then put up in a dry situation. For use, one of these discs is to be broken into pieces, laid in warm water, and set in a warm place during 12 hours. The soft mass will then serve the purpose of beer yeast.

Or we may mix equal parts of barley malt, wheat malt, and crushed rye; pour water at the temperature of 122° F. over them into a tub till it stands a span above their surface; then stir well together, and allow the whole to remain at rest for a few hours, till it cools to about 65° F. We must now add for each pound of the mingled meals, a quarter of an ounce of beer barm. The tub must be then covered, and preserved at a temperature of 63° F. The husks, as they begin to rise to the surface, in consequence of the fermentation, must be taken off, and squeezed through a cloth over the vessel. When the meal comes afterwards to subside to the bottom, the whole must be strained through a canvas bag, and freed from the superfluous moisture by squeezing. The bag with its doughy mass must next be surrounded with dry ashes, to remove the remaining humidity, and to arrest any further fermentation. This consistent ferment may be used instead of beer yeast.

It is difficult to prepare an artificial yeast without barm. The best process for this purpose is the following. Take five parts of honey, one part of powdered tartar, and sixteen parts of wheat or barley malt, stir the whole in water of the temperature of 122° F., and place in a fermenting heat; when the yeast will, as usual, be eliminated.

The change which gluten or vegetable albumen undergoes in the different kinds of meal, when it becomes a ferment, consists apparently in an oxidation, since analysis shows that this ferment contains more oxygen than gluten does.

It has been already stated that yeast in its liquid condition readily putrefies, and becomes altogether useless for the process of fermentation. In order to preserve it for some time, it must be dried to such a degree as to resist spontaneous decomposition without losing its fermentative faculty; but completely dried yeast loses that property, and does not recover it by being again moistened. Beer barm may be dried after being washed several times with cold water, till the last quantity comes off clear; but the insoluble portion must be allowed to settle fully before the water is poured away from it. The residuum being freed as much as possible from water, by drainage and pressure between flannel cloths, is to be dried in the shade by a current of warm air as quickly as possible, with the aid of frequent turning over. It must be afterwards kept in dry earthen vessels. Yeast may also be preserved a short time in activity by being kneaded with as much barley or wheat flour as it can take up without losing the doughy consistence. Dried yeast has, however, always an impaired activity. The easiest and most certain method of preserving yeast in its primitive power, is by mixing it, after pressure in flannel, with as much pulverized sugar as will render it dry, and putting up the mixture in air-tight vessels. The fermentative power of yeast is destroyed by the following means; 1. as already stated, by making it completely dry either by the evaporation of the water, or its abstraction by alcohol; 2. by boiling, which if continued for ten minutes renders yeast quite inoperative; 3. by the action of such substances as dissolve out its essential constituents; by alkalis, for instance, since the particles of yeast seem to be operative only in their insoluble granular state; 4. by such substances as form combinations with it, and thereby either alter its nature, or at least increase the cohesion of its constituent parts, so that they can no longer operate upon sweet liquors by the decomposing affinity of its ultimate particles. Such bodies are the acids, especially the mineral ones, tannin and most salts, particularly the metallic, which unite with the yeast into new compounds. The volatile oils which contain sulphur exercise the same paralyzing influence upon yeast.

The circumstances which promote, and are necessary to, the vinous fermentation are, conformably to the above views, the following: — 1. The presence of the proper quantity of active yeast, and its proper distribution through the worts. If in the course of a slack fermentation the yeast subsides to the bottom, the intestine motions cease entirely, but they may be excited anew by stirring up the ingredients, or rousing the tun, as the brewers say. 2. A certain degree of warmth, which should never be less than 51° F., nor more than 86°; the temperature of from 68° to 77° being the most

propitious for the commencement and progress of fermentation. When other circumstances are the same, the rapidity of the fermentation is proportional to the temperature within certain limits, so that, by lowering it, the action may be moderated at pleasure. 3. The fermentation proceeds the better and more equably the greater the mass of fermenting liquor, probably on account of the uniformly high temperature, as well as the uniform distribution of the active particles of the yeast by the greater energy of the intestine movements. 4. The saccharine solution must be sufficiently diluted with water; when too much concentrated it will not ferment. Hence very sweet musts furnish wines containing much undecomposed sugar. For a complete fermentative action, one part of sugar should be dissolved in ten parts of water.

Fermentation may be tempered or stopped: 1. by those means which render the yeast inoperative, particularly by the oils that contain sulphur, as oil of mustard; as also by the sulphurous and sulphuric acids. The operation of the sulphurous acid in obstructing the fermentation of must consists partly, no doubt, in its absorbing oxygen, whereby the elimination of the yeasty particles is prevented. The sulphurous acid, moreover, acts more powerfully upon fermenting liquors that contain tartar, as grape juice, than sulphuric acid. This acid decomposes the tartaric salts, and, combining with their bases, sets the vegetable acid free, which does not interfere with the fermentation; but the sulphurous acid operates directly upon the yeast: 2. by the separation of the yeast, either with the filter or by subsidence: 3. by lowering the temperature to 45° F. If the fermenting mass become clear at this temperature, and be drawn off from the subsided yeast, it will not ferment again, though it should be heated to the proper pitch.

The products of vinous fermentation are carbonic acid gas, and alcohol; of which the former escapes during the process, except in the case of the sparkling wines, like champagne, that are partially fermented in close vessels. The alcohol remains in the fermented liquor. 100 parts of sugar afford by complete decomposition nearly 50 parts of alcohol. According to Thenard, 100 parts of sugar are converted into 46·8 parts of carbonic acid, and 49·38 of alcohol; besides 3·82 parts of carbon otherwise employed, which the sugar contained, above what is present in the former two products. This chemist found in the fermented liquor 4 per cent. of an extractive matter, soluble in water, and having an acidulous reaction, to whose formation, probably, that excess of carbon may be necessary. In what way the action of the yeasty particles upon the saccharine substance is carried on in the vinous fermentation, or what may be the interior working of this process, is not accurately understood. The quantitative relation of the carbonic acid and alcohol to the sugar is pretty well made out; but the determination of the ultimate principles of the ferment itself, before and after the vinous change, and of the residuum dissolved in the fermented liquor, has not been well ascertained. It is probable that the yeast undergoes in the process a similar decomposition to that of the putrefactive, and that its elementary constituents enter into new combinations, and abstract so much carbon and hydrogen from the sugar, that the remainder, amounting to 96 per cent. of the whole, may constitute one atom of alcohol and one of carbonic acid.

3. *The Slimy or Glutinous Fermentation.* — This process takes place in weak solutions of sugar, at ordinary fermenting temperatures, where, from defect of good yeast, the vinous fermentation cannot proceed. In such circumstances from one part of sugar, one-third part of gum is formed. According to Desfosses, however, 100 parts of sugar afford 109·48 of gum or slime. This is formed when one part of sugar is dissolved in twenty parts of water, which had been previously boiled with washed barm or gluten, and then filtered. The process proceeds slowly and quietly, equally well in close vessels as with contact of air, and continues at ordinary temperatures about twelve days; but it goes on more rapidly and completely at the heat of from 77° to 86° F. A small quantity of hydrogen and carbonic acid gas is disengaged, in the proportion of two to one by volume. The fermented liquor becomes turbid, and assumes a tough thready appearance, like a decoction of linseed. A small addition of sulphuric or sulphurous acid, of muriatic acid and alum, or of tannin, impedes this species of fermentation; because these substances combine, as in the vinous fermentation, with the ferment into an insoluble precipitate, unsusceptible of further change. In many wines, especially when bottled, this slimy fermentation occurs, and occasions their ropiness, which may be best remedied or prevented by the addition of as much tannin as will precipitate the dissolved mucous matter. This species of fermentation attacks very rapidly the rinsing waters of the sugar refiner, which always contain some fermentative gluten. A little alum is the best preventative in this case, because it precipitates the dissolved ferment.

4. *The Acetous or Sour Fermentation.* — In this process, alcohol, more or less dilute, is resolved into water and vinegar, in consequence of the operation of the ferment; ox-

idizement of the alcohol being effected by the oxygen of the atmospherical air. The requisites of this process have been already detailed under the article ACETIC ACID. They are the presence of atmospherical air; alcohol diluted to a certain degree with water ferment or yeast, and a temperature above 66° F. The most active ferments are such substances as have already passed into the acetous state; hence vinegar, especially when it contains some yeasty particles, or is combined with porous and spongy bodies, so as to multiply its points of contact with the vinous liquor, is particularly powerful. Common yeast may also be employed for vinegar ferments, if it be imbued with a little vinegar, with leaven, crusts of bread soaked in vinegar, the stalks and husks of grapes, sawdust and shavings of beech or oak impregnated with vinegar, or the slimy sediment of vinegar casks called *mother*; all of which operate as ferments chiefly in consequence of the vinegar which they contain. The inside shavings of the staves of vinegar tuns act on the same principle.

The acetous fermentation may, moreover, go along with the vinous in the same liquor, when this contains sugar as well as alcohol. Whilst the acidification of the alcohol is effected by the absorption of oxygen from the atmosphere, the sugar becomes alcohol with disengagement of carbonic acid, and then passes into vinegar. Since most liquors intended for making vinegar, such as wine, juices of fruits, ales, &c., contain still a little sugar, they disengage always a little carbonic acid. Besides spirits, some other substances, such as gum, the mucilage of plants, and starch paste, directly ferment into vinegar. Sugar, also, seems to be convertible into vinegar without any vinous change. The albuminous matter of potato juice, precipitated by vinegar, serves as a proper ferment for that purpose, when added in its moist state to weak syrup. 5. See PUTREFACTION.

Mr. William Black, in his treatise on Brewing, has, with much ingenuity and apparent truth, endeavoured to show that the process of fermentation is strongly influenced by electricity, not only that of the atmosphere, as has been long known from the circumstance of beer and wine becoming speedily sour after thunderstorms, but the voltaic, produced by electric combinations of metals in the fermenting tuns. He therefore recommends these tuns to be made with as little metallic work as possible, and to be insulated from the floor of the brewhouse. For the propriety of this advice he adduces some striking examples. Wort which had become stationary in its fermentation, on being pumped out of square gyles imbedded in the floor, into casks placed upon wooden stillions, began immediately to work very well, and gained about 6 degrees of attenuation while throwing off its yeast. From the stagnation of the process in the gyles he had in the morning predicted an approaching thunderstorm, which accordingly supervened in the course of the evening. In further support of his views he instances the fact, that in dairies where the milk is put into porcelain vessels, and placed upon wooden shelves, it is seldom injured by lightning; but when contained in wooden or leaden vessels, and placed upon the ground, it almost invariably turns sour in thundery weather. His general conclusion is "that the preservation or destruction of beer depends upon electricity; and the most certain mode of preservation is to insulate, as much as possible, both the squares and all other utensils or vessels connected with the brewing or storing of beer."

Mr. Black further considers that unsoundness of worts is often the result of electricity excited between the mash tun and the copper.

Why is beer liable to get spoiled in thunderstorms, though apparently well insulated in glass bottles?

I shall add to this article Mr. Black's description of the phenomena of beer fermentation. In every regular process there are five distinct stages. In the first we see a substance like cream forming round the edges of the gyle tun; which extends towards the centre until the whole is creamed over, constituting the first change. Next a fine curl appears like cauliflower, which also spreads over the square surface, and, according to the strength and appearance of this curl, the quality of the fermentation may be predicated. This he calls the second stage. What is technically called the *stomach* or vinous vapour now begins to be smelt, and continues to gain strength till the process is concluded. From the vinous energy of this odour, and the progressive attenuation of the wort, the vigour of the fermentation may be inferred. The experienced brewer is much guided in his operations by the peculiarity of this effluvium. The third change is when the cauliflower or curling top rises to a fine rocky or light yeasty head; and when this falls down, the fourth stage has arrived. Finally, the head should rise to what is called close yeasty, having the appearance of yeast all over. About this period the gas becomes so powerful as to puff up occasionally in little bells or bladders about the size of a walnut, which immediately break. The bells should appear bright and clear. If they be opaque or whey-coloured, there is some unsoundness in the wort.

The great point is to add just so much yeast as to carry the fermentation completely through these five changes at the regular periods.

The term fermentation has been of late extended to several operations besides those formerly included under it. The phenomena which it exhibits under these different phases and the changes which it effects among the various subjects of its operations, are no less striking and mysterious in their principle than important in their application to the arts of life. Fermentations are now arranged into twelve classes—1. the alcoholic; 2. the glucosic or saccharine; 3. the viscous or mucous; 4. the lactic; 5. the acetic; 6. the gallic; 7. the pectic; 8. the benzoilic; 9. the sinapic; 10. the ammoniacal; 11. the putrid; and 12. the fatty.

Fermentation, in the most general sense, may be defined to be a spontaneous reaction, a chemical metamorphosis, excited in a mass of organic matter by the mere presence of another substance, which neither extracts from, nor gives to, the matter which it decomposes any thing whatever. This process requires the following conditions: — 1. A temperature from 45° to 90° F.; 2. Water; 3. The contact of air; 4. The presence of a neutral organic azotized matter, in a very small quantity, and of a crystallizable non-azotized substance, in considerable quantity. The former is the ferment; the latter undergoes fermentation. In ordinary chemical actions we perceive one body unite to another to form a new compound; or one body turn another out of a combination, and take its place, in virtue of a superior affinity. These effects are foreseen and explained by the intervention of that molecular force which governs all chemical operations, that attractive power which unites the particles of dissimilar bodies. Thus, also, in the ordinary phenomena of decomposition, we perceive the agency of heat at one time, at another of light, or of electricity; forces of which, though we are not acquainted with the essence, yet we know the exact effect under determinate circumstances. But fermentation, on the contrary, can be explained neither by the known laws of chemical affinity, nor by the intervention of the powers of light, electricity, or heat. Fermentation reduces complex organic substances to simpler compounds, thereby reducing them nearer to the constitution of mineral nature. It is an operation analogous, in some respects, to that effected by animals upon their vegetable food.

With a good microscope, any person may convince himself that ferment or yeast is an organised matter, formed entirely of globules, or of corpuscles slightly ovoid, from the three to the four-thousandth part of an inch in diameter. Sometimes their surface seems to have a little tail, which has been regarded as a bud or germ attached to the mother cell. Whenever the fermentation begins, the yeast does not remain an instant idle. These small round bodies become agitated in all directions, and if the substance undergoing fermentation is mixed with an azotized matter, as in beer worts, the corpuscles become larger, the small tails get developed, and on acquiring a certain size they separate from the parent globule, to live by themselves, and give birth to new corpuscles.* In the fermentation of beer from malt, this series of multiplications produces a quantity of yeast seven times greater than what was added at the commencement. Were the above ingenious speculations demonstrated with certainty, we should be led to admit, in all these phenomena, actions truly vital, and a reproduction like that of buds in the vegetable kingdom. The existence of a vital force seems to be rendered probable by the fact, that in incomplete fermentation, such as that of fine syrup with too little yeast, the ferment loses its properties and powers. If, however, we add to the solution of pure sugar an albuminous substance, a caseous or fleshy matter, the development of yeast becomes manifest, and an additional quantity of it is found at the end of the operation. Thus with nourishment, ferment engenders ferment. It is for this reason that a little fermenting must, added to a body of fresh grape-juice, excites fermentation in the whole mass. These effects are not confined to alcoholic fermentation. The smallest portions of sour milk, of sour dough, or sour juice of beet-root, of putrefied flesh or blood, occasion like alterations in fresh milk, dough, juice of beet-roots, flesh, and blood. But further, and which is a very curious circumstance, if we put into a liquid containing any fermenting substance, another in a sound state, the latter would suffer decomposition under the influence of the former. If we place urea in presence of beer-yeast, it experiences no change; while, if we add it to sugar-water in a fermenting state, the urea is converted into carbonate of ammonia. We thus possess two modes of decomposition, the one direct, the other indirect.

Although yeast has all the appearances of an organised substance, it is merely by analogy that its multiplication by growth is assumed, for this is a phenomenon very difficult of experimental demonstration. When blood, cerebral substance, gall, pus, and such like substances, in a putrid state, are laid upon fresh wounds in animals, vomiting,

* M. Turpin, M. Cagniard Latour, M. Quévenne, and Professor Mitscherlich

debility, and death soon supervene. The scratches from bones in putrid bodies have been often the causes of disease and death to anatomists. The poison in bad sausages is of the same class of ferments. In Wurtemberg, where sausages are prepared from very miscellaneous matters, as blood, livers, brains, and offal of many other kinds, with bread, meal, salt, and spices, fatal results from eating them are not uncommon. Death in these cases is preceded by the gradual wasting of the muscular fibre, and of all the like constituents of the human body; so that the patient becomes emaciated, dries into a complete mummy, and soon expires. The cadaver is stiff as if frozen, and is not subject to putrefaction. During the progress of the *sausage* disease, the saliva becomes viscid, and emits an offensive smell. No peculiar poison can be detected by analysis in the sausages; but they are rendered wholesome food for animals by the action of alcohol, or by that of boiling water, which destroy the noxious *fomes* without acquiring it themselves; and thus decompose the putrefactive ferment of the sausages. When this, however, passes unchanged through the stomach into the circulating system, it imparts its peculiar action to the constituents of the blood, operating upon it as yeast does upon wort. Poisons of a like kind are produced by the body itself in some diseases. In plague, small-pox, measles, &c., substances of a peculiar fermentative nature are generated from the blood, which are capable of inducing in the blood of a healthy person a decomposition like that of which themselves are the subjects. The morbid virus reproduces itself, and multiplies indefinitely, just as the particles of yeast do in the fermentation of beer. The temperature of boiling water, and alcohol applied to matters imbued with such poisonous secretions, renders their poison inert. Many acids, chlorine, iodine, bromine, empyreumatic oils, smoke, creosote, strong decoction of coffee, have the same salutary effect. All these agents are known to counteract fermentation, putrefaction, and that dry wasting of organic matter called *eremacausis*, or *slow combustion*. It is most deserving of remark, that the poisons chemically neutral or alkaline, such as those of small-pox in man, and of *typhus ruminantium* in cows, lose their baneful power when subjected to the action of the stomach; whereas that of bad sausages, which is acid, resists the modifying power of the digestive organs.

Alcoholic fermentation has been copiously discussed in this Dictionary. I may here add that ammonia, being a product of that change in solution of pure sugar, proves the presence of azote in the yeast; and that sulphuretted hydrogen, being made manifest in the disengaged gaseous products, by their blackening paper imbued with acetate of lead, proves the presence of sulphur. The acid liquor accompanying yeast may be washed away, without impairing materially its fermenting power, while the acid so removed has of itself no such virtue.

Yeast, freed from all soluble matters by water, alcohol, and ether, contains, independently of ashes, carbon, 50·6; hydrogen, 7·3; azote, 15; oxygen, sulphur, and phosphorus, 27·1, in 100 parts. Viewed atomically, yeast bears a close analogy to albumen. Like albuminous matter, yeast takes a violet tint with muriatic acid, and it may be replaced as ferment by gluten. Caseum (the curd of milk) and flesh operate the same effect. All these fermentative powers have the same globular appearance in the microscope with yeast. When the activity of yeast has been destroyed by heat, &c., it can be restored by the positive energy of the voltaic battery, which causes its combination with oxygen. The best proportion of sugar and water, for exhibiting the phenomena of fermentation, is 1 of the former to 3 or 4 of the latter, and 5 parts of sugar to 1 of fresh yeast may be added; though in the course of fermentation, 100 parts of sugar do not consume 2 parts of yeast, estimated in the dry state. The quickest fermenting temperature is from 68° to 86°. A very little oil of turpentine or creosote, or of the mineral acids, prevents or stops fermentation completely; oxalic and prussic acids have the same effect, as also corrosive sublimate and verdigris. It has been known from time immemorial in Burgundy, that a little red precipitate of mercury, when added to the must-tun, stopped the fermentation. All alkalis counteract fermentation, but when they are saturated it recommences. The first person who described the microscopic globules of yeast with precision was Désmazières, who arranged them among the mycodermes (*fungus-skinned*), under the name of *mycoderma cerevisiæ*. They have not the flattened form of the globules of blood, but are rather egg-shaped. One small black point may be seen on their surface, which, after some days, is associated with 3, 4, or 5 others. Their average diameter is from $\frac{1}{3000}$ to $\frac{1}{4000}$ of an inch. Sometimes more minute globules cluster round one of ordinary size, and whirl about with it, when the liquor in which the globules float is agitated.

Fresh yeast loses, by drying, 68 parts in the 100, and becomes solid, horny-looking, and semi-transparent, breaking readily into gray or reddish fragments. With water, it resumes immediately its pristine appearance. When fresh yeast is triturated with its own weight of white sugar, it forms a liquid possessing the fluidity of oil of almonds, and a yellow colour. The globules continue unchanged, except perhaps becoming

somewhat smaller. Yeast in the dry state retains its fermentative virtue for a long time.

Saccharine Fermentation is that by which starch and dextrine are converted into sugar, as shown remarkably in the action of diastase upon these bodies. If we mix 2 parts of starch paste with 1 part of dry gluten, and keep the mixture at a temperature of from 122° to 140° F., we obtain a good deal of sugar and dextrine. Some lactic acid is also formed. Flour paste, long kept, spontaneously produces sugar by a like reaction.

Lactic Fermentation. — Almost all azotized organic matters, after being modified by the contact of air, become capable of giving rise to this fermentation. Oxygen does not come into play, except as the means of transforming the animal substances into a ferment. Diastase and caseum are well adapted to exhibit this change. The body that is to furnish the lactic acid may be any one of the neutral vegetable matters, possessing a like composition with lactic acid, such as cane sugar, grape or potato sugar, dextrine, and sugar of milk. All the agents which stop the alcoholic, stop also the lactic fermentation; while diastase and caseum are its two best exciters. For producing abundance of lactic acid, we have merely to moisten malt, to expose it to the air for a few days, then to triturate it with a quantity of water, and leave the emulsion for some days more in the air, at a temperature between 67° and 86° F. We then saturate the liquor with chalk, after having filtered it, and thereby obtain the lactate of lime, which may be crystallized in alcohol, to deprive it of the dextrine and earthy phosphates; and then decomposed by sulphuric acid.

Lactic Acid, formed from curd (caseum), exhibits more remarkable phenomena. Thus when milk is left alone for some time it becomes sour, and coagulates. The coagulum is formed of caseum and butter; while the whey of it contains sugar of milk and some salts. The coagulation of the caseum has been occasioned by the lactic acid, which was generated in consequence of an action which the caseum itself exercised upon the sugar of milk. Thus with the concourse of air, the caseum becomes a ferment, and excites the conversion of the sugar of milk into lactic acid. The lactic acid in its turn coagulates the caseum, which in the consolidation of its particles attracts the butter. The caseum then ceases to act upon the sugar of milk, and consequently produces no more lactic acid.

But now, if the lactic acid already formed be saturated, the caseum will re-dissolve, and the phenomena will re-commence in the same order. This is easily done by adding a due dose of bicarbonate of soda to the soured milk. In the course of 30 hours, a fresh portion of lactic acid will be generated, and will have coagulated the milk again. We may also add some sugar of milk to the liquid, and to a certain extent convert it into lactic acid. Milk boiled, and kept from contact of air, will not coagulate, and remains fresh for many months. Animal membranes, modified by exposure to moist air for some time, form a true ferment for the lactic fermentation, and acidify solutions of sugar, dextrine, and gum, but the membranes must not be putrescent. Cane-sugar, starch-sugar, and sugar of milk, by assuming or losing a little water, acquire the constitution of lactic acid.

Viscous or Mucous Fermentation. — Every one is acquainted with this spontaneous modification of white wine and ale, which gives them a stringy or oily aspect, and is called in French *graisse*, or fat of wines, and in English the ropiness of beer. The viscous fermentation may be excited by boiling yeast with water, and dissolving sugar in the decoction, after it has been filtered. The syrup should have a specific gravity from 1·040 to 1·055, and be kept in a warm place. It soon assumes the consistence and aspect of a thick mucilage, like linseed tea, with the disengagement of a little carbonic acid and hydrogen, in the proportion of 2 or 3 of the former gas to 1 of the latter. A ferment of globular texture like that of yeast is formed, which is capable of producing viscous fermentation in any saccharine solution to which it is added, provided the temperature be suitable. The viscid matter being evaporated to dryness forms transparent plates, of a sub-nauseous taste, and soluble in water, but less easily than gum arabic. Its mucilage is, however, thicker than that of gum, and yields with nitric acid oxalic acid, but no mucic acid. Four parts of sugar, treated as above described, furnish 2·84 of unchanged sugar, and 1·27 of the mucilage; from which it appears that water becomes fixed in the transformation. Muriatic, sulphuric, sulphurous acids, and alum, prevent the production of the viscous fermentation, by precipitating its ferment. It is probably the soluble portion of gluten which is the cause of this species of fermentation. It has been found, accordingly, that tannin, which precipitates the said glutinous ferment, completely stops the viscous fermentation, or *graisse*, of wines. It is owing to the tannin which the red wines derive from the grape stalks, with which they are long in contact during fermentation, that they are preserved from this malady of the white wines. The gluten of must is of two

kinds, the one soluble in virtue of the alcohol and tartaric acid, and producing the viscous, the other insoluble, and producing the alcoholic fermentation. The art of the wine maker consists in precipitating the injurious ferment, without impeding the action of the beneficial one; an art of considerable delicacy with regard to sparkling wines.

Acid Fermentation has been fully discussed under acetic acid. It requires the presence of ready formed alcohol and air. The lactic fermentation, on the contrary, may take place with starchy or saccharine substances, without the intervention of alcohol or constant exposure to the atmosphere; and when once begun, it can go on without air. Acetification has a striking analogy with nitrification, as is shown by the necessity of a high temperature, and the utility of porous bodies for exposing the liquid on a great surface to the air.

Benzoic Fermentation is that which transforms the azotized neutral crystalline matter, existing in bitter almonds, which has no action upon the animal economy, into new and remarkable products, amongst others the hydrure of benzöile and hydrocyanic (prussic) acid, which together constitute the liquid called oil, or essence, of bitter almonds, a compound possessed of volatility and poisonous qualities. The attentive study of this fermentation has revealed a great fact in vegetable physiology, the spontaneous production, by means of certain artifices, of certain volatile oils, not pre-existing in the plants, yet capable of being generated in the products of their decomposition. The volatile oil of bitter almond constitutes in this respect a starting point, from which have proceeded the oil of mustard, the oil of spiræa, and which will likely lead to other discoveries of the same kind. See Almond and Amygdaline.

Sinapic Fermentation is that by which the oil of mustard is formed, and which takes place by the contact of water, under certain conditions, of too refined and scientific a nature for this practical work.

Pectic Fermentation. — Pectic acid may be obtained from the expressed juice of carrots, and it seems to be formed in the process of extraction by the reaction of albumine in the carrots upon a substance called pectine; a transformation analogous therefore with that which takes place in the formation of the essence of bitter almonds.

Gallic Fermentation. — Gallic acid does not exist ready formed in nut-galls, but is generated from their tannin when they are ground, made pasty with water, and exposed to the air. This conversion may be counteracted by the red oxide of mercury, alcohol, sulphuric, muriatic, and nitric acids, bromine, essence of turpentine, creosote, oxalic, acetic, and prussic acids. The tannin disappears in the sequel of the above metamorphosis.

Fatty Fermentation. — All fats are transformed by the action of an alkaline or other base into certain acids, the stearic, margaric, the oleic, ethalic, &c. When these acids are once formed, they cannot by any means, hitherto known, be reconverted into the primitive fat. By the fixation of water in the acid and the base (called *glycérine*), a change is effected which cannot be undone, because the glyceric base is incapable by itself of displacing the water, once combined in the hydrated fat acid. The circumstances necessary to the fatty fermentation, are like those of other fermentations; namely, the co-operation of an albuminoid matter, along with water, and a temperature of from 60° to 86° F.; under these conditions, the matter becomes warm, and assumes speedily the character of rancidity; acid is generated, and the carbonate of soda can then form salts, while the fatty acid is liberated; a circumstance impossible when the fat was acted upon in the neutral state. This altered fat, treated with water, gives up to it *glyceric alcohol.*

Digestive Fermentation.—Digestion of food may be considered in its essential features as a peculiar fermentative process. The gastric juice is a genuine ferment. Tiedmann, Gmelin, and Prout have shown that the gastric juice contains muriatic acid; and Eberli has made interesting experiments on the digestion of food out of the body, with water containing a few drops of the same acid. He observed that when this liquid contained none of the mucous secretion of the stomach, it did not dissolve the aliments put into it; but with a little of that mucus it acquired that property in an eminent degree. Even the mucus of the bladder had a like effect. Schwann and Vogel have produced this digestive principle in a pure state, called by them *pepsine*, as obtained most abundantly from the stomachs of swine. The glandular part of that viscus being separated from the serous, is cut into small pieces, and washed with cold distilled water. After digestion for 24 hours, that water is poured off, and fresh water is poured on. This operation is repeated for several days, till a putrid odour begins to be felt. The watery infusion thus obtained is precipitated by acetate of lead. This white flaky precipitate contains the *pepsine*, accompanied with much albumen. It is then washed, mixed with water, and subjected to a stream of sulphuretted hydrogen. The whole being now thrown on a filter, the coagulated albumen remains on the paper, along with the sul-

phuret of lead, while the pepsine liquor passes, associated with some acetic acid. If to this liquor a very small quantity of muriatic acid be added, it becomes capable of carrying on artificial digestion. Dry pepsine may be obtained by evaporating the above filtered liquor on a water bath, to a syrupy consistence, then adding to it absolute alcohol, which causes a bulky whitish precipitate. This dried in the air constitutes *pepsine*. It contains a minute quantity of acetic acid, which may be removed completely, by heating it some hours on the water bath. The white powder then obtained is soluble in water, and betrays the presence of no acid whatever. According to Vogel, this substance is composed of, carbon, 57·72; hydrogen, 5·67; azote, 21·09; oxygen, &c. 15·52 = 100. Vogel has proved the analogy between the action of pepsine and diastase by the following experiment:

He dissolved two grains of pepsine in very weak muriatic acid, and put into this liquor heated to 81° F. small bits of boiled beef. In the course of a few hours the pieces became transparent on their edges, and not long after they were completely dissolved. He now added fresh morsels in succession, till those last put in remained unchanged. He found by analysis, that 1·98 grains of the pepsine were left, showing how minute a portion of this ferment was necessary to establish and effect digestion. In fact, we may infer that pepsine, like yeast, serves to accomplish digestion without any waste of its own substance whatever, or probably with its multiplication.

Rennet, with which milk is coagulated in making cheese, is somewhat of the same nature as pepsine. It has been called *chymosine*. But the simplest digesting liquor is the following:

If 10,000 parts of water by weight be mixed with 6 parts of ordinary muriatic acid and a little rennet, a liquor is obtained capable of dissolving hard boiled white of egg, beef, gluten, &c., into a transparent jelly in a few hours.

Ammoniacal Fermentation. — Under this title may be described the conversion of urea into carbonate of ammonia under the influence of water, a ferment, and a favourable temperature. Urea is compased in atoms; reckoned

In volumes,	Carbon 4;	hydrogen 8;	azote 4;	oxygen 2;
which by fixing	—	4;		2;
give	4;	12;	4;	4;

which is 4 vol. of carbonic acid, and 8 of ammonia; equivalent to ordinary carbonate of ammonia. The fermentation of urea plays an important part in the reciprocal offices of vegetable and animal existence. By its conversion into carbonate of ammonia, urea becomes a food fit for plants; and by the intervention of the mucous ferment which urine contains, that conversion is effected. Thus the urea constitutes a neutral and innocuous substance while it remains in the bladder, but is changed into a volatile, alkaline, and acrid substance when it is acted upon by the air. Yeast added to pure urea mixed with water, exercises no action on it in the course of several days; but when added to urine, it soon causes decomposition, with the formation of carbonate of ammonia, and disengagement of carbonic acid. The deposit on chamberpots ill-cleaned acts as a very powerful ferment on urine, causing the complete decomposition of fresh urine in one-fifth of the time that would otherwise be requisite.

Nitrous Fermentation, as exhibited in the formation of nitric acid from the atmosphere, and consequent production of nitrates in certain soils, has been with much probability traced to the action of ammonia on oxygen as the intermedium or ferment.

Caseous and putrid Fermentations. — Curd *is converted into cheese, when after being coagulated by rennet*, it is left to itself under certain conditions; and this constitutes the true distinctive character of caseum. In the production of cheese there is evidently the intervention of a peculiar ferment which is gradually formed, and the decomposition of the curd into new products.

For animal and vegetable matters to run into putrefaction, they must be in contact with air and water, at a certain temperature; viz. between the freezing and boiling points of water. The contact of a putrid substance acts as a ferment to fresh animal and vegetable matters. The reagents which counteract fermentation in general stop also putrefaction. In this process, myriads of microscopic animalcules make their appearance, and contribute to the destruction of the substances.

A dispute having taken place between some distillers in Ireland and officers of Excise, concerning the formation of alcohol in the vats or tuns by spontaneous fermentation, without the presence of yeast, the Commissioners of Excise thought fit to cause a series of experiments to be made upon the subject, and they were placed under my general superintendence. An experiment was made on the 6th of October, with the following mixture of corn: —

	lbs.	oz.
2 Bushels of Barley, weighing - - -	100	5
½ Bushel of Malt - - - -	21	7
½ Bushel of Oats - - - -	20	12
Total, 3 Bushels, weighing - -	142	8

The bruised corn was wetted with 26 gallons of water at the temperature of 160° F., and, after proper stirring, had 8 gallons more of water added to it at the average temperature of 194°. The mash was again well stirred, and at the end of 45 minutes the whole was covered up, having at that time a temperature of 138° F. Three hours afterwards, 16 gallons of wash only were drawn off; being considerably less than should have been obtained, had the apparatus been constructed somewhat differently, as shall be presently pointed out. The gravity of that wash was 1·060, or, in the language of the distiller, 60°. After a delay of two hours more, twenty additional gallons of water at the temperature of 200° were introduced, when the mash was well stirred, and then covered up for two hours, at which period 23 gallons of fine worts of specific gravity 1·042 were drawn off. An hour afterwards 12 gallons of water at 200° were added to the residual grains, and in an hour and a half 11 gallons of wort of the density 1·033 were obtained. Next morning the several worts were collected in a new mash tun. They consisted of 48 gallons at the temperature of 80°, and of a specific gravity 2·0465 when reduced to 60°. Being set at 80°, fermentation soon commenced; in two days the specific gravity had fallen to 1·0317, in three days to 1·018, in four days to 1·013, and in five days to 1·012, the temperature having at last fallen to 78° F. The total attenuation was therefore 34½°, indicating the production of 3·31 gallons of proof spirit, while the produce by distillation in low wines was 3·22; and by rectification in spirits and feints it was 3·05. The next experiment was commenced on the 12th of October, upon a similar mixture of corn to the preceding. 48 gallons of worts of 1·043 specific gravity were set at 82° in the tun, which next day was attenuated to 1·0418, in two days to 1·0202, in three days to 1·0125, and in five days to 1·0105, constituting in the whole an attenuation of 32½°, which indicates the production of 3·12 gallons of proof spirits; while the produce of the first distillation was 2·93 in low wines, and that of the second in feints and spirits was 2·66. In these experiments the wash, when fermenting most actively, seemed to simmer and boil on the surface, with the emission of a hissing noise, and the copious evolution of carbonic acid gas. They prove beyond all doubt that much alcohol may be generated in grain worts without the addition of yeast, and that, also, at an early period; but the fermentation is never so active as with yeast, nor does it continue so long, or proceed to nearly the same degree of attenuation. I was never satisfied with the construction of the mash tun used in these experiments, and had accordingly suggested another form, by which the mash mixture could be maintained at the proper temperature during the mashing period. It is known to chemists that the diastase of malt is the true saccharifying ferment which converts the fecula, or starch of barley and other corn, into sugar; but it acts beneficially only between the temperatures of 145° and 168° F. When the temperature falls below the former number, saccharification languishes; and when it rises much above the latter, it is entirely checked. The new mash tun was made of sheet zinc, somewhat wider at bottom than top; it was placed in a wooden tun, so much larger as to leave an interstitial space between the two of a couple of inches at the sides and bottom. Through this space a current of water at 160° was made to circulate slowly during the mashing period. Three bushels of malt, weighing 125 lbs. 3 oz., were wetted with 30 gallons of water at 167°, and the mixture being well agitated, the mash was left covered up at a temperature of 140° during three hours, when 19 gallons of fine worts were drawn off at the specific gravity of 1·0902 or 90·2°. Twenty gallons more water at 167° were then added to the residuum, which afforded after two hours 28 gallons of wort at the gravity 1·036; 12 gallons of water at 167° were now poured on, which yielded after other two hours 15 gallons at the gravity 1·0185. Forty gallons of fine worts at 1·058 gravity, and 68° temperature were collected in the evening of the same day, and let into the tun with 5 per cent. of yeast. The attenuation amounted in six days to 54°. The third wort of this brewing, amounting to 15 gallons, being very feeble, was mixed with 7 gallons of the first and second worts, put into a copper, and concentrated by boiling to 11 gallons, which had a gravity of 1·058 at 60° F. They were separately fermented with 5 per cent. of yeast, and suffered an attenuation of 48½°. The produce of spirit from both indicated by the attenuation was 5·36 gallons; the produce in low wines was actually 5·52, and that in spirits and feints was 5·33, being a perfect accordance with the Excise tables.

The next experiments were made with a view of determining at what elevation of temperature the activity or efficiency of yeast would be paralysed, and how far the

attenuation of worts could be pushed within six hours, which is the time limited by law for worts to be collected into the tun, from the time of beginning to run from the coolers. When worts of the gravity 1·0898 were set at 96° Fahr., with 5 per cent. of yeast, they attenuated 26·9° in 6 hours; worts of 1·0535 gravity set at 110° with 5 per cent. of yeast, attenuated 16° in about 5 hours; but when worts of 1·0533 were set, as above, at 120°, they neither fermented then, nor when allowed to cool; showing that the activity of the yeast was destroyed. When fresh yeast was now added to the last portion of worts, the attenuation became 5·8° in 2 hours, and 28·4° in 3 days; showing that the saccharine matter of the worts still retained its fermentative faculty. Malt worts, being brewed as above specified, were set in the tun, one portion at a temperature of 70°, with a gravity of 1·0939, and 5 per cent. of yeast, which attenuated 66° in 3 days; other two portions of the same gravity were set at 120° with about 10 per cent. of yeast, which underwent no fermentative change or attenuation in 6 hours, all the yeast having fallen to the bottom of the tuns. When these two samples of worts were allowed, however, to cool to from 74° to 72°, fermentation commenced, and produced in two days an attenuation of about 79°. It would appear, from these last two experimens, that yeast to the amount of 5 per cent. is so powerfully affected by strong worts heated to 120° as to have its fermentative energy destroyed; but that when yeast is added to the amount of 10 per cent., the 5 parts of excess are not permanently decomposed, but have their activity merely suspended till the saccharine liquid falls to a temperature compatible with fermentation. Yeast, according to my observations, when viewed in a good acromatic microscope, consists altogether of translucent spherical and spheroidal particles, each of about the 6000th part of an inch in diameter. When the beer in which they float is washed away with a little water, they are seen to be colourless; their yellowish tint, when they are examined directly from the fermenting square or round of a porter brewery, being due to the infusion of the brown malt. The yeast of a square newly set seems to consist of particles smaller than those of older yeast, but the difference of size is not considerable. The researches of Schulze, Cagniard de la Tour, and Schwann, appear to show, that the vinous fermentation, and the putrefaction of animal matters — processes which have been hitherto considered as belonging entirely to the domain of chemical affinity — are essentially the result of an organic development of living beings. This position seems to be established by the following experiments: —1. A matrass or flask containing a few bits of flesh, being filled up to one-third of its capacity with water, was closed with a cork, into which two slender glass tubes were cemented air-tight. Both of these tubes were passed externally through a metallic bath, kept constantly melted at a temperature approaching to that of boiling mercury. The end of one of the tubes, on emerging from the bath, was placed in communication with a gasometer. The contents of the matrass were now made to boil briskly, so that the air contained in it and the glass tubes was expelled. The matrass being then allowed to cool, a current of atmospheric air was made constantly to pass through it from the gasometer, while the metallic bath was kept constantly hot enough to decompose the living particles in the air. In these experiments, which were many times repeated, no infusoria or fungi appeared, no putrefaction took place, the flesh underwent no change, and the liquor remained as clear as it was immediately after being boiled. As it was found very troublesome to maintain the metallic bath at the melting pith, the following modification of the apparatus was adopted in subsequent researches. A flask of three ounces capacity, being one-fourth filled with water and flesh, was closed with a tight cork, secured in its place by wire. Two glass tubes were passed through the cork; the one of them was bent down, and dipped at its end into a small capsule containing quicksilver, covered with a layer of oil; the other was bent on leaving the cork, first into a horizontal direction, and downwards for an inch and a half, afterwards into a pair of spiral turns, then upwards, lastly horizontal, whence it was drawn out to a point. The pores of the cork having been filled with caoutchouc varnish, the contents of the flask were boiled till steam issued copiously from both of the glass tubes, and the quicksilver and oil also became as hot as boiling water. In order that no living particles could be generated in the water condensed beneath the oil, a few fragments of corrosive sublimate was laid upon the quicksilver. During the boiling, the flame of a spirit lamp was drawn up over the spiral part of the second glass tube, by means of a glass chimney placed over it, so as to soften the glass, while the further part of the tube was heated by another spirit lamp, to prevent its getting cracked by the condensation of the steam. After the ebullition had been kept up a quarter of an hour, the flask was allowed to cool, and get filled with air through both of the glass tubes, and the quicksilver and oil also became as hot as boiling water. In order that no living particles could be generated in the water condensed beneath the oil, a few fragments of corrosive sublimate was laid upon the quicksilver. During the boiling, the flame of a spirit lamp was drawn up over the spiral part of the second glass tube, by means of a glass chimney placed over it, so as to soften the glass, while the further part of the tube was heated by another spirit lamp, to prevent its getting cracked by the condensation of the steam. After the ebullition had been kept up a quarter of an hour, the flask was allowed to cool, and get filled with air through both of the glass tubes, and the quicksilver and oil also became as hot as boiling water. In order that no living particles could be generated in the water condensed beneath the oil, a few fragments of corrosive sublimate was laid upon the quicksilver. During the boiling, the flame of a spirit lamp was drawn up over the spiral part of the second glass tube, by means of a glass chimney placed over it, so as to soften the glass, while the further part of the tube was heated by another spirit lamp, to prevent its getting cracked by the condensation of the steam. After the ebullition had been kept up a quarter of an hour, the flask was allowed to cool, and get filled with air through the hot spiral of the second tube. When the contents were quite cold, the end of this tube was hermetically sealed, the part of it between the point and the spiral was heated strongly with the flames, and the lamps were then withdrawn. The matrass now contained nothing but

boiled flesh and gently ignited air. The air was renewed occasionally through the second tube, its spiral part being first strongly heated, its point then broken off, and connected with a gasometer, which caused the air to pass onwards slowly, and escape at the end of the first tube immersed in the quicksilver. The end of the second tube was again hermetically closed, while the part interjacent between it and the spiral was exposed to the spirit flame. By means of these precautions, decoctions of flesh were preserved during a period of six weeks, in a temperature of from 14° to 20° R. (63½° to 77° F.), without any appearance of putrefaction, infusoria, or mouldiness; on opening the vessel, however, the contents fermented in a few days, as if they had been boiled in the ordinary manner. In conducting such researches, the greatest pains must be taken to render the cork and junctions of the glass tubes perfectly air-tight. The following more convenient modification of the experiment, but one equally successful and demonstrative, was arranged by F. Schulze. The glass tubes connected with the flask were connected each with a bulb at a little distance from the cork; into one of which globes caustic alkaline lye being put, and into the other strong sulphuric acid, air was slowly sucked through the extremity of the one tube, while it entered at the other, so as to renew the atmosphere over the decoction of flesh in the flask. In another set of experiments, four flasks being filled with a solution of cane-sugar containing some beer-yeast, were corked and plunged in boiling water till they acquired its temperature. They were then taken out, inverted in a mercurial bath, uncorked, and allowed to cool in that position. From one-third to one-fourth of their volume of atmospherical air was now introduced into each of the flasks; into two of them through slender glass tubes kept red hot at a certain point, into the other two through glass tubes not heated. By analysis it was found that the air thus heated contained only 19·4 per cent. of oxygen, instead of 20·8; but, to compensate for this deficiency, a little more air was admitted into the two flasks connected with the heated tubes than into the two others. The flasks were now corked and placed in an inverted position, in a temperature of from 10° to 14° R. (54½° to 63½° F.). After a period of from four to six weeks, it was found that fermentation had taken place in both of the flasks which contained the non-ignited air—for, in loosening the corks, some of the contents were projected with force—but, in the other two flasks, there was no appearance of fermentation, either then, or in double the time. As the extract of nux vomica is known to be a poison to *infusoria* (animalcules), but not to vegetating mould, while arsenic is a poison to both, by these tests it was proved that the living particles instrumental to fermentation belonged to the order of plants of the Confervoid family. Beer yeast, according to Schwann, consists entirely of microscopic fungi, in the shape of small oval grains of a yellowish white colour, arranged in rows oblique to each other. Fresh grape must contain none of them; but after being exposed to the air at 20° R., for 36 hours, similar grains become visible in the microscope, and may be observed to grow larger in the course of an hour, or even half that time. A few hours after these plants are first perceived, gas begins to be disengaged. They multiply greatly in the course of fermentation, and at its conclusion subside to the bottom of the beer in the shape of a yellow white powder.

FERRIC ACID. This new compound having been prescribed as a source of supplying oxygen to persons confined in diving-bells and in mines, by M. Payerne, in a patent recently granted to him, merits notice in a practical work. M. Fremy is the discoverer of this new acid, which he obtains in the state of ferrate of potash, by projecting 10 parts of dry nitre in powder upon 5 parts of iron filings, ignited in a crucible; when a reddish mass, containing much ferrate of potash, is formed. The preparation succeeds best when a large crucible, capable of holding about a pint of water, is heated so strongly that the bottom and a couple of inches above it, appear faintly, but distinctly red, in which state the heat is still adequate to effect due deflagration without decomposition. An intimate mixture of about 200 grains of *dried* nitre with about one-half its weight of the finest iron filings, is to be thrown at once upon the side of the crucible. The mixture will soon swell and deflagrate. The crucible being taken from the fire, and the ignited mass being cooled, is to be taken out with an iron spoon, pounded, and immediately put into a bottle, and secluded from the air, in which it would speedily attract moisture, and be decomposed. It is resolved by the action of water, especially with heat, into oxygen gas, peroxide, and nitrate of iron.

Mr. J. D. Smith prepares the ferrate of potash by exposing to a full red heat a mixture of finely powdered peroxide of iron with four times its weight of dry nitre. It has an amethyst hue, but so deep so to appear black, except at the edges. Oxygen is rapidly evolved by the action of the sulphuric or nitric acid upon its solution. He considers the atom of iron to exist in this compound, associated with 3 atoms of oxygen, or double the proportion of that in the red oxide. Hence 52 grains of pure

ferric acid should give off 12 grains of oxygen, equal to about 35 cubic inches; but how much of the ferrate of potash may be requisite to produce a like quantity of oxygen cannot be stated, from the uncertainty of the operation by which it is produced.

FERRIC-CYANIDE OF POTASSIUM, or *Red Prussiate of Potash*. This beautiful and useful salt, discovered by L. Gmelin, is prepared by passing chlorine gas through a weak solution of the prussiate of potash (ferro-cyanide of potassium) till it ceases to affect solution of red sulphate of iron, taking care to agitate the liquid all the while, and not to add an excess of chlorine. On looking through the weak solution to the flame of a candle, one may see the period of change from the greenish to the red hue, which indicates the completion of the process. The liquor being filtered and evaporated in a dish with upright sides, will eventually afford crystalline needles, possessed of an almost metallic lustre, and a yellow colour, inclining to red. These being dissolved and re-crystallized, will become extremely beautiful. This salt is composed of 33·68 parts of potassium, 16·48 of iron, and 47·84 of cyanogen. It is therefore a dry salt. It dissolves in 38 parts of cold water, and as it forms then the most delicate test of the protoxide of iron, is very useful in *Chlorometry*.

The solution of this salt affords the following coloured precipitates with the solutions of the respective metals: —

Titanium	Brownish yellow.
Uranium	Reddish brown.
Manganese	Brownish grey.
Cobalt	Deep reddish brown.
Nickel	Yellowish brown.
Copper	Dirty yellowish brown.
Silver	Orange yellow.
Mercury	Yellow, with both the protoxide and peroxide salts.
Tin	White.
Zinc	Orange yellow.
Bismuth	Yellowish brown.
Lead	No precip.
Iron protoxide	Blue.
—— peroxide	No precip.

The ferric-cyanide of potassium has been introduced into dyeing and calico-printing.

In case an excess of chlorine has been used in preparing the above salt, Posselt recommends to add to its solution, when near the crystallizing point, a few drops of potash lye, in order to decompose a green substance that is present, which takes place with the precipitation of a little peroxide of iron.

FERROCYANATE, or, more correctly, FERROCYANIDE. (*Ferrocyanure*, Fr.; *Eisencyanid*, Germ.) Several compounds of cyanogen and metals possess the property of uniting together into double cyanides; of which there are none so remarkable in this respect, as the protocyanide of iron. This appears to be capable of combining with several simple cyanides, such as that of potassium, sodium, barium, strontium, calcium, and ammonium. The only two of these double cyanides of any importance in manufactures are those which are described under their commercial names, PRUSSIATE OF POTASH, and PRUSSIAN BLUE.

FERROPRUSSIATES; another name for Ferrocyanides.

FIBRE, VEGETABLE, called also LIGNINE; (*Ligneux*, Fr.; *Pflanzen-faserstoff*, Germ.) is the most abundant and general ingredient of plants, existing in all their parts, the root, the leaves, the stem, the flowers, and the fruit; amounting in the compact wood to 97 or 98 per cent. It is obtained in a pure state by treating saw-dust successively with hot alcohol, water, dilute muriatic acid, and weak potash lye, which, dissolve, first, the resinous; second, the extractive and saline matters; third, the carbonate and phosphate of lime; and, lastly, any residuary substances. Ligneous fibres, such as saw-dust, powdered barks, straw, hemp, flax, linen, and cotton cloth, are convertible by the action of strong sulphuric acid into a gummy substance analogous to *dextrine*, and a sugar resembling that of the grape.

If we put into a glass mortar 24 parts, by weight, of dry old cordage, chopped small, and sprinkle over it 34 parts of sulphuric acid, by degrees, so as to avoid heating the mixture, while we constantly stir it; and if, in a quarter of an hour, we triturate the mass with a glass pestle, the fibres will disappear without the disengagement of gas. A tenacious mucilage will be produced, almost entirely soluble in water. The gum being thus formed, may be separated from the acid by dilution with water, and addition of the requisite quantity of chalk; then straining the saturated liquid through linen cloth, concentrating it by evaporation, throwing down any remaining lime by oxalic

acid, filtering anew, and mixing the mucilage with alcohol in great excess, which will take up the free acid, and throw down the gum. From 24 parts of hemp fibres thus treated, fully 24 parts of a gummy mass may be obtained, containing, however, probably some water.

When, instead of saturating the diluted acid paste with chalk, we boil it for 10 hours, the gummy matter disappears, and is replaced by sugar, which may be purified without any difficulty, by saturation with chalk, filtration, and evaporation to the consistence of syrup. In 24 hours crystallization begins, and, in 2 or 3 days, a concrete mass of grape sugar is formed; which needs merely to be pressed strongly between old linen cloths doubled, and then crystallized a second time. If this syrup be treated with bone black, a brilliant white sugar will be procured. 20 parts of linen rags yield 23 of good sugar. *Braconnot.* Guerin got 87½ of dry sugar from 100 parts of rags, treated with 250 of sulphuric acid. See Wood.

FIBRINE, (Eng. and Fr.; *Thierischer Faserstoff*, Germ.) constitutes the principal part of animal muscle; it exists in the chyle, the blood, and may be regarded as the most abundant constituent of animal bodies. It may be obtained in a pure state by agitating or beating new drawn blood with a bundle of twigs, when it will attach itself to them in long reddish filaments, which may be deprived of colour by working them with the hands under a streamlet of cold water, and afterwards freed from any adhering grease by digestion in alcohol or ether.

Fibrine, thus obtained, is solid, white, flexible, slightly elastic, insipid, inodorous, denser than water, but containing 4 fifths of its weight of it, and without action on litmus. When dried, it becomes semi-transparent, yellowish, stiff, and brittle: water restores its softness and flexibility. 100 parts of fibrine consist of 53·36 carbon, 19·68 oxygen, 7·02 hydrogen, and 19·31 azote. As the basis of flesh, it is a very nutritious substance, and is essential to the sustenance of carnivorous animals.

FILE (*Lime*, Fr.; *Feile*, Germ.), is a well known steel instrument, having teeth upon the surface for cutting and abrading metal, ivory, wood, &c.

When the teeth of these instruments are formed by a straight sharp-edged chisel, extending across the surface, they are properly called files; but when by a sharp-pointed tool, in the form of a triangular pyramid, they are termed rasps. The former are used for all the metals, as well as ivory, bone, horn, and wood; the latter for wood and horn.

Files are divided into two varieties, from the form of their teeth. When the teeth are a series of sharp edges, raised by the flat chisel, appearing like parallel furrows, either at right angles to the length of the file, or in an oblique direction, they are termed *single cut*. But when these teeth are crossed by a second series of similar teeth, they are said to be *double cut*. The first are fitted for brass and copper, and are found to answer better when the teeth run in an oblique direction. The latter are suited for the harder metals, such as cast and wrought iron and steel. Such teeth present sharp angles to the substance, which penetrate it, while single cut files would slip over the surface of these metals. The double cut file is less fit for filing brass and copper, because its teeth would be very liable to become clogged with the filings.

Files are also called by different names according to their various degrees of fineness. Those of extreme roughness are called rough; the next to this is the bastard cut; the third is the second cut; the fourth, the smooth; and the finest of all, the dead smooth. The very heavy square files used for heavy smith-work, are sometimes a little coarser than the rough; they are known by the name of rubbers.

Files are also distinguished from their shape, as flat, half-round, three-square, four-square, and round. The first are sometimes of uniform breadth and thickness throughout, and sometimes tapering. The cross section is a parallelogram. The half-round is generally tapering, one side being flat, and the other rounded. The cross section is a segment of a circle, varying a little for different purposes, but seldom equal to a semicircle. The three-square generally consists of three equal sides, being equilateral prisms, mostly tapering; those which are not tapering are used for sharpening the teeth of saws. The four-square has four equal sides, the section being a square. These files are generally thickest in the middle, as is the case with the smith's rubber. In the round file, the section is a circle, and the file generally conical.

The heavier and coarser kinds of files are made from the inferior marks of blistered steel. Those made from the Russian iron, known by the name of old sable, called from its mark CCND, are excellent. The steel made from the best Swedish iron, called hoop L or Dannemora, makes the finest Lancashire files, for watch and clock makers; a manufacture for which the house of Stubbs in Warrington is celebrated.

The steel intended for files is more highly converted than for other purposes, to give them proper hardness. It should however be recollected, that if the hardness be not accompanied with a certain degree of tenacity, the teeth of the file break, and do but little service.

Small files are mostly made of cast steel, which would be the best for all others, if

it were not for its higher price. It is much harder than the blistered steel, and from having been in the fluid state, is entirely free from those seams and loose parts so common to blistered steel, which is no sounder than as it comes from the iron forge before conversion.

The smith's rubbers are generally forged in the common smith's forge, from the converted bars, which are, for convenience, made square in the iron before they come into this country. The files of lesser size are made from bars or rods, drawn down from the blistered bars, and the cast ingots, and known by the name of tilted steel.

The file-maker's forge consists of large bellows, with coak as fuel. The anvil-block, particularly at Sheffield, is one large mass of mill-stone girt. The anvil is of considerable size, set into and wedged fast into the stone; and has a projection at one end, with a hole to contain a sharp-edged tool for cutting the files from the rods. It also contains a deep groove for containing dies or bosses, for giving particular forms to the files.

The flat and square files are formed entirely by the hammer. One man holds the hot bar, and strikes with a small hammer. Another stands before the anvil with a two-handed hammer. The latter is generally very heavy, with a broad face for the large files. They both strike with such truth as to make the surface smooth and flat, without what is called hand-hammering. This arises form their great experience in the same kind of work. The expedition arising from the same cause is not less remarkable.

The half-round files are made in a boss fastened into the groove above mentioned. The steel being drawn out, is laid upon the rounded recess, and hammered till it fills the die.

The three-sided files are formed similarly in a boss, the recess of which consists of two sides, with the angle downwards. The steel is first drawn out square, and then placed in a boss with an angle downwards, so that the hammer forms one side, and the boss two. The round files are formed by a swage similar to those used by common smiths, but a little conical.

The file-cutter requires an anvil of a size greater or less, proportioned to the size of his files, with a face as even and flat as possible. The hammers weigh from one to five or six pounds. The chisels are a little broader than the file, sharpened to an angle of about 20 degrees. The length is just sufficient for them to be held fast between the finger and thumb, and so strong as not to bend with the strokes of the hammer, the intensity of which may be best conceived by the depth of the impression. The anvil is placed in the face of a strong wooden post, to which a wooden seat is attached, at a small distance below the level of the anvil's face. The file is first laid upon the bare anvil, one end projecting over the front, and the other over the back edge of the same. A leather strap now goes over each end of the file, and passes down upon each side of the block to the workman's feet, which, being put into the strap on each side, like a stirrup, holds the file firmly upon the anvil as it is cut. While the point of the file is cutting, the strap passes over one part of the file only, the point resting upon the anvil, and the tang upon a prop on the other side of the strap. When one side of the file is single cut, a fine file is run slightly over the teeth, to take away the roughness; when they are to be double cut, another set of teeth is cut, crossing the former nearly at right angles. The file is now finished upon one side, and it is evident that the cut side cannot be laid upon the bare anvil to cut the other. A flat piece of an alloy of lead and tin is interposed between the toothed surface and the anvil, while the other side is cut, which completely preserves the side already formed. Similar pieces of lead and tin, with angular and rounded grooves, are used for cutting triangular and half-round files.

Rasps are cut precisely in the same way, by using a triangular punch instead of a flat chisel. The great art in cutting a rasp is to place every new tooth as much as possible opposite to a vacancy.

Many abortive attempts have been made to cut the teeth of files by machinery. The following plan, for which a patent was obtained by Mr. William Shilton, of Birmingham, in April 1833, is replete with ingenious mechanical resources, and deserves to succeed.

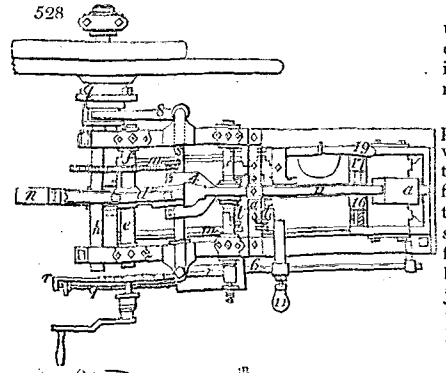
The blanks of steel for making the files and rasps, are held in a pair of clamps in connexion with a slide, and are moved forward at intervals under the head of the tilt hammer which carries the tool; the distance which the blank is to be advanced at every movement being dependent upon the required fineness or coarseness of the cut of the file, which movement is effected and regulated by a rack and pinion, actuated by a pall and ratchet wheel, or the movement may be produced by any other convenient means.

When the machine is employed for cutting or indenting the teeth of rasps, the cutting tool being pointed and only producing one tooth at a blow, the tilt hammer carrying the tool must be made to traverse at intervals across the width of the blank piece of steel

from one edge to the other and back again; the blank being advanced in length only when the hammer has produced the last cut or tooth toward either edge of the rasp.

In order to render this invention better understood, two views of the apparatus for producing the cross-cut or teeth of the files, are given.

528



527

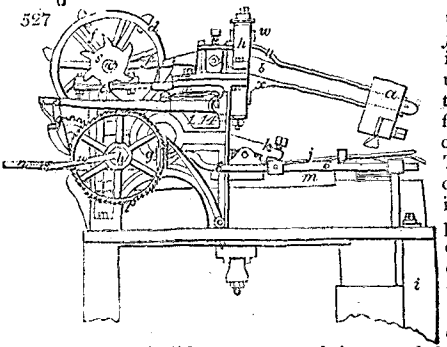


Fig. 527. is an elevation of the upper part of the file-cutting machine, as seen on one side; *fig.* 528. is a plan or horizontal view, as the machine appears on the top.

a, is the head of the tilt hammer placed in the end of the lever *b*, which is mounted on an axle *c*, turning in proper bearings in the frame work of the machine; *d*, is the tilt wheel mounted on another axle *s*, also turning in bearings on the frame work of the machine, and having any required number of projections or tappets upon it for depressing the tail or shorter end of the hammer or tilt lever *b*.

The tilt wheel *d*, receives its rotatory motion from the toothed wheel *f*, mounted upon the same axle, and it takes into geer with a pinion *g*, upon the main shaft *h*, which is actuated by a band passed from any first mover to the rigger on its end, or in any other convenient manner. The bed upon which the blank piece of steel bears is marked *i*. This bed is firmly supported upon masonry placed upon proper sleepers: *j*, is one of the blank pieces of steel under operation, and is shown secured in the pair of jaws or holding clamps *k*, mounted on centre pins in the slide *l*, *fig.* 528.; which slide is held down by a spring and slide beneath, and is moved backwards and forwards in the machine upon the (v) edges *m*, *m*, of the frame, by means of the rack *n*, and its pinion; the latter being mounted upon the axle of the ratchet wheel *p*, and which ratchet wheel is made to turn at intervals by means of the pall *q*, upon the end of the lever *r*, *fig.* 528. This lever is depressed, after every cut has been effected upon the blank by means of the teeth or tappets of the wheel *s*, coming in contact with the inclined plane *t*, upon the lever *r*. The tappet wheel *s*, is mounted upon the end of the axle *e*, of the tilt wheel, and consequently revolves with it, and by depressing the lever *r*, every time that a tooth passes the inclined plane *t*, the click *q*, is made to drive the ratchet wheel *p*, and thereby the advancing movement of the blank is effected after each blow of the tilt hammer.

There is a strong spring *u*, attached to the upper side of the tilt hammer, its end being confined under an adjustable inclined plane *v*, mounted in the frame *w*, which inclined plane can be raised or lowered by its adjusting screws as required, to produce more or less tension ot the spring.

A similar spring is placed on the under side of the tilt hammer, to raise and sustain the cutter or tool clear of the bed after every blow, and in conjunction with safety holders or catchers, to counteract any vibration or tendency the spring *u*, may have to cause the hammer to reiterate the blow.

The end of the lower spring acts on an inclined plane, mounted in the frame *w*, which has an adjusting screw similar to *v*, to regulate the tension of the spring.

In case the under spring should raise, that is, return the hammer, with sufficient force or velocity to cause the top spring *u*, to reiterate the blow, the ends of the safety holders or catchers are made to move under and catch the tail of the lever *b*, immediately on its being raised by the under springs, which is effected by the following means:—The holders are mounted upon a plate or carriage 1, *fig.* 527., which turns upon a small pin or axle mounted in the ears of a cross bar; the upper ends of the holders are kept inclined towards the tail of the tilt hammer by means of a spring fixed to the cross bar, and which acts upon one end of the plate or carriage 1.

In order that the holders may be removed out of the way of the tail of the hammer *b*, when the tilt wheel is about to effect a blow, the tooth of the tilt wheel which last acted upon the hammer comes in contact with an inclined plane fixed on the plate or carriage 1, and by depressing that end of the plate, causes the upper ends of the holders to be withdrawn from under the tail of the hammer *b*. The tilt wheel continuing to revolve, the next tooth advances, and depresses the tail of the hammer, but before it leaves the tail of the hammer, the tooth last in operation will have quitted the inclined plane and allowed the spring to return the holders into their former position. After the tooth has escaped from the tail of *b*, the hammer will immediately descend and effect the blow or cut on the blank, and as the tail of the hammer rises, it will come in contact with the inclined planes at the upper ends of the holders, and force them backwards; and as soon as the tail of the hammer has passed the top of the holders, the spring will immediately force the holders forward under the tail of the hammer, and prevent the hammer rising again until the next tooth of the tilt wheel is about to depress the end of the hammer, when the same movements of the parts will be repeated, and the machine will continue in operation until a sufficient length of the blank of steel (progressively advanced under the hammer) has been operated upon, when it will be thrown out of geer by the following means:—

Upon the sliding bar 6, there is placed an adjustable stop, against which the foremost end of the slide *l l*, *fig.* 528. comes in contact, as it is moved forward by the rack *n*, and its pinion. The sliding bar 6, is connected at its left end to the bent lever 8, the other end of this lever being formed into a forked arm, which embraces a clutch upon the main shaft, and as the slide *l* continues to advance, it will come in contact with a stop; and when it has brought a sufficient length of the blank pieces of steel under the operation of the cutting tool, the slide *l*, in its progress, will have moved that stop and the bar 6 forward, and that bar, by means of the bent lever 8, will withdraw the clutch on the main shaft, from locking into the boss of the fly-wheel, and consequently stop the further progress of the machine; the rigger and fly-wheel turning loosely upon the main shaft.

The cut file can now be removed from out of the clamps, and reversed to cut the other side, or another blank piece put in its place; and after throwing back the pall *q* of the ratchet wheel *p*, the slide *l*, and with it the fresh blank may be moved back into the machine by turning the winch handle, on the axle of the ratchet wheel *p*, the reverse way, which will turn the pinion backwards, and draw back the rack *n*, without affecting any other parts of the machine; and on moving back the bar 6, by the handle 11, placed on the stop, the clutches will be thrown into geer again, and the machine proceed to cut the next blank.

When the blanks have been thus cut on one side, and are reversed in the machine to form the teeth upon the other side, there should be a piece of lead placed between the blank and the bed to protect the fresh cut teeth.

It will be seen that the position of the stop upon the bar 6, will determine the length or extent of the blank piece of steel which shall be cut or operated upon; and in order that the progressive movement of the blanks under the cutting tool may be made to suit different degrees of fineness or coarseness of the teeth (that is the distance between the cuts), there is an adjusting screw upon the lever *r*, the head of which screw stops against the under side of an ear projecting from the frame-work, and thereby determines the extent of the motion of the lever *r*, when depressed by the tappets of the wheel *s*, acting upon the inclined plane *t*, consequently determining the number of teeth the ratchet wheel *p* shall be moved round by the pall *q*; and hence the extent of motion communicated by the rack and pinion to the slide *l*, and the blank *j*, which regulates the distance that the teeth of the file are apart, and the lever *r* is forced upwards by a spring pressing against its under side.

It will be perceived that the velocity of the descent of the hammer, and consequently the force of the blow, may be regulated by raising or lowering the inclined plane *v* of the spring *u*; and in order to accommodate the bed upon which the blanks rest to the different inclinations they may be placed at, that part of the bed is formed of a semi-globular piece of hardened steel, which fits loosely into a similar concavity in the bed *r*, and is therefore capable of adjusting itself, so that the blanks shall be properly presented to the cutting tool, and receive the blow or cut in an equal and even manner; or the piece of steel may be of a conical shape, and fit loosely in a similar shaped concavity.

There are guides 16, placed on the top of the bed *i*, for the purpose of keeping the blanks in their proper position towards the cutting tool, and these can be regulated to suit blanks of any width, by turning the right and left handed screw 17. There is also another adjustable stop on the jaws or clamps *k* which serves as a guide when placing the blanks within the jaws: and 19 is a handle or lever for raising the clamps when required, which has a weight suspended from it for the purpose of keeping down the blanks with sufficient pressure upon the bed.

The cutting tool in the face of the hammer, can be placed at any required angle or

inclination with the blank, it being secured in the head of the hammer by clamps and screws. In cutting fine files a screw is employed in preference to the rack and pinion, for advancing the slide *l*, and the blank piece of steel in the machine.

Hardening of files. — This is the last and most important part of file making. Whatever may be the quality of the steel, or however excellent the workmanship, if it is not well hardened all the labour is lost.

Three things are strictly to be observed in hardening; first, to prepare the file on the surface, so as to prevent it from being oxidated by the atmosphere when the file is red hot, which effect would not only take off the sharpness of the tooth, but render the whole surface so rough that the file would, in a little time, become clogged with the substance it had to work. Secondly, the heat ought to be very uniformly red throughout, and the water in which it is quenched, fresh and cold, for the purpose of giving it the proper degree of hardness. Lastly, the manner of immersion is of great importance, to prevent the files from warping, which in long thin files is very difficult.

The first object is accomplished by laying a substance upon the file, which when it fuses, forms as it were, a varnish upon the surface, defending the metal from the action of the oxygen of the air. Formerly the process consisted in first coating the surface of the file with ale grounds, and then covering it over with pulverized common salt, (muriate of soda.) After this coating became dry, the files were heated red hot, and hardened; after this, the surface was lightly brushed over with the dust of cokes, when it appeared white and metallic, as if it had not been heated. This process has lately been improved, at least so far as relates to the economy of the salt, which from the quantity used, and the increased thickness, had become a serious object. Those who use the improved method are now consuming about one fourth the quantity of salt used in the old method. The process consists in dissolving the salt in water to saturation, which is about three pounds to the gallon, and stiffening it with ale grounds, or with the cheapest kind of flour, such as that of beans, to about the consistence of thick cream. The files require to be dipped only into this substance, and immediately heated and hardened. The grounds or the flour are of no other use, than to give the mass consistence, and by that means to allow a larger quantity of salt to be laid upon the surface. In this method, the salt forms immediately a firm coating. As soon as the water is evaporated, the whole of it becomes fused upon the file. In the old method the dry salt was so loosely attached to the file, that the greatest part of it was rubbed off into the fire, and was sublimed up the chimney, without producing any effect.

The carbonaceous matter of the ale grounds is supposed to have some effect in giving hardness to the file, by combining with the steel, and rendering it more highly carbonated. It will be found, however, upon experiment, that vegetable carbon does not combine with iron, with sufficient facility to produce any effect, in the short space of time a file is heating, for the purpose of hardening. Some file makers are in the habit of using the coal of burnt leather, which doubtless produces some effect; but the carbon is generally so ill prepared for the purpose, and the time of its operation so short, as to render the result inconsiderable. Animal carbon, when properly prepared and mixed, with the above hardening composition, is capable of giving hardness to the surface even of an iron file.

This carbonaceous matter may be readily obtained from any of the soft parts of animals, or from blood. For this purpose, however, the refuse of shoemakers and curriers is the most convenient. After the volatile parts have been distilled over, from an iron still, a bright shining coal is left behind, which, when reduced to powder, is fit to mix with the salt. Let about equal parts, by bulk, of this powder, and muriate of soda be ground together, and brought to the consistence of cream, by the addition of water. Or mix the powdered carbon with a saturated solution of the salt, till it become of the above consistence. Files which are intended to be very hard, should be covered with this composition, previous to hardening. All files intended to file iron or steel, particularly saw files, should be hardened with the aid of this mixture, in preference to that with the flour or grounds. Indeed, it is probable, that the carbonaceous powder might be used by itself, in point of economy, since the ammonia or hartshorn, obtained by distillation, would be of such value as to render the coal of no expense. By means of this method the files made of iron, which, in itself, is unsusceptible of hardening, acquire a superficial hardness sufficient for any file whatever. Such files may, at the same time, be bent into any form; and, in consequence, are particularly useful for sculptors and die-sinkers.

The next point to be considered is the best method of heating the file for hardening. For this purpose a fire, similar to the common smiths' fire, is generally employed. The file is held in a pair of tongs by the tang, and introduced into the fire, consisting of very small cokes, pushing it more or less into the fire for the purpose of heating it regularly. It must frequently be withdrawn with the view of observing that it is not too hot in any part. When it is uniformly heated, from the tang to the point, of a

cherry red colour, it is fit to quench in the water. At present an oven, formed of fire-bricks, is used for the larger files, into which the blast of the bellows is directed, being open at one end, for the purpose of introducing the files and the fuel. Near to the top of the oven are placed two cross bars, on which a few files are placed, to be partially heating. In the hardening of heavy files, this contrivance affords a considerable saving, in point of time, while it permits them also to be more uniformly and thoroughly heated.

After the file is properly heated for the purpose of hardening, in order to produce the greatest possible hardness, it should be cooled as soon as possible. The most common method of effecting this is by quenching it in the coldest water. Some file-makers have been in the habit of putting different substances in their water, with a view to increase its hardening property. The addition of sulphuric acid to the water was long held a great secret in the hardening of saw files. After all, however, it will be found, that clear spring water, free from animal and vegetable matter, and as cold as possible, is the best calculated for hardening files of every description.

In quenching the files in water, some caution must be observed. All files, except the half-round, should be immersed perpendicularly, as quickly as possible, so that the upper part shall not cool. This management prevents the file from warping. The half-round file must be quenched in the same steady manner; but, at the same time that it is kept perpendicular to the surface of the water, it must be moved a little horizontally, in the direction of the round side, otherwise it will become crooked backwards.

After the files are hardened, they are brushed over with water, and powdered cokes, when the surface becomes perfectly clean and metallic. They ought also to be washed well in two or three clean waters, for the purpose of carrying off all the salt, which, if allowed to remain, will be liable to rust the file. They should moreover be dipped into lime-water, and rapidly dried before the fire, after being oiled with olive oil, containing a little oil of turpentine, while still warm. They are then finished.

FILLIGREE (*Filigrane*, Fr.; *Filigran*, or *Feine Drahtgeflecht*, Germ.); is, as the last term justly expresses it, intertwisted fine wire, used for ornamenting gold and silver trinkets. The wire is seldom drawn round, but generally flat or angular; and soldered by gold or silver solder with borax and the blowpipe. The Italian word, *filigrana*, is compounded of *filum* and *granum*, or granular net-work; because the Italians, who first introduced this style of work, placed small beads upon it.

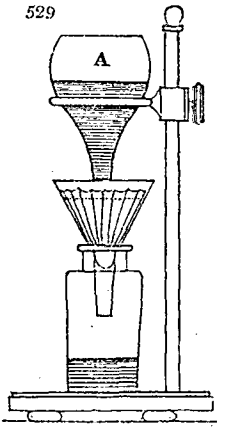
FILTRATION (Eng. and Fr.; *Filtriren*, Germ.), is a process purely mechanical, for separating a liquid from the undissolved particles floating in it, which liquid may be either the useful part, as in vegetable infusions, or of no use, as the washings of mineral precipitates. The filtering substance may consist of any porous matter in a solid, foliated, or pulverulent form; as porous earthen ware, unsized paper, cloth of many kinds, or sand. The white blotting paper sold by the stationers answers extremely well for filters in chemical experiments, provided it be previously washed with dilute muriatic acid, to remove some lime and iron that are generally present in it. Filter papers are first cut square, and then folded twice diagonally into the shape of a cornet, having the angular parts rounded off. Or the piece of paper being cut into a circle, may be folded fan-like from the centre, with the folds placed exteriorly, and turned out sharp by the pressure of the finger and thumb, to keep intervals between the paper and the funnel into which it is fitted, to favour the percolation. The diameter of the funnel should be about three-fourths of its height, measured from the neck to the edge. If it be more divergent, the slope will be too small for the ready efflux of the fluid. A filter covered with the sediment is most conveniently washed by spouting water upon it with a little syringe. A small camel's-hair paint brush is much employed for collecting and turning over the contents in their soft state. Agitation or vibration is of singular efficacy in quickening percolation, as it displaces the particles of the moistened powders, and opens up the pores which had become closed. Instead of a funnel, a cylindrical vessel may be employed, having its perforated bottom covered with a disc of filtering powder folded up at the edges, and made tight there by a wire ring. Linen or calico is used for weak alkaline liquors; and flannels, twilled woollen cloth, or felt-stuff for weak acid ones. These filter bags are often made conical like a fool's cap, and have their mouths supported by a wooden or metallic hoop. Cotton wool put loose into the neck of a funnel answers well for filtering oils upon the small scale. In the large way, oil is filtered in conical woollen bags, or in a cask with many conical tubes in its bottom, filled with tow or cotton wool. Stronger acid and alkaline liquors must be filtered through a layer of pounded glass, quartz, clean sand, or bruised charcoal. The alcarrhazas are a porous biscuit of stone ware made in Spain, which are convenient for filtering water, as also the porous filtering stone of Teneriffe, largely imported into England at one time, but now superseded in a great measure by the artificial filters patented under many forms, consisting essentially of strata of gravel, sand, and charcoal powder.

It is convenient to render the filter self-acting, by accommodating the supply of liquid

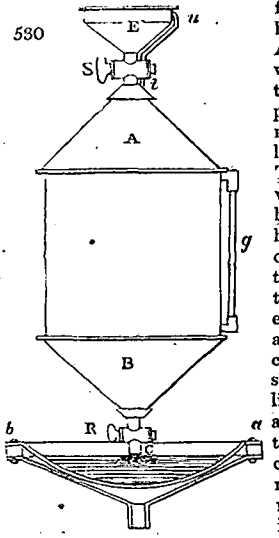
to the rate of percolation, so that the pressure upon the porous surface may be always equally great. Upon the small scale, the lamp-fountain or bird's-glass form so generally used for lamps, will be found to answer.

Fig. 529. represents a glass bottle A, partly filled with the fluid to be filtered, supported in the ring of a chemical stand, and having its mouth inverted into the same liquor in the filter funnel. It is obvious, that whenever this liquor by filtration falls below the lip of the bottle, air will enter into it, let down a fresh supply to feed the filter, and keep the funnel regularly charged. If larger quantities are to be operated upon, the following apparatus may be employed. *Fig.* 530.

529



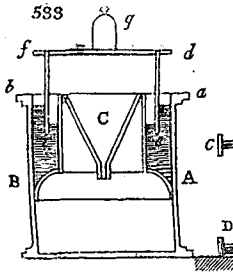
530



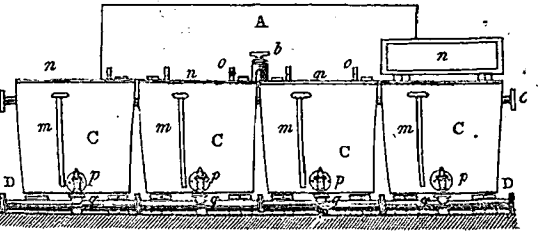
A B is a metallic vessel which may be made air-tight; c is the under pipe provided with a stopcock R, for letting down the liquor into the filter *a b*. The upper pipe *t*, through which the fluid is poured by means of the funnel E, has also a stopcock which opens or shuts, at the same time, the small side tube *u t*, through which, during the entrance of the fluid, the air is let off from the receiver. A glass tube *g*, shows the level of the liquor in the body of the apparatus. In using it, the cock R must be first closed, and the cock S must be opened to fill the receiver. Then the filter is set a going, by re-opening the cock R, so as to keep the fluid in the filter upon a level with the opening of the tube c. Both these pieces of apparatus are essentially the same.

In many manufactures, self-acting filters are fed by the plumber's common con-

533

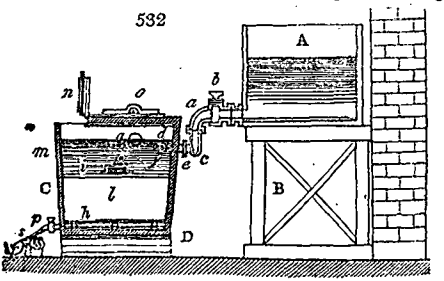


531



trivance of a ball-cock in which the sinking and rising of the ball, within certain limits, serves to open or shut off the supply of liquor, as it may be required or not. Dumont has adopted this expedient for his system of filtering syrup through a stratum of granularly ground animal charcoal or bone-black. *Fig.* 531. is a front view of this apparatus with 4 filters c; and *fig.* 532. is a cross section. The framework B supports the cistern A, in which the syrup is contained. From it the liquor flows through the stop-cock

532



b, and the connection-tube *a*, into the common pipe *c*, which communicates, by the short branch tubes *e*, with each of the four filters. The end of the branch tube, which is inside of the filter tub, is provided with a stopcock *d f*, whose opening, and thereby the efflux of the liquor from the cistern through the tube *a*, is regulated by means of the float-ball *g*. Upon the brickwork D the filter tub stands, furnished at *h* with a false bottom of zinc or copper pierced with fine holes; besides which, higher up at *i* there is another such plate of metal furnished with a strong handle *k*, by which it may be removed, when the bone-black needs to be changed. In the intervening space *l*, the granular coal is placed. *o* is the cover of the filter tub, with a handle also for lifting it. One portion of it may be raised by a hinge, when it is desired to inspect the progress of the filtration within. *m m* is a slender vertical tube, forming a communication between the bottom part *h*, and the upper portion of the filter, to admit of the easy escape of the air from that space, and from among the bone-black as the syrup descends; otherwise the filtration could not go on. *p* is the stopcock through which the fluid collected in the space under *h* is let off from time to time into the common pipe *q*, *fig.* 531. *r* is a trickling channel or groove lying parallel to the tube *q*, and in which, by means of a tube *s*, inserted at pleasure, the syrup is drawn off in case of its flowing in a turbid state, when it must be returned over the surface of the charcoal.

The celerity with which any fluid passes through the filter depends, 1. upon the porosity of the filtering substance; 2. upon the pressure exercised upon it; and 3. upon the extent of the filtering surface. Fine powders in a liquor somewhat glutinous, or closely compacted, admit of much slower filtration than those which are coarse and free; and the former ought, therefore, to be spread in a thinner stratum and over a more extensive surface than the latter, for equal effect; a principle well exemplified in the working of Dumont's apparatus, just described.

In many cases filtration may be accelerated by the increase of hydrostatic or pneumatic pressure. This happens when we close the top of a filtering cylinder, and connect it by a pipe with a cistern of fluid placed upon a higher level. The pressure of the air may be rendered operative also either by withdrawing it partially from a close vessel, into which the bottom of the filter enters, or by increasing its density over the top of the liquor to be filtered. Either the air pump or steam may be employed to create a partial void in the receiver beneath the filter. In like manner, a forcing pump or steam may be employed to exert pressure upon the surface of the filtering liquor. A common syphon may, on the same principle, be made a good pressure filter, by making its upper leg trumpet-shaped, covering the orifice with filter paper or cloth, and filling the whole with liquor, the lower leg being of such length so as to create considerable pressure by the difference of hydrostatic level. This apparatus is very convenient either on the small or great scale, for filtering off a clear fluid from a light muddy sediment. The pressure of the atmosphere may be elegantly applied to common filters, by the apparatus represented in *fig.* 533., which is merely a funnel inclosed within a gasometer. The case A B bears an annular hollow vessel *a b*, filled with water, in which receiver the cylindrical gasometer *d, e, f, i*, is immersed. The filter funnel c is secured at its upper edge to the inner surface of the annular vessel *a b*. In consequence of the pressure of the gasometer regulated by the weight *g*, upon the air inclosed within it, the liquid is equally pressed, and the water in the annular space rises to a corresponding height on the outer surface of the gasometer, as shown in the figure. Were the apparatus made of sheet iron, the annular space might be charged with mercury.

In general, relatively to the application of pressure to filters, it may be remarked, that it cannot be pushed very far, without the chance of deranging the apparatus, or rendering the filtered liquor muddy. The enlargement of the surface is, generally speaking, the safest and most efficacious plan of increasing the rapidity of filtration, especially for liquids of a glutinous nature. This expedient is well illustrated in the creased bag filter now in use in most of the sugar refineries of London. See SUGAR.

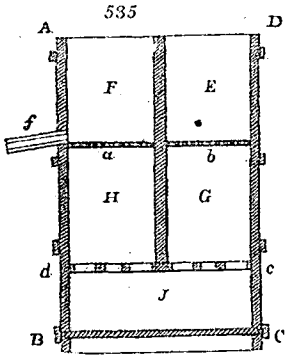
In many cases it is convenient so to construct the filtering apparatus, as that the liquid shall not descend, but mount by hydrostatic pressure. This method has two advantages: 1. that without much expensive apparatus, any desired degree of hydrostatic pressure may be given, as also that the liquid may be forced up through several filtering surfaces placed alongside of each other; 2. that the object of filtering, which is to separate the particles floating in the fluid without disturbing the sediment, may be perfectly attained, and thus very foul liquids be cleared without greatly soiling the filtering surface.

Such a construction is peculiarly applicable to the purification of water, either alone, or combined with the downwards plan of filtration. Of the former variety an example is shown in *fig.* 534. The wooden or zinc conical vessel is provided with two perforated bottoms or sieves *e e*, betwixt which the filtering substance is packed. Over this, for the formation of the space *h h*, there is a third shelf, with a hole in its middle, through which the tube *d b* is passed, so as to be water tight. This places the upper

open part of the apparatus in communication with the lowest space *a*. From the compartment *h h* a small air tube *l* runs upwards. The filtering substance consists at bottom of pebbles, in the middle of gravel, and at the top of fine sand, which may be mixed with coarsely ground bone-black, or covered with a layer of the same. The water to be filtered being poured into the cistern at top, fills through the tube *b d* the inferior compartment *a*, from which the hydrostatic pressure forces the water upward through the perforated shelf, and the filtering materials. The pure water collects in the space *h h*, while the air escapes by the small tube *l*, as the liquid enters. The stopcock *i* serves to draw off the filtered water. As the motion of the fluid in the filter is slow, the particles suspended in it have time to subside by their own gravity; hence there collects over the upper shelf at *d*, as well as over the under one at *a*, a precipitate or deposit which may be washed out of the latter cavity by means of the stopcock *m*.

As an example of an upwards and downwards filter, *fig. 535.* may be exhibited. A B C D is a wooden or metallic cistern furnished with the perforated shelf *c d* near its under part, upon which a vertical partition is fixed through the axis of the vessel. A semicircular perforated shelf is placed at *a*, and a second similar one at *b*. These horizontal shelves rest upon brackets in the sides of the cisterns, so that they may be readily lifted out. The space G is filled with coarse sand, J with moderately fine, and H with very fine. The foul water is poured into the chamber E, and presses through G J H and into the space F; whence it may be drawn by the stopcock *f*.

535



534

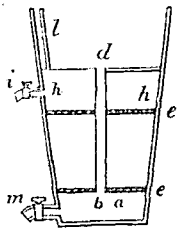


Fig. 536 represents in section a filtering apparatus consisting of two concentric chambers; the interior being destined for downwards filtration, and the exterior for upwards. Within the larger cistern A, a smaller one B is placed concentrically, with its under part, and is left open from distance to distance, to make a communication between the interior cavity and the exterior annular space. These cavities are filled to the marked height with sand and gravel. The inner cylindrical space has fine sand below, then sharper sand with granular charcoal, next coarse sand, and lastly gravel. The annular space has in like manner fine sand below. The foul water is introduced by the pipe E, the orifice at whose end is acted upon by a ball-cock with its lever *a*; whereby the water is kept always at the same level in the inner vessel. The water sinks through the sand strata of the middle vessel, passes outwards at its bottom into the annular space, thence up through the sand in it, and collecting above it, is let off by the stopcock on the pipe *b*. When a muddy deposit forms after some time, it may be easily cleared out. The cord *e*, running over the pulleys *f f*, being drawn tight, the ball lever will shut up the valve. The stopcock *d* made fast to the conducting tube E must then be opened, so that the water now overflows into the annular space at A; the tube *c*, in communication with the inner space B, being opened by taking out the stopper *h*. The water thereby percolates through the sand strata in the reverse direction of its usual course, so as to clear away the impurities in the space B, and to discharge them by the pipe *c h*. An apparatus of this kind of moderate size is capable of filtering a great body of water. It should be constructed for that purpose of masonry; but upon a small scale it may be made of stone-ware.

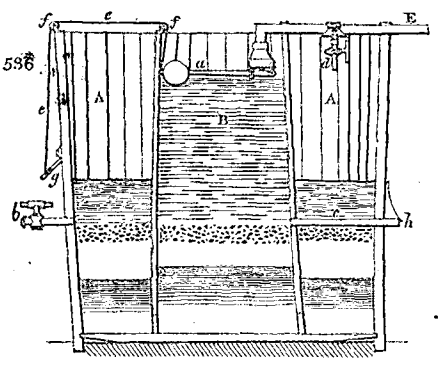
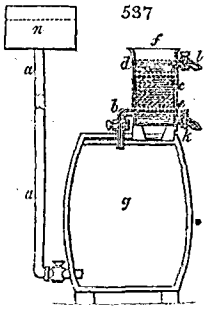
536



A convenient apparatus for filtering oil upwards is represented in *fig. 537*. *g* is an oil cask, in which the impure parts of the oil have accumulated over the bottom. Immediately above this, a pipe *a* is let in, which communicates with an elevated water cistern

n. *f* is the filter, (placed on the lid of the cask) furnished with two perforated shelves, one at *e* and another at *d*; which divide the interior of the filter into three compartments. Into the lower space immediately over the shelf *e*, the tube *b*, furnished with a stopcock enters, to establish a communication with the cask; the middle cavity *c* is filled with coarsely ground charcoal or other filtering materials; and the upper one has an eduction pipe *l*. When the stopcocks of the tubes *a* and *b* are opened, the water passes from the cistern into the oil cask, occupies from its density always the lowest place, and presses the oil upwards, without mixing the two liquids; whereby first the upper and purer portion of the oil is forced through tube *b* into the filter, and thence out through the pipe *l*. When the fouler oil follows, it deposits its impurities in the space under the partition *e*, which may from time to time be drawn off through the stopcock *k*, while the purer oil is pressed upwards through the filter. In this way the different strata of oil in the cask may be filtered off in succession, and kept separate, if found necessary for sale or use, without running any risk of mixing up the muddy matter with what is clear. According to the height of the water cistern *n*, will be the pressure, and of course the filtering force. When the filter gets choked with dirt, it may be easily re-charged with fresh materials.

537



In filtering caustic alkaline lyes through linen or quartz, it is proper to exclude the free contact of air; which is done by inclosing the upper vessel, and attaching a pipe of communication between its cover, and the shoulder of the lower vessel, or recipient of the lyes. In proportion as these flow down, they will displace their bulk of air, and drive it into the top of the upper vessel above the foul lyes.

Many modifications of the above described apparatus are now on sale in this country; but certainly the neatest, most economical, and effective means of transforming the water of a stagnant muddy pool, into that of a crystalline fountain, is afforded by the Royal Patent Filters of George Robins.

FIRE ARMS, MANUFACTURE OF. This art is divided into two branches, that of the metallic and of the wooden work. The first includes the barrel, the lock, and the mounting, as also the bayonet and ramrod, with military arms. The second comprises the stock, and in fowling pieces, likewise the ramrod.

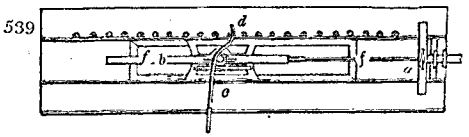
1. *The Barrel.* Its interior is called the bore; its diameter, the calibre; the back end, the breech; the front end, the muzzle; and the closing of the back end, the breech pin or plug. The barrel is generally made of iron. Most military musquets and low-priced guns are fashioned out of a long slip of sheet-iron folded together edge-wise round a skewer into a cylinder, are then lapped over at the seam, and welded at a white heat. The most ductile and tenacious soft iron, free from all blemishes, must be selected for this slip. It is frequently welded at the common forge, but a proper air-furnace answers better, not being so apt to burn it. It should be covered with ashes or cinders. The shape of the bore is given by hammering the cylinder upon a steel mandril, in a groove of the anvil. Six inches of the barrel at either end are left open for forming the breech and the muzzle by a subsequent welding operation; the extremity put into the fire being stopped with clay, to prevent the introduction of cinders. For every length of two inches, there are from two to three welding operations, divided into alternating high and low heats; the latter being intended to correct the defects of the former. The breech and muzzle are not welded upon the mandril, but upon the horn of the anvil; the breech being thicker in the metal, is more highly heated, and is made somewhat wider to save labour to the borer. The barrel is finally hammered in the groove of the anvil without the mandril, during which process it receives a heat every two minutes. In welding, the barrel extends about one-third in length; and for musquets, is eventually left from 3 to 3½ feet long; but for cavalry pistols, only 9 inches.

The best iron plates for gun-barrels are those made of *stub* iron, that is of old horse-shoe nails welded together, and forged into thin bars, or rather narrow ribands. At one time *damascus* barrels were much in vogue; they were fashioned either as above described, from plates made of bars of iron and steel laid parallel, and welded together, or from ribands of the same damascus stuff coiled into a cylinder at a red heat, and then welded together at the seams. The best modern barrels for fowling pieces are constructed of stub-nail iron in this manner. The slip or fillet is only half an inch broad or sometimes less, and is left thicker at the end which is to form the breech, and thinner at the end which is to form the muzzle, than in the intermediate portion. This fillet being moderately heated to increase its pliancy, is then lapped round the mandril in a spiral direction till a proper length of cylinder is formed; the edges being made to overlap a little in order to give them a better hold in the welding process. The coil

being taken off the mandril and again heated, is struck down vertically with its muzzle end upon the anvil, whereby the spiral junctions are made closer and more uniform. It is now welded at several successive heats, hammered by horizontal strokes, called *jumping*, and brought into proper shape on the mandril. The finer barrels are made of still narrower stub-iron slips, whence they get the name of wire twist. On the Continent, barrels are made of steel wire, welded together lengthwise, then coiled spirally into a cylinder. Barrels that are to be rifled, require to be made of thicker iron, and that of the very best quality, for they would be spoiled by the least portion of scale upon their inside. Soldiers' musquets are thickened a little at the muzzle, to give a stout holding to the bayonet.

The barrels thus made are annealed with a gentle heat in a proper furnace, and slowly cooled. They are now ready for the borer, which is an oblong square *bit* of steel, pressed in its rotation against the barrel, by a slip of wood applied to one of its flat sides, and held in its place by a ring of metal. The boring bench works horizontally, and has a very shaky appearance, in respect at least of the bit. In some cases, however, it has been attempted to work the barrels and bits at an inclination to the horizon of 30°, in order to facilitate the discharge of the borings. The barrel is held in a slot by only one point, to allow it to humour the movements of the borer, which would otherwise be infallibly broken. The bit, as represented in *fig.* 538., has merely its square head inserted into a clamp-chuck of the lathe, and plays freely through the rest of its length.

538



539

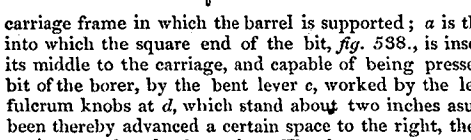


Fig 539. represents in plan the *boring bench* for musquet barrels; *f f* is the sledge or carriage frame in which the barrel is supported; *a* is the revolving chuck of the lathe, into which the square end of the bit, *fig.* 538., is inserted; *b* is the barrel, clamped at its middle to the carriage, and capable of being pressed onwards against the tapering bit of the borer, by the bent lever *c*, worked by the left hand of the operative against fulcrum knobs at *d*, which stand about two inches asunder. Whenever the barrel has been thereby advanced a certain space to the right, the bent end of the lever is shifted against another knob or pin. The borer appears to a stranger to be a very awkward and unsteady mechanism, but its perpetual vibrations do not affect the accuracy of the bore. The opening broach may be of a square or pentagonal form; and either gradually tapered from its thickest part, or of uniform diameter till within two inches of the end, whence it is suddenly tapered to a point.

A series of bits may be used for boring a barrel, beginning with the smallest and ending with the largest. But this multiplication of tools becomes unnecessary, by laying against the cutting part of the bit, slips of wood, called *spales*, of gradually increasing thickness, so that the edge is pressed by them progressively further from the axis. The bore is next polished. This is done by a bit with a very smooth edge, which is mounted as above, with a wedge of wood besmeared with a mixture of oil and emery. The inside is finished by working a cylindrical steel file quickly backwards and forwards within it, while it is revolving slowly.

In boring, the bit must be well oiled or greased, and the barrel must be kept cool by letting water trickle on it; for the bit, revolving at the rate of 120 or 140 times a minute, generates a great deal of heat. If a flaw be detected in the barrel during the boring, that part is hammered in, and then the bit is employed to turn it out.

Many sportsmen are of opinion that a barrel with a bore somewhat narrowed towards the muzzle serves to keep shot better together; and that roughening its inside with pounded glass has a good effect, with the same view. For this purpose, also, fine spiral lines have been made in their interior surface. The justness of its calibre is tried by means of a truly turned cylinder of steel, 3 or 4 inches long, which ought to move without friction, but with uniform contact from end to end of the barrel. Whatever irregularities appear must be immediately removed.

The outer surface of the barrel is commonly polished upon a dry grindstone, but it is better finished, and less dangerously to the workman, at a turning lathe with a slide rest. If a stone be used, it should be made to revolve at the mouth of a tunnel of some kind, into which there is a good draught to carry off the ferruginous particles. A piece of moist cloth or leather should be suspended before the orifice.

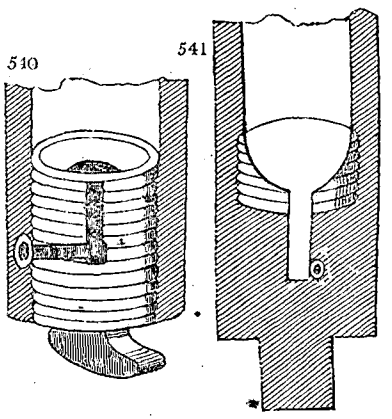
Rifle barrels have parallel grooves of a square or angular form cut within them, each groove being drawn in succession. These grooves run spirally, and form each an aliquot part of a revolution from the chamber to the muzzle. Rifles should not be too deeply indented; only so much as to prevent the ball turning round within the barrel,

and the spires should be truly parallel, that the ball may glide along with a regular pace. See *infra.*

The Parisian gun-makers, who are reckoned very expert, draw out the iron for the barrels at hand forges, in fillets only one-ninth of an inch thick, one inch and a half broad, and four feet long. Twenty-five of these ribands are laid upon each other, between two similar ones of double thickness, and the bundle, weighing 60 pounds, bound with wire at two places, serves to make two barrels. The thicker plates are intended to protect the thinner from the violence of the fire in the numerous successive heats necessary to complete the welding, and to form the bundle into a bar two-thirds of an inch broad, by half an inch thick; the direction of the individual plates relatively to the breadth being preserved. This bar folded flat upon itself, is again wrought at the forge, till it is only half an inch broad, and a quarter of an inch thick, while the plates of the primitive ribands are now set perpendicular to the breadth of the narrow fillet; the length of which must be 15 or 16 feet French (16 or 17 English), to form a fowling piece from 28 to 30 inches long. This fillet, heated to a cherry red in successive portions, is coiled into as close a spiral as possible, upon a mandril about two-fifths of an inch in diameter. The mandril has at one end a stout head for drawing it out, by means of the hammer and the grooves of the anvil, previous to every heating. The welding is performed upon a mandril introduced after each heat; the middle of the barrel being first worked, while the fillets are forced back against each other, along the surface of the mandril, to secure their perfect union. The original plates having in the formation of the ultimate long riband become very thin, appear upon the surface of the barrel like threads of a fine screw, with blackish tints to mark the junctions. In making a double-barrelled gun, the two are formed from the same bundle of slips, the coils of the one finished fillet being turned to the right hand, and those of the other to the left.

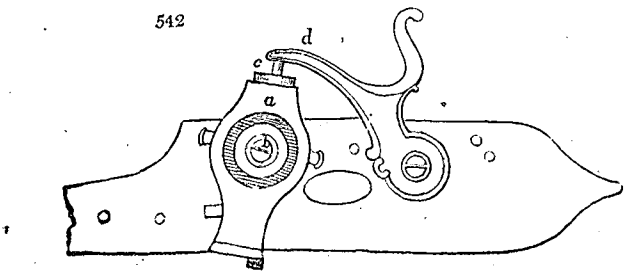
The Damascus barrels forged as above described, from a bundle of steel and iron plates laid alternately together, are twisted at the forge several times, then coiled and welded as usual. Fifteen Parisian workmen concur in one operation: six at the forge; two at the boring mill; seven at filing, turning, and adjusting; yet all together make only six pairs of barrels per week, which are sold at from 100 to 300 francs the pair, ready for putting into the stock.

The breeching is of three kinds: the common; the chamber, plug, or mortar, *fig.* 540.; and the patent, *fig.* 541. The common was formerly used for soldiers' musquets and inferior pieces. The second is a trifling improvement upon it. In the patent breeching, the screws do not interfere with the touch-hole, and the ignition is quicker in the main chamber.



The only locks which it is worth while to describe are those upon the percussion principle, as flint locks will certainly soon cease to be employed even in military musquets. Forsyth's lock (*fig.* 542.) was an ingenious contrivance. It has a magazine *a*, for containing the detonating powder, which revolves round a roller *b*, whose end is screwed into the breech of the barrel. The priming powder passes through a small hole in the roller, which leads to a channel in communication with the chamber of the gun.

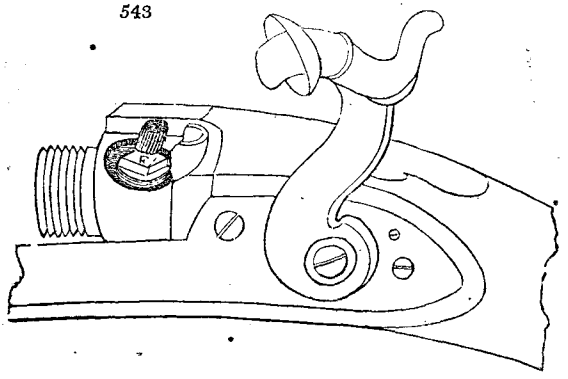
The pan for holding the priming is placed immediately over the little hole in the roller. There is a steel punch *c*, in the magazine, whose under end stands above the pan, ready



to ignite the priming when struck upon the top by the cock *d*, whenever the trigger is drawn. The punch immediately after being driven down into the pan is raised by the action of a spiral spring. For each explosion, the magazine must be turned so far round as to let fall a portion of the percussion powder into the pan; after which it is turned back, and the steel punch recovers its proper position for striking another blow into the pan.

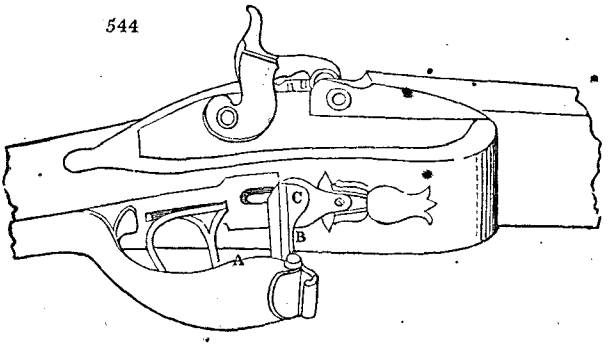
The invention of the copper percussion cap was another great improvement upon the detonating plan. *Fig.* 543. represents the ordinary percussion lock, which is happily divested of three awkward projections upon the flint lock, namely, the hammer, hammer spring, and the pan. Nothing now appears upon the plate of the lock, but the cock or striking hammer, which inflicts the proper blow upon the percussion cap. It is concave, with a small metallic ring or border, called a shield or fence, for the purpose of enclosing the cap, as it were, and preventing its splinters doing injury to the sportsman, as also protecting against the line of flame which may issue from the touch-hole in the cap nipple. This is screwed into the patent breech, and is perforated with a small hole.

543



The safety lock of Dr. Somerville is a truly humane invention. Its essential feature is a slide stop or catch, placed under the trigger A, *fig.* 544. It is pulled forward into a notch in the trigger, by means of a spring B, upon the front of the guard, which is worked by a key *c*, pressing upon the spring when the piece is discharged. In another safety plan there is a small movable curved piece of iron, A, which rises through an opening B, in the lock-plate C, and prevents the cock from reaching the nipple, as represented in the figure, until it is drawn back within the plate of the lock when the piece is fired.

544



To fire this gun, two different points must be pressed at the same time. If by accident the key which works the safety be touched, nothing happens, because the trigger is not drawn; and the trigger touched alone can produce no effect, because it is locked. The pressure must be applied to the trigger and the key at the same instant, otherwise the lock will not work.

The French musquet is longer than the British, in the proportion of 44·72 inches to 42; but the French bayonet is 15 inches, whereas the British is 17.

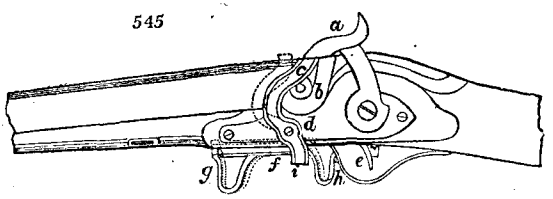
Length of the barrel and bayonet -	- 59·00	59·72

Within these few years a great many contrivances have been brought forward, and several have been patented for fire arms. The first I shall notice is that of Charles Random, Baron de Berenger. *Fig.* 545. shows the lock and breech of a fowling piece, with a sliding protector on one of the improved plans; *a* is the hammer, *b* the nipple of the touch-hole, *c* a bent lever, turning upon a pin, fixed into the lock-plate at *d*. The upper end of this bent lever stands partly under the nose of the hammer, and while in that situation stops it from striking the nipple. A slider *g f h*, connected with the under part of the gun-stock, is attached to the tail of the bent lever at *i*; and when the piece is brought to the shoulder for firing, the hand of the sportsman pressing against the bent part of the slider at *g*, forces this back, and thereby moves the end of the lever *c* forwards

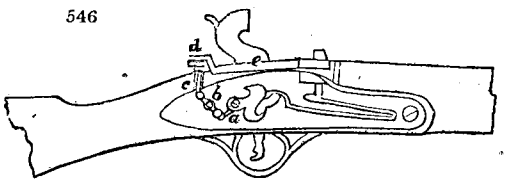
545



from under the nose of the cock or hammer, as shown by the dotted lines. The trigger being now drawn, the piece will be discharged; and on removing the hand from the end *g*, of the slider *f*, the spring at *h* acting against the guard, will force the slider forward, and the lever into the position first described.

Mr. Redford, gun-maker of Birmingham, proposes a modification of the lock for small fire-arms, in which the application of pressure to the sear spring for discharging the piece is made by means of a plug, depressed by the thumb, instead of the force of the finger exerted against the trigger. *Fig.* 546. represents a fowling piece partly in

546



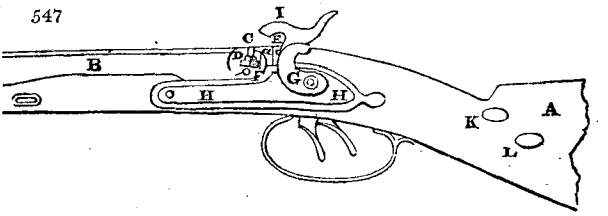
section. The sear spring is shown at *a*. It is not here connected with the trigger as in other locks; but is attached by a double-jointed piece to a lever *b*, which turns upon a fulcrum pin in its centre. At the reverse end of this lever an arm extends forwards, like that of an ordinary sear spring, upon which arm the lower end of the plug *c* is intended to bear; and when this plug is depressed by the thumb bearing upon it, that end of the lever *b* will be forced downwards, and the reverse end will be raised, so as to draw up the end of the sear spring, and set off the piece. For the sake of protection, the head of the plug c is covered by a movable cap *d*, forming part of a slider *e*, which moves to and fro in a groove in the stock, behind the breech end of the barrel; this slider *e* is acted upon by the trigger through levers, which might be attached to the other side of the lock-plate; but are not shown in this figure to avoid confusion. When the piece is brought to the shoulder for firing, the fore-finger must be applied as usual to the trigger, but merely for the purpose of drawing back the slider *e*, and uncovering the head of the plug; when this is done, the thumb is to be pressed upon the head of the plug, and will thus discharge the piece. A spring bearing against the lever of the slider *e*, will, when the finger is withdrawn from the trigger, send the slider forward again, and cover the head of the plug, as shown.

It is with pleasure I again advert to the humane ingenuity of the Rev. John Somerville, of Currie. In April, 1835, he obtained a patent for a further invention to prevent the accidental discharge of fire arms. It consists in hindering the hammer from reaching the nipple of a percussion lock, or the flint reaching the steel of an ordinary one, by the interposition of movable safety studs or pins, which protrude from under the false breech before the hammers of the locks, and prevent them from descending to strike.

These safety studs or pins are moved out of the way by the pressure of the right hand of the person using the gun only when in the act of firing, that is, when the force of the right hand and arm is exerted to press the butt end of the stock of the gun against the shoulder while the aim is taken and the trigger pulled. In carrying the gun at rest, the proper parts of the thumb or hand do not come over Mr. Somerville's movable buttons or studs.

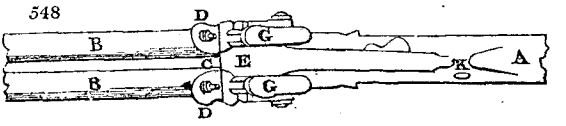
Fig. 547. is a side view of part of a double percussion gun; and *fig.* 548. is a top or plan view, which will serve to explain these improvements, and show one, out of many, methods of carrying them into effect. A is the stock of the gun; B the barrels; C the breech; D the nipples; E the false breech, on the under side of which the levers which work the safety studs or pins are placed; F is the shield of the false breech; G, triggers; H the lock-plate; and I the hammers: all of which are constructed as usual: *a a* are the safety studs or pins, which protrude before the shield F, and work through guide pieces on the under side of the false breech. The button piece is placed in the position for the thumb of the right hand to act upon it; but when the pressure of the ball of the right thumb is to produce the movement of the safety studs, it must be

547

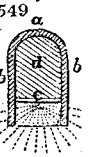


placed in or near the position K; and when the heel of the right hand is to effect the movements of the safety studs, the button piece must be placed at L, or nearly so.

548



549



In these last two positions, the lever (which is acted upon by the button piece to work the safety studs through a slide) would require to be of a different shape and differently mounted. When the hammers are down upon the nipples after discharging the gun, the ends of the safety pins press against the inner sides of the hammers. When this invention is adapted to single-barrelled guns, only one pin, *a*, one lever and button piece will be required.

Mr. Richards, gun-maker, Birmingham, patented, in March, 1836, a modification of the copper cap for holding the percussion powder, as represented *fig.* 549.; in which the powder is removed from the top of the cap, and brought nearer the mouth; *a* being the top, *b* the sides, and c the position of the priming. The dotted lines show the direction of the explosion, whereby it is seen that the metal case is opened or distended only in a small degree, and not likely to burst to pieces, as in the common caps, the space between *a* and *c* being occupied by a piece of any kind of hard metal *d*, soldered or otherwise fastened in the cap.

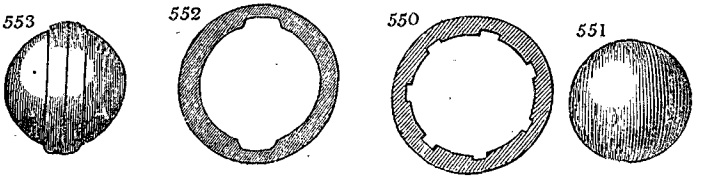
George Lovell, Esq., director of the Royal Manufactory of Arms at Enfield, has recently made a great improvement upon the priming chamber. He forms it into a vertical double cone, joined in the middle by the common apex; the base of the upper cone being in contact with the percussion cap, presents the most extensive surface to the fulminate upon the one hand, while the base of the under one being in a line with the interior surface of the barrel, presents the largest surface to the gunpowder charge, upon the other. In the old nipple the apex of the cone being at its top, afforded very injudiciously the *minimum* surface to the exploding force.

Guns, Rifling of the Barrels. — The outside of rifle barrels is, in general, octagonal. After the barrel is bored, and rendered truly cylindrical, it is fixed upon the rifling machine. This instrument is formed upon a square plank of wood 7 feet long, to which is fitted a tube about an inch in diameter, with spiral grooves deeply cut internally through its whole length; and to this a circular plate is attached, about 5 inches diameter, accurately divided in concentric circles, into from 5 to 16 equal parts, and supported by two rings made fast to the plank, in which rings it revolves. An arm connected with the dividing graduated plate, and pierced with holes, through which a

pin is passed, regulates the change of the tube in giving the desired number of grooves to the barrel. An iron rod, with a movable handle at the one end, and a steel cutter in the other, passes through the above rifling tube. This rod is covered with a core of lead one foot long. The barrel is firmly fixed by two rings on the plank, standing in a straight line on the tube. The rod is now drawn repeatedly through the barrel, from end to end, until the cutter has formed one groove of the proper depth. The pin is then shifted to another hole in the dividing plate, and the operation of grooving is repeated till the whole number of riflings is completed. The barrel is next taken out of the machine, and finished. This is done by casting upon the end of a small iron rod a core of lead, which, when besmeared with a mixture of fine emery and oil, is drawn, for a considerable time, by the workmen, from the one end of the barrel to the other, till the inner surface has become finely polished. The best degree of spirality is found to be from a quarter to half a revolution in a length of three feet.

Military Rifles. — An essential improvement in this destructive arm has lately been introduced into the British service, at the suggestion of Mr. Lovell.

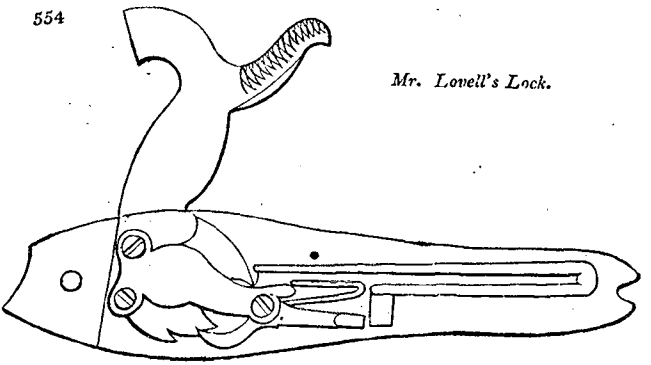
The intention in all rifles is to impart to the ball a rotatory or spinning motion round its axis, as it passes out through the barrel. This object was attained, to a certain degree, in the rifles of the old pattern, by cutting seven spiral grooves into the inside of the barrel, in the manner shown by *fig.* 550., the spherical ball, *fig.* 551., being



a little larger than the bore, was driven down with a mallet, by which the projecting ribs were forced into the surface of the ball, so as to keep it in contact with their curvatures, during its expulsion. Instead of this laborious and insecure process, the barrel being now cut with only two opposite grooves, *fig.* 552., and the ball being formed with a projecting belt, or zone, round its equator, of the same form as the two grooves, *fig.* 553., it enters so readily into these hollows, that little or no force is required to press it down upon the powder. So much more hold of the barrel is at the same time obtained, that instead of one *quarter* of a turn, which was the utmost that could be safely given in the old way, without danger of stripping the ball, a *whole* turn round the barrel, in its length, can be given to the two grooved rifles; whereby a far more certain and complete rotatory motion is imparted to the ball. The grand practical result is, that better practice has been performed by several companies of the Rifle Corps, at 300 yards, than could be produced with the best old military rifles at 150 yards; the soldier being meanwhile enabled to load with much greater ease and despatch. The belt is bevelled to its middle line, and not so flat as shown in the figure.

This mode of rifling is not, however, new in England. In fact, it is one of the oldest upon record; and appears to have fallen into disuse from faults in the execution. The idea was revived within the last few years in Brunswick, and it was tried in

554



Mr. Lovell's Lock.

Hanover also, but with a lens-shaped (Linsenförmig) ball. The judicious modifications and improvements it has finally received in Mr. Lovell's hands, have brought out all its

advantages, and rendered it, when skilfully used, a weapon of unerring aim, even at the prodigious distance of 700 yards.

The locks, also, for the military service generally, are now receiving an important improvement by means of his labours, having been simplified in a remarkable manner. The action of the main spring is reversed, as shown by *fig. 554.*; thus rendering the whole mechanism more solid, compact, and convenient; while the ignition of the charge being effected by percussion powders in a copper cap, the fire of the British line will, in future, be more murderous than ever, as a miss-fire is hardly ever experienced with the fire-arms made at the Royal manufactory, under Mr. Lovell's skilful superintendence.

Barrel-welding by Machinery. — The barrels of musquets, birding-guns, &c. or what are called *plain*, to distinguish them from those denominated *stub* or *twisted* barrels, have of late years been formed by means of rolls, a process in which the welding is first effected on a short slab of thick iron, and then the barrel is brought down to its destined length, and form, by repeatedly passing it between a pair of rolls, that have been previously grooved to the exact shape of the barrel intended to be made.

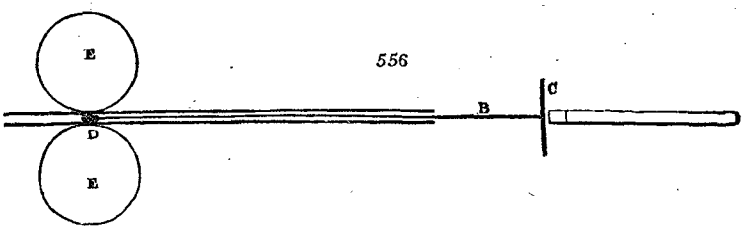
This method has entirely superseded the skelp-welding by hand described in the *Dict. of Man.* p. 718., and is conducted as follows: —

The iron being thoroughly refined, and reduced into flat bars by the process described at length at p. 705., is cut by the shears into slabs or lengths of 10 to 12 inches, and 10 to 10½ lbs. weight, or less, according to the description of gun-barrel that is intended to be made. These slabs are then heated, and bent in their whole length, by means of conveniently grooved bending rolls, until they assume the form of rough tubes, of the kind of section shown by A, *fig. 555.* They are then placed on the hearth of the reverberatory furnace (*Dict.* p. 701.), and brought to a full welding heat, and as soon as the edges of a tube come to a semi-fluid state, it is taken out and passed between rolls having grooves somewhat smaller in diameter than the exterior of the tube, by which means the tube is perfectly welded from end to end; and if care be taken in the management of the heat, and the juncture be kept clear of dirt and cinders, the iron will be found perfectly homogeneous in every part, and there will be no appearance whatever of the seam where the edges came together. These tubes are repeatedly heated, and passed between the barrel rolls, which are of sufficient diameter to admit of gradually decreasing grooves, the whole length of the intended barrel being indented on their surfaces.

555

To preserve the tubular form, and ensure regularity in the size of the bore during the welding process, they are taken out of the furnace, by thrusting into them a tool called a mandril, B, which consists of a long rod of iron, having a short steel treblett on its end, of the diameter that the bore of the barrel is meant to be. This rod is so adjusted by means of a strong iron plate C, near its handle, which is of wood, and long, that when passed with the heated tube on it between two transverse holding bars, the short steel treblett D shall be found exactly between the point of impact of the barrel-rolls, E, E.

556



The adhesion of the hot iron to the surface of the rolls is strong enough to draw the tube off the mandril, which thus keeps the bore open from end to end, and by repeating the process through the whole series of grooves in the rolls, the barrel is gradually elongated, and brought down to the exact form required; any superfluous length at the muzzle is then cut off. The breach end is then adjusted by the hammer — a triple-seat welded on by hand if it be intended for a percussion lock, and then the barrel is ready to go forward to the mill to be bored, turned, and finished.

Gun barrels formed by this mechanical method are found to stand proof better than those worked by hand, because the heat is more equalised; and any imperfections in the original mass of iron are more dispersed over the whole extent of the tube.

Mr. Wells Ingram, of Bradford Street, Birmingham, has lately perfected a very complete lathe for turning the exterior of gun barrels of all descriptions, a process which is

fast superseding the use of the grindstone, for equalising the barrels of all kinds of fire-arms.

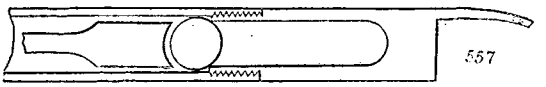
I am indebted for this article to Mr. Lovell, Director of the Royal Arms Manufactory. See MUSQUET.

Since the first edition of the Dictionary large strides have been made towards increasing the efficacy of military fire-arms; the French had found in their skirmishes with Abd-el-Kader in Africa, that the long matchlocks of the Arabs told at fearful odds against their men at distances where the ordinary French musquet was powerless of offence.

After a while it was found that this increased range was due solely to the greater elevation taken by the natives in aiming, and their expertness in judging their distances, taught by long practice and experience; for the Arab arms and ammunition taken at Constantine were found of the rudest construction.

These observations led the French officers of artillery to institute all sorts of experiments to render their small arms more effective; by the adoption of wallpieces of wider bore; by introducing a more general use of rifled barrels, but at the same time avoiding the tedious method of loading by means of mallets formerly observed with such kind of arms.

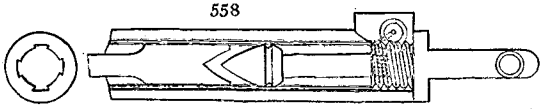
The first attempt towards such object was that proposed by M. Delvigne, an officer of the royal ex-guard, (*fig. 557.*), in which the upper orifice of the chamber that



557

contained the powder took the form of a cup, wherein the ball (somewhat wider in diameter) was received, and by two or three smart blows of a heavy-headed rammer (also cupped out for the purpose) became expanded laterally, and thus the rotary motion was imparted to it by the spiral grooves of the barrel in passing out Colonel Poncharra suggested the addition of a wood bottom or sabôt under the ball and a greased woollen patch; and Colonel Thouvesino proposed (*fig. 558.*) a steel stem or pillar about 2 inches

558



long inserted into the face of the breech-pin; round this pin the charge of powder was received, and the diameter of the ball, when resting on the top of the pin, was enlarged by the blows of the heavy-headed rammer, as suggested by Delvigne.

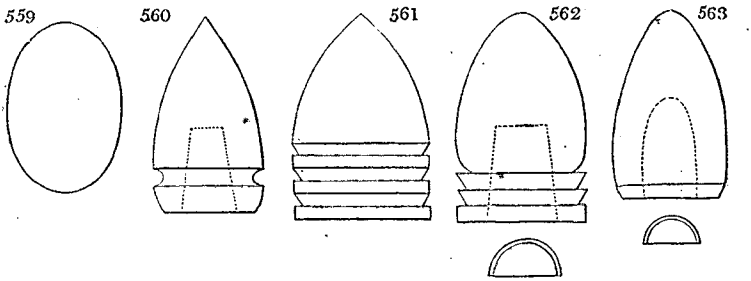
This system took the name of "Carabine à Tige," and has been very generally introduced for the service of fusilier battalions in continental armies: very grave objections, however, have been found against it in use, from the impossibility of keeping the chamber (or part round the pin) clear; and from the severe labour to the soldier in ramming down and enlarging the diameter of the ball sufficiently to ensure the rotary motion desired.

But if the ultimate results thus attained with spherical balls turned out not entirely satisfactory, it was made clearly manifest, in the course of the experiments carried on, that no insuperable difficulty stands in the way of rendering the fire of infantry very much more accurate and powerful, by the use of rifled barrels throughout the army, and thus leading to a verification of the prediction made by Robins above one hundred years ago, that "whatever State shall thoroughly comprehend the nature and advantages of rifled barrel pieces, and having facilitated and completed their construction, shall introduce into their armies their general use, with dexterity in the management of them, will by this means acquire a superiority which will almost equal any thing that has been done at any time."

But besides smoothing the way to such an essential improvement, it has been elicited of late years, that when the accuracy of flight is secured by the rotary motion derived from the rifling, the bullet, instead of being limited to the form of a sphere as heretofore, may, up to certain limits, be elongated with considerable increase of destructive effect; and with an augmentation of range very much beyond any thing that has hitherto been considered to lie within the reach of small arms — placing them, in fact, with reference to artillery and cavalry, in the first place instead of the last.

An immensely extended field has thus been opened to experimenters. 1st. Mons. Didion proposed a true oval (*fig. 559.*) as the best form of bullet, so that, when shortened by the blows of the heavy rammer and widened in its diameter, it might be brought nearer to the spherical shape before leaving the barrel.

2nd. Mons. Delvigne took a patent for a bullet (*fig. 560.*) under the designation of "Cylindro Ogivale;" it had a conical opening behind, in which he imagined that the force of the powder would exert itself with sufficient energy to expand the lead permanently, and so make the ball take the rotary movement derived from the rifling, without any fatigue to the soldier in loading: with this projectile, indeed, the operation is but slightly more difficult than with the ordinary cartridge and smooth barrels.



The bullet (*fig. 561.*) of the "Carabine à Tige" was called "Cylindro Conique," and was said to possess this advantage over the preceding, that, being brought more to a point in front, it bored its way through the air with greater ease, and thus retained greater velocity, and of course more extended range; and with this bullet it was that Mons. Tamisier introduced three sharp-edged channels round it, which he stated were necessary to keep its flight steady, by offering a resistance to the action of the air.

Finally Mons. Minié, an officer of the French line, suggested (*fig. 562.*) the addition of a dénoyau or culot to the hollow ball of Delvigne. This, in the form of a little cup made of sheet iron, is placed in the orifice of the conical hollow of the ball behind, and by the energy of the powder is driven into the ball, enlarging its diameter permanently, and thus giving all the accuracy of the rifle, with nearly the same facility of loading as with the plain barrel.

The principle of the invention, as thus developed, has, we learn, been adopted by our government for the general use of the army, seeing that it offers so great advantages over the system of plain barrels, but the bullet (*fig. 563.*), as modified by the Inspector of Small Arms, has on its exterior no channels, they being found not only useless as to steadying the flight of the projectile, but absolutely injurious in lowering its velocity. The bullet in its improved form too, being more truly balanced in its proportions, and made by mechanical means instead of by casting, has no tendency to the gyrations which appear to have so puzzled French artillerists, and for which they have invented the word "derivation," and wasted much learned disquisition.

Though well satisfied with the results of their course of experiments, our neighbours, however, do not appear to have come to any final decision as yet; indeed, the fact of being able to make use of an elongated projectile with a rifle has let loose such a crowd of inventors, that they seem to be entirely bewildered. In Switzerland every Canton has its peculiar form of bullet, each one, of course, being the best, and from the length and size of a small caterpillar upwards, every man seems to have his own maggot, which he vaunts before the world.

But even if it were ever to happen, which is not likely, that these various projectors could be brought to agree as to the best form of projectile, they will then find out, that although by the general introduction of rifled and elongated bullets an immense advantage has been realised over plain barrels, their plans, based as they all are upon a system of *loading* at the *muzzle*, are at best but one step in advance; and that a good sound military fire-arm *loading* at the *breach* will, after all, remain the great desideratum — an arm that, without any less accuracy or power to reach masses of artillery or cavalry at a thousand yards' distance, will enable the soldier to triple the quantity of his fire at any moment that he may be called upon to repel a charge of cavalry or attack or defend a breach at close quarters; of such simple construction, and so easily handled in every position of the body, that the soldier can pour every shot of his most murderous fire upon the enemy with unerring precision, whilst he himself may lay coolly behind a stone or in a ditch in entire security.

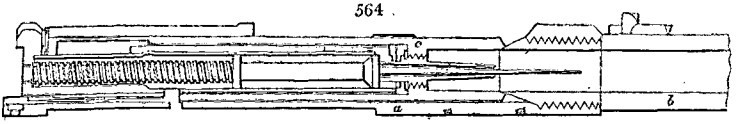
These are no longer wild imaginings, although so many hundreds of attempts towards the same object, from the earliest period to the present day, have been one after another seen invariably to fail. The Germans have been long and steadily pursuing the great object, until at length Herr Dreysa, of Sömmerda in Thuringia, has succeeded, after more than twenty years of continued labour, in establishing a musquet, under the name

of "Zündnadelgewehr," which, if not quite perfect, has been found to work so well in the hands of the men, that the Prussian government has already 80,000 in possession, and they are going on to arm the whole of their line regiments and Landwehr with them.

Even with the assistance of a diagram, it is hardly possible to convey a clear notion of the construction of this musquet, because the several parts work one within the other, and their combination, which is without pin or screw, is hard to comprehend by a mere description.

There is a strong socket, (*fig. 564.*), *a*, open on the upper side, screwed on to the barrel,

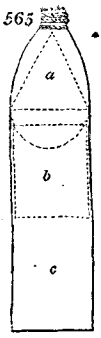
564



b, which is rifled in the usual manner: within this socket is a slider *c*, which in fact constitutes the lock, as it contains the spiral spring and mechanism that produces ignition by percussion; it has a stout hebel or handle, by which it is moved backwards and forwards freely.

The cartridge (*fig. 565.*) consists of the ball *a*, the sabôt *b*, or bottom of hard paper, and holding the priming matter, and lastly, the charge of powder, *c*, the whole being made up in paper pasted together. In use, the slider being drawn back, the soldier puts the cartridge with the point of the ball in front into the open breech of the barrel, pushes the slider forward, and secures its close junction by a turn to the right against an inclined edge of the open socket. The spiral spring is then brought into action (or the gun is cocked) by pressing the spring case forward with the thumb.

565



On pulling the trigger, the interior needle, from which the musquet takes its name, is darted forward through the charge of powder into the percussion primer in the sabôt, and thus effects the ignition inside the barrel.

The principle of loading at the *breech* carries with it so many other advantages beyond that by the muzzle, that many ingenious men are occupying themselves with its improvement: Lefaucheur and Robert in France; Montigny in Belgium; Kufahl Schultz and Friedrix in Prussia; Sears and Needham in England, have lately brought forward various plans; and now that the idea is taken up upon a right base, there can be little doubt that eventually a system will be hit upon, that shall secure all the requisites for military service, and avoid all objections.

But it is clear, from the recent publications on gunnery and the observations of *ancient* warriors, that the advocates for heavy battalion movements, for drawing up their infantry in long lines and compact bodies for destruction by artillery, will be with difficulty brought to look with patience upon the scrambling and desultory sort of warfare which the general introduction of these improved rifles must bring about. Time, however, daily goes on to work wonders upon prejudice, and the day will come when it will be found that cross-belts and blank-cartridges may be abolished without utter ruin to the army; and that men behind trees, with effective weapons in their hands, may be more dangerous enemies, at long ranges, than when strapped up and paraded out in masses, and carrying arms that at any distance over 300 are powerless of offence.

FIRE-DAMP; the explosive carburetted hydrogen of coal mines. See PITCOAL.

FIRE-WORKS. (*Feux d'artifice*, Fr.; *Feuerwerke*, Germ.) The composition of luminous devices with explosive combustibles, is a modern art resulting from the discovery of gunpowder. The finest inventions of this kind are due to the celebrated Ruggieri, father and son, who executed in Rome and Paris, and the principal capitals of Europe, the most brilliant and beautiful fire-works that were ever seen. The following description of their processes will probably prove interesting to many of my readers.

The three prime materials of this art are, nitre, sulphur, and charcoal, along with filings of iron, steel, copper, zinc, and resin, camphor, lycopodium, &c. Gunpowder is used either in grain, half crushed, or finely ground, for different purposes. The longer the iron filings, the brighter red and white sparks they give; those being preferred which are made with a very coarse file, and quite free from rust. Steel filings and cast-iron borings contain carbon, and afford a more brilliant fire, with wavy radiations. Copper filings give a greenish tint to flame; those of zinc a fine blue colour; the sulphuret of antimony gives a less greenish blue than zinc, but with much smoke; amber affords a yellow fire, as well as colophony, and common salt; but the last must be very dry. Lampblack produces a very red colour with gunpowder, and a pink with

nitre in excess. It serves for making golden showers. The yellow sand or glistening mica communicates to fire-works golden radiations. Verdigris imparts a pale green; sulphate of copper and sal-ammoniac, a palm-tree green. Camphor yields a very white flame and aromatic fumes, which mask the bad smell of other substances. Benzoin and storax are used also on account of their agreeable odour. Lycopodium burns with a rose colour and a magnificent flame; but it is principally employed in theatres to represent lightning, or to charge the torch of a fury.

Fire-works are divided into three classes: 1. those to be set off upon the ground; 2. those which are shot up into the air; and 3. those which act upon or under water.

Composition for *jets of fire*; the common preparation for rockets not more than $\frac{3}{4}$ of an inch in diameter, is: gunpowder, 16 parts; charcoal, 3 parts. For those of larger diameter: gunpowder, 16; steel filings, 4.

Brilliant revolving wheel; for a tube less than $\frac{3}{4}$ of an inch: gunpowder, 16; steel filings, 3. When more than $\frac{3}{4}$: gunpowder, 16; filings, 4.

Chinese or Jasmine fire; when less than $\frac{3}{4}$ of an inch: gunpowder, 16; nitre, 8; charcoal (fine), 3; sulphur, 3; pounded cast-iron borings (small), 10. When wider than $\frac{3}{4}$: gunpowder, 16; nitre, 12; charcoal, 3; sulphur, 3; coarse borings, 12.

A fixed brilliant; less than $\frac{3}{4}$ in diameter: gunpowder, 16; steel filings, 4; or, gunpowder, 16, and finely pounded borings, 6.

Fixed suns are composed of a certain number of jets of fire distributed circularly, like the spokes of a wheel. All the fusees take fire at once through channels charged with quick matches. *Glories* are large suns with several rows of fusees. *Fans* are portions of a sun, being sectors of a circle. The *Patte d'oie* is a fan with only three jets.

The *mosaic* represents a surface covered with diamond shaped compartments, formed by two series of parallel lines crossing each other. This effect is produced by placing at each point of intersection, four jets of fire, which run into the adjoining ones. The intervals between the jets must be associated with the discharge of others, so as to keep up a succession of fire in the spaces.

Palm trees. Ruggieri contrived a new kind of fire, adapted to represent all sorts of trees, and especially the palm. The following is the composition of this magnificent green fire-work: crystallized verdigris, 4 parts; sulphate of copper, 2; sal-ammoniac, 1. These ingredients are to be ground and moistened with alcohol. An artificial tree of any kind being erected, coarse cotton rovings about 2 inches in diameter, impregnated with that composition, are to be festooned round the trunk, branches, and among the leaves; and immediately kindled before the spirits have had time to evaporate.

Cascades, imitate sheets or jets of water. The Chinese fire is best adapted to such decorations.

Fixed stars. The bottom of a rocket is to be stuffed with clay, and one diameter in height of the first preparation being introduced, the vacant space is to be filled with the following composition, and the mouth tied up. The pasteboard must be pierced into the preparation, with five holes, for the escape of the luminous rays, which represent a star.

Composition of fixed stars. —

	Ordinary.	Brighter.	Coloured.
Nitre	16	12	0
Sulphur	4	6	6
Gunpowder meal	4	12	16
Antimony	2	1	2

Lances, are long rockets of small diameter, made with cartridge paper. Those which burn quickest should be the longest. They are charged by hand without any mould, with rods of different lengths, and are not strangled at the mouth, but merely stuffed with a quick match of tow. These lances form the figures of great decorations; they are fixed with springs upon large wooden frame works, representing temples, palaces, pagodas, &c. The whole are placed in communication by *conduits*, or small paper cartridges like the lances, but somewhat conical, that they may fit endwise into one another to any extent that may be desired. Each is furnished with a match thread fully $1\frac{1}{2}$ inches long, at its two ends.

Composition for the *white lances*: nitre, 16; sulphur, 8; gunpowder, 4 or 3. For a *bluish-white*: nitre, 16; sulphur, 8; antimony, 4. For *blue lances*: nitre, 16; antimony, 8. For *yellow*: nitre, 16, gunpowder, 16; sulphur, 8; amber, 8. For *yellower* ones: nitre, 16; gunpowder, 16; sulphur, 4; colophony, 3; amber, 4. For *greenish* ones: nitre, 16; sulphur, 6; antimony, 6; verdigris, 6. For *pink lances*: nitre, 16; gunpowder, 3; lampblack, 1. Others less vivid are made with: nitre, 16; colophony, 3; amber, 3; lycopodium, 3.

Cordage is represented in fire-works, by imbuing soft ropes with a mixture of, nitre, 2; sulphur, 16; antimony, 1; resin of juniper, 1.

The Bengal flames rival the light of day. They consist of, nitre, 7; sulphur, 2; antimony, 1. This mixture is pressed strongly into earthen porringers, with some bits of quick match strewed over the surface. These flames have a fine theatrical effect for conflagrations.

Revolving suns, are wheels upon whose circumference rockets of different styles are fixed, and which communicate by *conduits*, so that one is lighted up in succession after another. The composition of their common fire is, for sizes below $\frac{3}{4}$ of an inch: gunpowder meal, 16; charcoal, not too fine, 3. For larger sizes: gunpowder, 20; charcoal, not too fine, 4. For *fiery radiations:* gunpowder, 16; yellow micaceous sand, 2 or 3. For *mixed radiations:* gunpowder, 16; pitcoal, 1; yellow sand, 1 or 2.

The *waving or double Catherine wheels*, are two suns turning about the same axis in opposite directions. The fusees are fixed obliquely and not tangentially to their peripheries. The wheel spokes are charged with a great number of fusees; two of the four wings revolve in the one direction, and the other two in the opposite; but always in a vertical plane.

The *girandoles, caprices, spirals*, and some others have on the contrary a horizontal rotation. The fire-worker may diversify their effects greatly by the arrangement and colour of the jets of flame. Let us take for an example the *globe of light.* Imagine a large sphere turning freely upon its axis, along with a hollow hemisphere, which revolves also upon a vertical axis passing through its under pole. If the two pieces be covered with coloured lances or cordage, a fixed luminous globe will be formed, but if horizontal fusees be added upon the hemisphere, and vertical fusees upon the sphere, the first will have a relative horizontal movement, the second a vertical movement, which being combined with the first, will cause it to describe a species of curve, whose effect will be an agreeable contrast with the regular movement of the hemisphere. Upon the surface of a revolving sun, smaller suns might be placed, to revolve like satellites round their primaries.

Ruggieri exhibited a luminous serpent pursuing with a rapid winding pace a butterfly which flew continually before it. This extraordinary effect was produced in the following way. Upon the summits of an octagon he fixed eight equal wheels turning freely upon their axles, in the vertical plane of the octagon. An endless chain passed round their circumference, going from the interior to the exterior, covering the outside semi-circumference of the first, the inside of the second, and so in succession; whence arose the appearance of a great festooned circular line. The chain, like that of a watch, carried upon a portion of its length a sort of scales pierced with holes for receiving coloured lances, in order to represent a fiery serpent. At a little distance there was a butterfly constructed with white lances. The piece was kindled commonly by other fire-works, which seemed to end their play, by projecting the serpent from the bosom of the flames. The motion was communicated to the chain by one of the wheels, which received it like a clock from the action of a weight. This remarkably curious mechanism was called by the artists a *salamander.*

The rockets which rise into the air with a prodigious velocity, are among the most common, but not least interesting fire-works. When employed profusely they form those rich volleys of fire which are the crowning ornaments of a public fête. The cartridge is similar to that of the other jets, except in regard to its length, and the necessity of pasting it strongly, and planing it well; but it is charged in a different manner. As the sky-rockets must fly off with rapidity, their composition should be such as to kindle instantly throughout their length, and extricate a vast volume of elastic fluids. To effect this purpose, a small cylindric space is left vacant round the axis; that is, the central line is tubular. The fire-workers call this space the soul of the rocket (*ame de la fusée*). On account of its somewhat conical form, hollow rods, adjustable to different sizes of broaches or skewers, are required in packing the charge; which must be done while the cartridge is sustained by its outside mould, or copper cylinder. The composition of sky-rockets is as follows (see next page):

The cartridge being charged as above described, the *pot* must be adjusted to it, with the *garniture;* that is, the serpents, the crackers, the stars, the showers of fire, &c. The pot is a tube of pasteboard wider than the body of the rocket, and about one-third of its length. After being strangled at the bottom like the mouth of a phial, it is attached to the end of the fusee by means of twine and paste. These are afterwards covered with paper. The garniture is introduced by the neck, and a paper plug is laid over it. The whole is enclosed within a tube of pasteboard terminating in a cone, which is firmly pasted to the pot. The quick-match is now finally inserted into the *soul* of the rocket. The rod attached to the end of the sky-rockets to direct their flight, is made of willow or any other light wood. M. Ruggieri replaced the rod by conical wings containing explosive materials, and thereby made him fly further and straighter.

The *garnitures* of the sky-rocket pots are the following: —

1. *Stars* are small, round, or cubic solids, made with one of the following compo-

When the bore is	⅛ of an Inch;	¼ to 1;	1⅛;
Nitre - - -	16	16	16
Charcoal - -	7	8	2
Sulphur - -	4	4	4
Brilliant Fire.			
Nitre - - -	16	16	16
Charcoal - -	6	7	8
Sulphur - -	4	4	4
Fine steel filings -	3	4	5
Chinese Fire.			
Nitre - - -	16	16	16
Charcoal - -	4	5	6
Sulphur - -	3	3	4
Fine borings of cast iron	3 coarser	4 mixed	5

sitions, and soaked in spirits. *White stars*, nitre, 16; sulphur, 8; gunpowder, 3. Others more vivid consist of nitre, 16; sulphur, 7; gunpowder, 4.

Stars for golden showers, nitre, 16; sulphur, 10; charcoal, 4; gunpowder, 16; lamp-black, 2. Others yellower are made with nitre, 16; sulphur, 8; charcoal, 2; lamp-black, 2; gunpowder, 8.

The *serpents* are small fusees made with one or two playing cards; their bore being less than half an inch. The *lardons* are a little larger, and have three cards; the *vetilles* are smaller. Their composition is, nitre, 16; charcoal, not too fine, 2; gunpowder, 4; sulphur, 4; fine steel filings, 6.

The *petards* are cartridges filled with gunpowder and strangled.

The *saxons* are cartridges clayed at each end, charged with the brilliant turning fire, and perforated with one or two holes at the extremity of the same diameter.

The *cracker* is a round or square box of pasteboard, filled with granulated gunpowder, and hooped all round with twine.

Roman candles are fusees which throw out very bright stars in succession. With the composition (as under) imbued with spirits and gum-water, small cylindric masses are made, pierced with a hole in their centre. These bodies, when kindled and projected into the air, form the stars. There is first put into the cartridge a charge of fine gunpowder of the size of the star; above this charge a star is placed; then a charge of composition for the Roman candles.

The *stars*, when less than ¾ of an inch, consist of nitre, 16; sulphur, 7; gunpowder, 5. When larger, of nitre, 16; sulphur, 8; gunpowder, 8.

Roman candles, nitre, 16; charcoal, 6; sulphur, 3. When above ¾ of an inch, nitre, 16; charcoal, 8; sulphur, 6.

The *girandes*, or bouquets, are those beautiful pieces which usually conclude a fire-work exhibition; when a multitude of jets seem to emblazon the sky in every direction, and then fall in golden showers. This effect is produced by distributing a number of cases open at top, each containing 140 sky-rockets, communicating with one another by quick-match strings planted among them. The several cases communicate with each other by *conduits*, whereby they take fire simultaneously, and produce a volcanic display.

The water fire-works are prepared like the rest; but they must be floated either by wooden bowls, or by discs and hollow cartridges fitted to them.

Blue fire for lances may be made with nitre, 16; antimony, 8; very fine zinc filings, 4; Chinese paste for the stars of Roman candles, bombs, &c.: — Sulphur, 16; nitre, 4; gunpowder meal, 12; camphor, 1; linseed oil, 1; the mixture being moistened with spirits.

The *feu grégois* of Ruggieri, the son: — Nitre, 4; sulphur, 2; naphtha, 1. See PYROTECHNY and ROCKETS.

The red fire composition is made by mixing 40 parts of nitrate of strontia, 13 of flowers of sulphur, 5 of chlorate of potash, and 4 of sulphuret of antimony.

White fire is produced by igniting a mixture of 48 parts nitre; 13¼ sulphur; 7¼ sulphuret of antimony; or, 24 nitre, 7 sulphur, 2 realgar; or, 75 nitre, 24 sulphur, 1 charcoal; or, finally, 100 of gunpowder meal, and 25 of cast-iron fine borings.

The blue fire composition is, 4 parts of gunpowder meal; 2 of nitre; sulphur and zinc, each 3 parts.

FISH-HOOKS (*Hamecons*, Fr.; *Fishangeln*, Germ.) are constructed with simple tools, but require great manual dexterity in the workmen. The iron wire of which

they are made should be of the best quality, smooth and sound. A bundle of such wire is cut in lengths, either by shears or by laying it down upon an angular wedge of hard steel fixed horizontally in a block or anvil, and striking off the proper lengths by the blows of a hammer. In fashioning the *barbs* of the hooks, the straight piece of wire is laid down in the groove of an iron block made on purpose, and is dexterously struck by the chisel in a slanting direction, across so much of the wire as may be deemed necessary. A sharp-pointed little wedge is thus formed, whose base graduates into the substance of the metal.

The end of the wire where the line is to be attached is now flattened or screw-tapped; the other end is sharp pointed, and the proper twisted curvature is given. The soft iron hooks are next case-hardened, to give them the steely stiffness and elasticity, by imbedding them in animal charcoal contained in an earthen or iron box; see CASE-HARDENING; after which they are brightened by heating and agitating them with bran, and finally tempered by exposure to a regulated temperature upon a hot iron plate. Hooks for salt-water fishing are frequently tinned, to prevent them wearing rapidly away in rust. See TIN PLATE.

FLAKE WHITE is the name sometimes given to pure white-lead.

FLAME (*Flamme*, Fr. and Germ.) is the combustion of an explosive mixture of an inflammable gas or vapour with air. That it is not, as many suppose, combustion merely at the exterior surface, is proved by plunging a fragment of burning phosphorus or sulphur into the centre of a large flame of alcohol. Either of these bodies will continue to burn there with its peculiar light; thus proving that oxygen is mixed with the whole of the burning vapour. If we mix good coal gas with as much atmospheric air as can convert all its carbon into carbonic acid, the mixture will explode with a feeble blue light; but if we mix the same gas with a small quantity of air, it will burn with a rich white flame. In the latter case, the carbonaceous particles are precipitated, as Sir H. Davy first showed, in the interior of the flame, become incandescent, and constitute white light: for from the ignition of solid matter alone can the prismatic rays be emitted in that concentrated union. Towards the interior of the flame of a candle, a lamp, or a gas jet, where the air is scanty, there is a deposition of solid charcoal, which first by its ignition, and afterwards by its combustion, increases in a high degree the intensity of the light. If we hold a piece of fine wire gauze over a jet of coal gas close to the orifice, and if we then kindle the gas, it will burn above the wire with its natural brilliancy; but if we elevate the gauze progressively higher, so as to mix more and more air with it before it reaches the burning point, its flame will become fainter and less white. At a certain distance it becomes blue, like that of the above explosive mixture. Since the combustion of all the constituents is in this case direct and complete, the heat becomes greatest in proportion nearly as the light is diminished. If a few platina wires be held in that dim flame they will grow instantly white hot, and illuminate the apartment. On reversing the order of this experiment, by lowering progressively a flat piece of wire gauze from the summit towards the base of a gas flame, we shall find no charcoal deposited at its top, because plenty of air has been introduced there to convert all the carbon of the gas into carbonic acid, and therefore the apex is blue; but as we descend, more and more charcoal will appear upon the meshes. At the very bottom, indeed, where the atmospheric air impinges upon the gauze, the flame is again blue, and no charcoal can therefore be deposited.

The fact of the increase of the brilliancy and whiteness of flame by the development and ignition of solid matter in its bosom, illustrates many curious phenomena. We can thus explain why olefiant gas affords the most vivid illumination of all the gases; because, being surcharged with charcoal, its hydrogen lets it go in the middle of the flame, as it does in an ignited porcelain tube, whereby its solid particles first get ignited to whiteness, and then burn away. When phosphorus is inflamed, it always yields a pure white light, from the ignition of the solid particles of the snowy acid thus produced.

In the blowpipe, the inner blue flame has the greatest heat, because there the combustion of the whole fatty vapour is complete. The feeble light of burning hydrogen, carbonic oxide, and sulphur, may, upon the principles now expounded, be increased by simply placing in them a few particles of oxide of zinc, slender filaments of amianthus, or fine platina wire. Upwards of twenty years ago, I demonstrated in my public lectures in Glasgow, that by narrowing the top of a long glass chimney over an argand flame either from oil or coal gas, the light could be doubled, at the same cost of material. The very tall chimneys used by the Parisian lampists are very wasteful. I find that with a narrow chimney of half the length of theirs, I can have as good a light, and save 30 per cent. of the oil. Thus the light of a flame may be increased by diminishing its heat, or the intensity of its combustion; and conversely the heat of a flame may be increased by diminishing its light.

FLANNEL; a plain woollen stuff of a rather open and slight fabric.

FLAX. The general appellation of the fibrous produce used in the manufacture of linen threads, &c. of the plant *Linum usitatissimum*, which is cultivated, not for this produce only, but for that of its seed, employed in agriculture for feeding and fattening cattle, as well as in commerce for making the oil so well known as "linseed oil."

This plant grows to the height of 2 or 3 feet, having a round and hollow stem, which divides into several branches, bearing blue flowers; these become the seed-pods of 10 cells, each of which contains one seed. As varieties, we distinguish the "spring" flax with short knotty stems, whose seed capsules at the period of maturity open with a perceptible sound; and the "close" flax, with longer smoother stems, whose capsules give out the seed only when thrashed; the latter variety is the one most generally cultivated. Owing to the many improvements recently made in the various processes of the flax manufacture, all the operations for converting the raw plant to its ultimate useful and ornamental state have been greatly simplified and facilitated, and much attention has been paid to improving its cultivation, which has necessarily produced many changes in the formerly established modes of husbandry.

Flax may be grown upon a great variety of soils: the best is a sound dry deep loam, with a clay subsoil; this should be properly drained, as too much underground or surface water is alike injurious. It is necessary that the land should be brought to an exceedingly fine state by frequent ploughing and harrowings, commenced in the autumn previous to the sowing, which should take place towards the end of March or beginning of April. From 2 to 2½ bushels of seed are required for one acre: the seed selected should be of a bright brown colour, heavy, shining, and of an oily feel, avoiding such as have hard ends. Riga is the best for the greatest variety of soils, though Dutch is frequently used with great success. American does not generally suit, as it is apt to produce a coarse branchy stem. The manner of sowing should be varied according to the purpose for which the crop is intended. When grain is the object of the grower, the sowing should be thin, as the plants then put out more branches, and thus yield more seed, but the fibrous produce becomes soft and meagre; the contrary is the case when the sowing is thick. Being one of the most tender plants of field cultivation, it requires very peculiar care in weeding, so as not to be injured by either the neglect or excess of this work, which should be done when the plants are about 3 inches high, that is, about a month after sowing. Guano and bone dust are suitable manures if farm dung is scarce. The following artificial manure, it has been said, will replace chemically the constituents of the plants produced from an acre of land, viz.: —

Muriate of potash - - - - -	80 lbs.?
Common salt - - - - -	28 lbs.
Burned gypsum, powdered - -	34 lbs.
Bone dust - - - - -	54 lbs.
Sulphate magnesia - - - -	56 lbs.

The average produce of seed is 12 bushels to the acre.

In regard to flax being considered a wasting crop for the land there are some observations to be made that may controvert that idea and establish one more sound in its place.

Assuming that the ashes of plants left after they are consumed by fire form a criterion of the quantity of nutritive matter they have extracted from the soil, there may at first sight appear much truth in the prevailing opinion as to the exhausting nature of the flax crop, since the ashes of this plant are 5% of the whole, which is a large proportion. But as no ashes result from burning the pure fibre, which is solely the part that may not be reconsumed upon the land, it proves that the fertility of the soil is not injured by that production. The nutrition withdrawn by the other parts can be as easily replaced by this plant as by any other, $\frac{5}{100}$ ths by the water alone in which the steeping is to be afterwards carried on, and which should therefore be kept and employed as a liquid manure, to which must be added that more solid resulting from feeding cattle on the seed or oil cake, and from the ashes of the chaff, and thus a far greater part of the constituent of this plant is returned than of almost any other. Though the colour of the flax is rather improved by letting the water run in a small stream through the steeping-pond during the operation, yet perhaps it may be a greater object to retain it for manure than to waste it for that purpose.

Whenever the flax is ripe, which is shown by the bottom of the stalk becoming yellow, and the leaves beginning to drop off, it must be immediately reaped by pulling it up by the roots. The seeds are still immature, fit merely for the oil press, and not for sowing When the seed crop is the object, the plant must be suffered to acquire its, full maturity; in which case the fibres are less fine and soft.

The flax is carried off the field in bundles to be rippled, or stripped of its seeds, which

is done by drawing it by handfuls, through an iron comb with teeth eight inches long, fixed upright in a horizontal beam. When the seeds are more fully ripened, they may be separated by the thrashing mill.

The operations next performed upon the flax will be understood by attending to the structure of the stem. In it, two principal parts are to be distinguished; the woody heart or boon, and the *harl* (covered outwardly with a fine cuticle), which encloses the former like a tube, consisting of parallel lines. In the natural state, the fibres of the harl are attached firmly, not only to the boon, but to each other by means of a green or yellowish substance. The rough stems of the flax, after being stripped of their seeds, lose in moisture by drying in warm air, from 55 to 65 per cent. of their weight; but somewhat less when they are quite ripe and woody. In this dry state, they consist in 100 parts of from 20 to 23 per cent. of *harl*, and from 80 to 77 per cent. of boon. The latter is composed upon the average of 69 per cent. of a peculiar woody substance, 12 per cent. of a matter soluble in water, and 19 per cent. of a body not soluble in water, but in alkaline lyes. The *harl* contains at a mean 58 per cent. of pure flaxen fibres, 25 parts soluble in water (apparently extractive and albumen), and 17 parts insoluble in water, being chiefly gluten. By treating the harl with either cold or hot water, the latter substance is dyed brown by the soluble matter, while the fibres retain their coherence to one another. Alkaline lyes, and also, though less readily, soap water, dissolve the gluten, which seems to be the cement of the textile fibres, and thus set them free.

The cohesion of the fibres in the rough harl is so considerable that by mechanical means, as by beating, rubbing, &c., a complete separation of them cannot be effected, unless with great loss of time, and rupture of the filaments. This circumstance shows the necessity of having recourse to some chemical method of decomposing the gluten. The process employed with this view is a species of fermentation, to which the flax stalks are exposed; it is called *retting*, a corruption of rotting, since a certain degree of putrefaction takes place. The German term is *rusting*. This is the first important step in the preparation of flax. After the retting is completed, the boon of the stalks must be removed by the second operation, called *breaking*, and other subordinate processes. The harl freed from the woody parts contains still a multitude of fibres, more or less coherent, or entangled, and of variable lengths, so as to be ill adapted for spinning. These are removed by the *hechle*, which separates the connected fibres into their finest filaments, removes those that are too short, and disentangles the longer ones.

1. *Of retting.* — The fermentation of this process may be either rendered rapid by steeping the flax in water, or slow by using merely the ordinary influence of the atmospheric damp, dews, and rain. Hence the distinction of water-retting and dew-retting. Both may also be combined.

Prior to being retted, the flax should be sorted according to the length and thickness of its stalks, and its state of maturity: the riper the plant, the longer must the retting last. The due length of the process is a point too little studied.

Water-retting. — When flax stalks are macerated in water, at a temperature not too low, fermentation soon begins, evinced in the dingy infusion, by disengagement of carbonic acid gas, and the production of vinegar. If the flax be taken out at the end of a few days, dried, and rubbed, the textile filaments are found to be easily separable from each other. By longer continuance of the steep, the water ceases to be acid, it becomes to a certain degree alkaline, from the production of ammonia, diffuses a fetid odour, from the disengagement of sulphuretted hydrogen gas, along with the carbonic acid; the acetous fermentation being in fact now changed into the putrid. The filaments become yellowish brown, afterwards dark brown, and lose much of their tenacity, if the process be carried further.

When the operation is conducted with discernment, the water-retting may be completed by the acetous fermentation alone, as the putrefaction should never be suffered to proceed to any length; because when over-retted, flax is partially rotten, gets a bad colour, and yields a large proportion of tow.

For water-retting, the flax must be loosely bound up in sheaves, placed in layers over each other in the water, or sometimes upright, with the roots undermost. Straw may be put below to keep it from touching the ground, and boards may be laid upon the top, with weights to hold it immersed about a foot beneath the surface, especially when the fermentative gases make it buoyant. As soon as it sinks at the end of the fermentation, it must be inspected at least twice a day, and samples must be taken out to see that no over-retting ensues. A single day too long often injures the flax not a little. In order to judge that the retting is sufficient, try some stalks of average thickness by breaking the boon or woody part in 2 pieces about 6 or 8 inches apart, at the middle of the stalk; catch the broken bit of wood, and if it will pull freely out downwards for that length without breaking or tearing the fibre, and with none of the fibre adhering to it, it is ready to take out: or when the boon breaks across without bending, and when several stalks knotted together sink to the bottom upon being thrown into the water. For this completion, a

shorter or longer time is required according to the quality of the flax, the temperature, &c., so that the term may vary from five to fourteen days. It may be done either in running or in stagnant water. For the latter purpose, tanks five feet deep are dug in the ground. In stagnant water, the process is sooner finished, but it is more hazardous, and gives a deeper stain to the fibres than in a stream, which carries off much of the colour. The best place for steeping flax is a pond with springs of water at its bottom; or a tank into which a rivulet of water can be occasionally admitted, while the foul water is let off. For every fresh quantity of flax, the pond should be emptied, and supplied with clear water. Water impregnated with iron stains flax a permanent colour, and should therefore never be used. After retting, the flax should be taken out without delay, rinsed in clean water, and exposed in an airy situation to dry by the sun.

Rough rippled flax stalks, well seasoned before being retted, and dried afterwards, show a loss of weight, amounting to 20 or 30 per cent., affecting both the boon and the harl. This loss is greater the finer the stems, and the longer the retting. The harl contains, besides the textile filaments, a certain portion of a glutinous cement; but nothing soluble in water. The destruction of the gluten cannot be pushed to the last point by steeping, without doing an essential injury to the filaments.

Dew-retting. — The fetid and noxious exhalations which the water-retting diffuses over an extensive district of country, and the danger of over-retting in that way, especially with stagnant water, are far from recommending that process to general adoption. Dew-retting accomplishes the same purpose, by the agency of the air, dews, and rain, in a much more convenient, though far slower manner. The flax, with this view, should be spread out thin upon meadow or grass lands, but never upon the bare ground, and turned over, from time to time, till the stems, on being rubbed between the fingers, show that the harl and the boon are ready to part. The duration of dew-retting is, of course, very various, from two to six or eight weeks, as it depends upon the state of the weather; a moist air being favourable, and dry sunshine the reverse. The loss of weight by dew-retting is somewhat less than by water-retting; and the textile fibres are of a brighter colour, softer and more delicate to the touch.

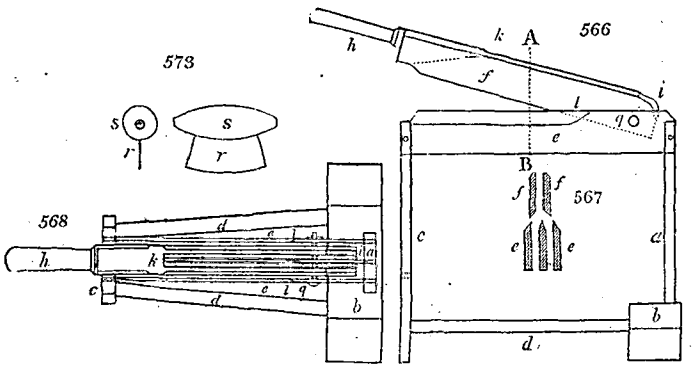
Mixed retting.—This may be fairly regarded as the preferable plan, the retting being begun in the water, and finished in the air. The flax should be taken out of the steep whenever the acetous fermentation is complete, before the putrid begins, and exposed, for two or three weeks, on the grass.

Within the last two years, the hazardous and tedious process above described has been attempted to be superseded by steeping the flax plant in vats of water artificially heated to 70° Fahr., whereby the effects are produced in sixty or seventy hours. Drying by fire in kilns is pernicious alike to the seed or fibrous produce; as in the former it dries up too soon the nutritious particles that would be absorbed by the seed from its pod or outer covering, and in the latter impairs the rich and oily property of the flax. The following is the description of an establishment for the prosecution of Mr. Schenck's process, situated at Newport river, county Mayo. The tenements containing the vats and drying shelves are simple wooden sheds of cheap construction. In one end of the building are four vats set parallel to each other the length of the house; they are made of inch deal in the form of a parallelogram, fifty feet long, six broad, and four deep. There are false bottoms perforated with holes; underneath these are introduced the steam-pipes, crossing the vats, and having stop-cocks at their entrance, by which the steam can be let on from the main pipe as required. The steam is generated in a small boiler, which also serves to turn two *hydro-extractors*, a patent apparatus used to drive off a portion of the water with which the flax is saturated, on being taken from the vats. The flax is packed into the empty vats, on the butt ends, in a half sloping position, precisely as in the case of a steep pool, only one layer being the depth. The water is then let in, and a frame fastened over the top of the flax, answering the end of stones and straw or soda in the steeping pools, for prevention of the rising of the flax in the course of fermentation. This process is now renounced.

The steam is then let into the pipes by turning the stop-cocks, and the water is some eighteen or twenty hours in becoming heated to the required point, 85° or 90°. The fermentation then commences, and no further steam is required, the action going on until the flax is thoroughly retted, which is in forty hours afterwards, being sixty from the time of the admission of the water. At the end of the sixty hours, the flax is taken out, the water allowed to run off, and the vat permitted to cool. The same process is then repeated with fresh water and fresh flax. When taken from the water, the flax is packed in the hydro-extractor, which is a round vessel of iron made to revolve by steam power with great velocity, the water being driven out of the flax on the principle of centrifugal force. Thirty beets or small handfuls are placed in this machine at a time, and about 20 lbs. of water are extracted in from three to five minutes. A few hours suffice for the contents of a vat, each vat containing 2 tons of flax straw. The hydro-extractor only separates a portion of the water; the flax now remains to be

thoroughly dried. In summer, or indeed, for six months in the year, this can be accomplished, as usual, by spreading upon grass land in the open air. During winter, however, it is necessary to procure other means of drying. A shed has therefore been erected, communicating by doors with the vat house, filled with ranges of shelves, composed simply of railings of lathwood in five or six tiers. The flax is spread lightly along these shelves by women, and the house is heated by steam-pipes. This house is capable of drying the full of one vat per diem. The flax, when dried, is made up in beets or handfuls, of a size suited for feeding into the breaking rollers of the mill.

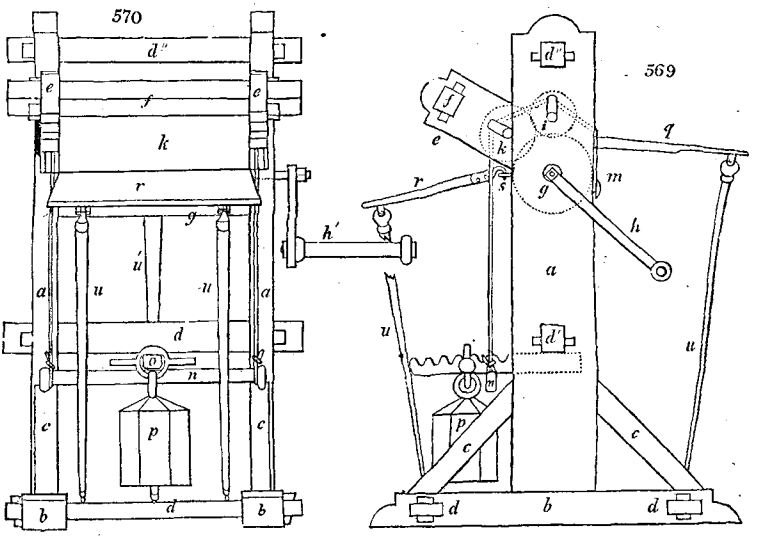
2. *The breaking* is performed by an instrument called a brake. In order to give the wood or boon such a degree of brittleness as to make it part readily from the harl, whereby the execution of this process is rendered easy, the flax should be well dried in the sun, or what is more suitable to the late period of the year, in a stove. Such is often attached to the bakers' ovens in Germany, and other flax-growing countries. The drying temperature should never exceed 120° F., for a higher heat makes it brittle, easy to tear, and apt to run into tow. Before subjecting the flax to the brake, the stems should be equalized and laid parallel by the hand, and the entangled portions should be straightened with a coarse heckle. The brake has one general construction, and consists of two principal parts, the frame or case, and the sword or beater. In the simplest brakes, the frame *e*, *fig. 566.*, is a piece of wood cleft lengthwise in the middle, supported by the legs *a* and *c*. The sword *f*, also of hard wood, is formed with an edge beneath, and turns round the centre of motion at *q*, when seized by the handle *h*, and moved up and down. As it descends, the sword enters the cleft of the frame, and breaks the flax stalks laid transversely upon it, scattering the boon in fragments.



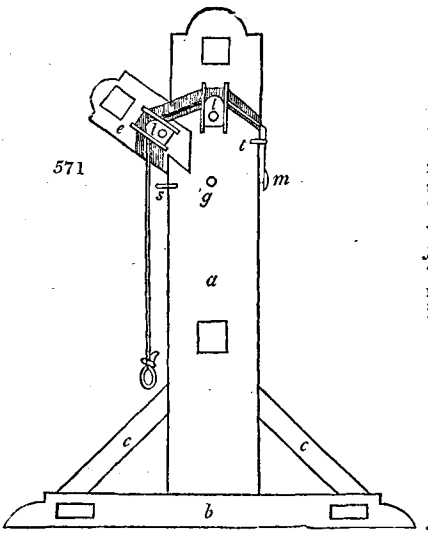
But those hand brakes are more convenient which are provided with a double cleft, or triple row of oblong teeth, with a double sword. This construction will be understood by inspecting *figs. 566, 567, 568. Fig. 566.* is the section of that side at which the operative sits; *fig. 567.* is a section in the line A B, of *fig. 566.*; and *fig. 568.*, the ground plan. The whole machine is made of hard wood, commonly red beech. Two planks, *a* and *c*, form the legs of the implement. *a* is mortised in a heavy block, to give the brake a solid bearing; two stretchers *d* bind *a* and *c* firmly together. The frame *e* consists of three thin boards, which are placed edgewise, and have their ends secured in *a* and *c*. The sword *f* is a piece of wood, so chamfered from *i* to *k*, that it appears forklike, and embraces the middle piece of the frame; its centre of motion is the wooden pin *q*; in front is the handle *h*, which the operative seizes with the right hand. Both the lathes of the frame and those of the sword are sharpened, from *l* to the front end, as is best shown in *fig. 567.*; but the edges must not be too sharp, for fear of injuring the flax; and, for the same reason, the sword should not sink too far between the lathes of the frame. Such hand-brakes are laborious in use, and often tear the harl into tow. The operative, usually a female, in working the brake, seizes with her left hand a bundle of flax, lays it transversely across the frame, and strikes it smartly with repeated blows of the sword, pushing forwards continually new portions of the flax into the machine. She begins with the roots, turns next round the tips, then goes on through the length of the stalks. Flax is frequently exposed twice to the brake, with a stove-drying between the two applications.

The brake machines afford a far preferable means of cleaning flax than the above hand tools. The essential part of such a machine consists in several deeply fluted rollers of wood or iron, whose teeth work into each other, and while they stretch out the flaxen stalks betwixt them, they break the wood or boon, without doing that violence

to the harl which hand mechanisms are apt to do. The following may be regarded as one of the best constructions hitherto contrived for breaking flax. *Fig.* 569. is a view of the right side of this machine. *Fig.* 570., the view from behind, where the broken



flax issues from between the rollers. The frame is formed by the two side pillars or walls *a*, *a*, which are mortised into the bottom *b*, *b*; and are firmly fixed to it by braces. Two transverse rods *d*, *d*, secure the base, two others *d' d''*, the sides. In each of these a lateral arm *e*, is mortised in an oblique direction; a cross bar *f*, unites both arms. *Fig.* 571. shows the inside of the left side of the frame, with the subsidiary parts. The three rollers, *g*, *i*, *k*, may be made of red beech, with iron gudgeons, and fluted in their length, each of the flutes being $\frac{5}{12}$ths of an inch broad, and $\frac{1}{12}$ths deep. The large roller *g*, bears upon the right side, a handle *h*, which on being turned, sets the whole train in motion. The side partitions *a*, *a*, are furnished with brasses in whose round holes *l*, *g*, *fig.* 571., the gudgeons *g* work. For the extremities of the two smaller rollers, there are at *a* and *e* slots in brasses, as may be seen in *fig.* 569. Within the partition *a*, there are movable brasses *l*, for the pivots of *i* and *k*, shown in *fig.* 571. Each brass slides in a groove, between two ledges. A strong cord made fast at *m* to the partition *a*, runs over the brass of *i*, next over that of *k*, then deseends perpendicularly, and passes over the cross bar *n*, *figs.* 569. and 570. This construction being repeated at both ends of the rollers, the rod *n* binds both cords. Against the cross bar *d'* of the frame, a lever *o* is sustained, which lies upon the rod *n*, and carries a weight *p*. The farther or nearer this weight hangs toward the end of the lever, it stretches the cord more or less, and presses by means of the brasses *l*, the rollers *i*, *k*, towards the main roller *g*. A table *q*, serves for spreading out the flax to be broken, and a second one *r*, for the reception of the stalks at their issuing from between the rollers. Both tables

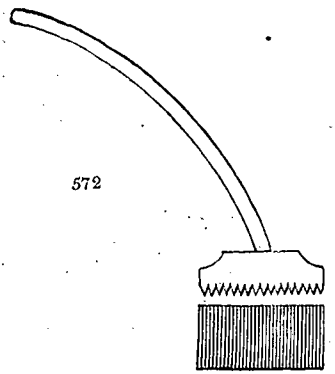


hang by means of iron hooks to rings of the frame *s*, *t*, *figs.* 569. and 571., and are supported by the movable legs *u*, *u*, *u*, *figs.* 569. and 570. In using the machine the operative lays an evenly spread handful of flax upon the table *q*, introduces their root ends with his left hand between the rollers *g* and *i*, and turns round the handle *h*, with the right. The stems are first broken betwixt *g* and *i*, then between *g* and *k*, and come out upon the table *r*. The handle is moved alternately forwards and backwards, in order that the flax may be rolled alternately in the same directions, and be more perfectly broken. The boon falls down in very small pieces, and the harl remains expanded in parallel bands. This should be drawn over the points of a heckle, then laid for a couple of days in a cellar to absorb some moisture, and afterwards worked once more through the machine, whereby the flax acquires a peculiar softness.

The advantages of this brake machine are chiefly the following:—

It takes up little room, and from its simplicity is easily and cheaply constructed; it requires no more power to work, than the ordinary hand-brake; it tears none of the filaments, and grinds nothing except the boon, in consequence of the flutings of the rollers going much less deep into each other, than the sword of the hand-brake; it prevents all entanglements of the flax, whence in the subsequent heckling the quantity of short fibres or tow is diminished; and it accomplishes the cleaning of even the shortest flax, which cannot be well done by hand machines.

The comminution of the boon of the stems, which is the object of the breaking process, can however be performed by thrashing or beating, although in this way the separation of the woody matter from the textile fibres is much less completely effected.



572

It is the practice in Great Britain, instead of breaking, to employ a water-driven wooden mallet, between which and a smooth stone the flax is laid. In that part of Belgium where the preparation of flax has been studied, the brake is not used, but beating by means of the *Bott-hammer*, to the great improvement, it is said, of the flax. The *Bott-hammer*, *fig.* 572., is a wooden block, having on its under face, channels or flutings, five or six lines deep, and it is fixed to a long bent helve or handle. In using it, a bundle of the dried flax stalks is spread evenly upon the floor, then powerfully beaten with the hammer, first at the roots, next at the points, and lastly at the middle. When the upper surface has been well beaten in this way, it is turned over, that the under surface may get its turn. The flax is then removed, and well shaken to free it from the boon.

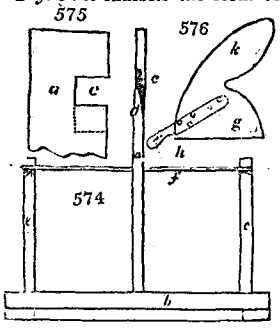
By the brake or the hammer the whole wood is never separated from the textile fibres, but a certain quantity of chaffy stuff adheres to them, which is removed by another operation. This consists either in rubbing or shaking. The rubbing is much practised in Westphalia, and the neighbouring districts. In this process, the operative lays the rubbing apron on a piece of dressed leather, one foot square, upon her knee; then seizes a bundle of flax in the middle with her left hand, and scrapes it strongly with the *Ribbe-knife* held in her right, *fig.* 573. This tool, which consists of a wooden handle *s*, and a thin iron blade *r*, with a blunt and somewhat bent edge, acts admirably in cleaning and also in parting the filaments, without causing needless waste in flax previously well broken.

The winnowing, which has the very same object as the rubbing, is, however, much more generally adopted than the latter. Two distinct pieces of apparatus belong to it, namely, the *swing-stock* and the *swing-knife*. The first consists of an upright board with a groove in its side, into which a handful of flax is so placed that it hangs down over half the surface of the board. While the left hand holds the flax fast above, the right carries the swing-knife, a sabre-shaped piece of wood from 1½ to 2 feet long, planed to an edge on the convex side, and provided with a handle. With this knife the flax is struck parallel to the board, with perpendicular blows, so as to scrape off its woody asperities. The breadth of the swing-knife is an important circumstance; when too narrow it easily causes the flax to twist round it, and thereby tears away a portion of the fibres. When 8 or 10 inches broad, it is found to act best. Knives made of iron will not answer, for they injure the filaments.

Figs. 574, 575. show the best construction of the swing-stock. The board *a* has for its base a heavy block of wood *b*, upon which two upright pins *e e*, are fixed. The band *f*, which is stretched between the pins, serves to guide the swing-knife in its movements, and prevent the operative from wounding his feet. The under edge of the

groove *c*, upon which the flax comes to be laid, is cut obliquely and rounded off (see *d* in *fig.* 574.); thus we perceive that the swing-knife can never strike against that edge, so as to injure the flax.

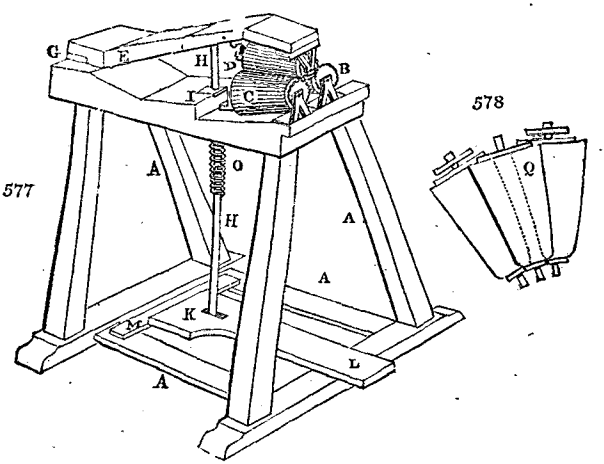
Fig. 576. exhibits the form of a very convenient implement which is employed in Belgium instead of the swing-knife. It is a sort of wooden hatchet, which is not above two lines thick, and at the edge *g h* is reduced to the thickness of the back of a knife. The fly *k* gives force to the blow, and preserves the tool in an upright position. The short flat-pressed helve *i* is glued to that side of the leaf which in working is turned from the swing-stock; and is, moreover, fastened with a wooden pin.



The rubbing and swinging throw off the coarsest sort of tow, by separating and shaking out the shortest fibres and those that happen to get torn. That tow is used for the inferior qualities of sacking, being mixed with many woody fibres.

We may in general estimate that 100 pounds of the stalks of retted flax, taken in the dry state, afford from 45 to 48 pounds of broken flax, of which, in the swinging or scutching, about 24 pounds of flax, with 9 or 10 pounds of scutch tow, are obtained. The rest is boon-waste. The breaking of 100 pounds of stalks requires, in the ordinary routine of a double process by hand, about 20 hours; and with the above described machine, from 17 to 18 hours. To scutch 100 pounds of broken flax clean, 130 hours of labour are required by the German swinging method.

Mr. Bundy obtained a patent in 1819, for certain machinery for breaking and preparing flax, which merits description here. *Fig.* 577. AAAA, is the frame made either of



wood or metal, which supports the two conical rollers B and C. These revolve independently of each other in proper brass bearings. A third conical roller D is similarly supported under the top piece E of the machine. All these rollers are *frusta* of cones, made of cast-iron. Whatever form of tooth be adopted, they must be so shaped and disposed with regard to each other as to have considerable play between them, in order to admit the quantity of flax stem which is intended to be broken and prepared. The upper piece E of the machine which carries the upper conical roller D, is fixed or attached to the main frame AAAA by strong hinges or any other movable joint at G, and rods of iron or other sufficiently strong material: HH is attached at its upper end by a joint to the top piece E, through a hole near I, and is fixed at its lower end by a joint K to the treadle or lever KL, which turns upon the joint or hinges M. A spring or weight (but the former is preferable for many reasons) is applied to the machine in such manner, that its action will always keep the upper piece E, and consequently the upper roller D, in an elevated or raised position above the rollers B and C, when the machine is not in action; and of course the end L of the treadle will also be raised, which admits of the flax to be worked being introduced between the rollers, viz. over the two lower

rollers B, C, and under the upper roller D; such a spring may be applied in a variety of ways, as between the top piece E, and the top or platform of the machine at N; or it may be a strong spiral wire spring, having its upper end fastened to the platform while its lower extremity is fixed to the rod H H, round which it coils as shown at O, or it may be placed under the end L of the treadle; but in every case its strength must be no more than will be just sufficient to raise the upper roller D about two inches from the lower rollers, otherwise it will occasion unnecessary fatigue to the person working the machine.

The manner of using it is as follows: the upper and lower rollers being separated as aforesaid, a small handful of dried flax or hemp stems is to be introduced between them, and held extended by the two hands, while the rollers are brought together by the pressure of the foot upon the treadle L. This pressure being continued, the flax or hemp is to be drawn backwards and forwards by the hands between the rollers, in a direction at right angles to their axes, and eventually withdrawn by pulling with one hand only. The foot is now to be removed until the flax or hemp is again replaced, and each end is this way to be drawn several times through the machine, until such ends are respectively finished.

By a succession of these operations, using the pressure of the foot upon L, each time that the flax or hemp is introduced between the rollers, and regulating such pressure according to the progress of the work, the flax or hemp will soon be sufficiently worked and the fibre brought into a clean and divided state fit for bleaching; or if it be required to spin it in the yellow state, it may be made sufficiently fine by a longer continuation of the same process, particularly if worked between the smaller ends of the rollers.

Indeed, the operation may be commenced and continued for some time, with the larger part of the rollers, and finished with their smaller ends; and, in this point of view, the invention of conical rollers will be found both convenient and useful; for as the flutes, grooves, or teeth vary in their distance from each other at all points between the large and small ends, so it becomes almost impossible for the workman to draw the flax or hemp through such rollers in the same track; and thus the breaking of the boon must be much more irregular, and the fibre will be much more effectually cleansed than it can be by the flutes, grooves, or teeth of cylinders, or other such contrivances formerly employed; because they would probably fall frequently upon the same points of the fibres. If it is intended that the flax shall be bleached before it is spun, then the second part of Mr. Bundy's invention may be had recourse to, which consists in moving certain trays or cradles in the water, or other fluid used for bleaching the flax or hemp in the manner following, viz.: The flax or hemp, after having been broken and worked in the machine, should be divided into smaller quantities of about one ounce each, and these should be tied loosely in the middle with a string, and in this state laid in the trays or cradles, and then be soaked in cold soft water for a day or two, when each parcel should be worked separately, while wet, through a machine, precisely similar to that already described, except only that the rollers should be cylindrical, and made entirely of wood with metal axles, and the teeth, which will be parallel, should be similar in form to those shown in section at Q, *fig.* 578. Such operation will loosen the gluten and colouring matter, for the rinsing and wringing which must follow. The flax must then be again disposed in a flat and smooth manner, in such trays or cradles, and once more set to soak in sufficient soft water to cover it, in which a small quantity of soap, in the proportion of about seven pounds of soap to each hundred weight of flax, has been previously dissolved, and in this state it should remain for two or three days longer, and then be finally worked through the machine, rinsed with clear water, and wrung; which will render it sufficiently white for most purposes.

Can flax be prepared without retting?—The waste of time and labour in the steeping of flax; the dyeing of the fibres consequent thereon, which must be undone by bleaching; the danger of injuring the staple by the action of putrescent water; and, lastly, the diminished value of flax which is much water-retted, are all circumstances which have of late years suggested the propriety of superseding that process entirely by mechanical operations. It was long hoped, that by the employment of breaking machines, the flax merely dried could be freed from its woody particles, while the textile filaments might be sufficiently separated by a subsequent heckling. Experience has, however, proved the contrary. The machines, which consisted for the most part of fluted rollers of iron or wood, though expensive, might have been expected to separate the ligneous matter from the fibres; but, in the further working of the flax no advantage was gained over the water-retting process.

1. Unretted flax requires a considerably longer time for breaking than retted, under the employment of the same manipulations.

2. Unretted stalks deliver in the breaking and heckling a somewhat greater product than the same weight of flax which has been retted; but there is no real advantage in

this, as the greater weight of the unretted flax consists in the remainder of ligneous or glutinous matter, which being foreign to the real fibre, must be eventually removed. In the bleaching process, the water and the alkaline lyes take away that matter, so that the weight of the bleached fibre is not greater from the unretted than the retted flax.

3. The parting of the fibres in the unretted stalks is imperfectly effected by the heckling; the flax either remains coarser as compared with the retted article, and affords a coarser thread, or if it be made to receive greater attenuation by a long-continued heckling, it yields incomparably more torn filaments and tow.

4. The yarn of unretted flax feels harder, less glossy, and rougher; and, on account of these qualities, turns out worse in the weaving than the retted flax. Nor is the yarn of unretted flax, whether unbleached or bleached, in any degree stouter than the yarn of the retted flax.

5. Fabrics of unretted flax require for complete bleaching about a sixth less time and materials than those of the retted. This is the sole advantage, but it is more than counterbalanced by the other drawbacks above specified.

The foregoing operations having brought the flax into the ordinary fibrous merchantable state, suitable for the spinner, it now remains to pass through the following processes, by which it is manufactured into yarns for sale or use, viz., 1st, heckling, 2nd, preparing, 3rd, spinning, 4th, reeling, 5th, drying, and 6th, making up.

6. *Heckling.* The operation of heckling has for its objects, 1st, that of combing or straightening the filaments entangled as coming from the scutching. 2d, that of splitting them, with a view of lessening and equalising their size. In accomplishing these objects the material is unavoidably divided into two portions. The long and straight fibres constituting the first, called "line," and the short, broken, and confused of the second, "tow." Both the line and tow are capable of being spun, but the line is much the more valuable, being used for the better descriptions of yarns, &c., with greater facility than the tow for the inferior. The aim, therefore, of good heckling is to produce the larger proportion of line from a given quantity of flax, the attainment of which leaves much scope for care and judgment, whether the older method of heckling by hand or the more recent by machine is adopted. In hand heckling the instruments are a comb-fashioned tool, called the *heckle* or *hackle*; a surface studded more or less thickly with metal points, called heckle teeth; over which the flax is drawn in such a way that the above three required operations may be properly accomplished.

The heckles ordinarily used for hand heckling in this country are in the form of rectangular parallelograms, presenting a line of 7 inches towards the worker, and 4 to 5 inches deep. The first tool employed is called the "ruffer," the pins of which are about $\frac{1}{4}$ inch square at their base, and 7 inches long, and brought to a fine point; the second is the "common 8," which is always used after the "ruffer;" then the "fine 8," the "10," the "12," the "18." The pins of all these tools are similarly placed to those of the ruffer, but are somewhat shorter in length and are more slender as the tools increase in fineness. In all these tools the pins are held in wooden stocks of about $\frac{3}{4}$ inch in thickness and covered with sheet tin. This sheet tin, through which the pins are driven, helps to support them and prevent the wood from splitting. These tin covered stocks are only of a size necessary for the extent of pins employed, and are themselves screwed to other larger pieces of board, a little broader and some inches longer than themselves, and by which they are ultimately fixed to the heckler's bench, inclining somewhat backward with their points from the worker, and a sloping board behind to prevent the flax entering too much in the pins, thus:

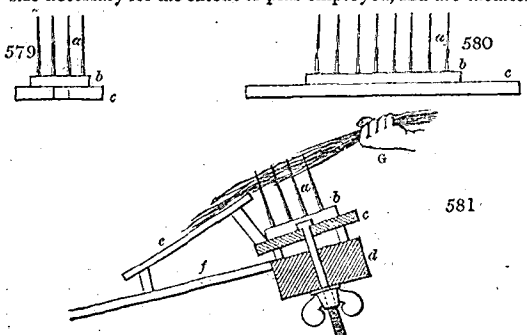


Fig. 579. end view of a heckle; *fig.* 580. front view of heckle; *fig.* 581. heckle, &c. fixed up for working. *a* pins; *b* tin covered stock; *c* foundation board; *d* beam of table or bench; *e* back board; *f* table to receive the tow, &c.; *g* hand of workman. Such is the form of heckle used in England, and also the manner they are, of whatever description, fixed for work.

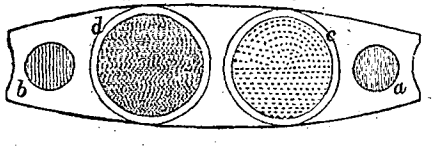
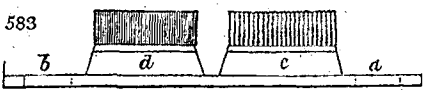
582



583



In Germany the common construction of the heckle is the following; (see *fig.* 582.) *Fig.* 582. is the ground plan, and *fig.* 583. is the section. Upon an oblong plank *a b*, two circular or square blocks of wood *c* and *d* are fixed, in which the heckle teeth stand upright. To give these a firmer hold they are stuck into holes in a brass or iron plate, with which the upper surface of *c* and *d* is covered. Both heckles may be either associated upon one board or separated; and of different finenesses; that is, the teeth of the one may be thinner, and stand closer together; because the complete preparation of the flax requires for its proper treatment, a twofold heckling; one upon the coarse, and one upon the fine heckle; nay, sometimes 3 or 4 heckles are employed of progressive fineness. The heckle teeth are usually made of iron, occasionally of steel, and from 1 to 2 inches long. Their points must be very sharp and smooth, all at an equal level, and must all graduate very evenly into a cylindrical stem, like that of a sewing needle, without any irregularity. The face of the heckle block must be uniformly beset with teeth, which is done by different arrangements, some persons setting them in a circle, and others in parallel rows. The coarse heckle is furnished with teeth about one-tenth of an inch thick, one and a quarter of an inch long, and tapering from the middle into a very fine point. In the centre of the circular heckle is a tooth planted; the rest are regularly set in 12 similar concentric circles, of which the outermost is $5\frac{3}{4}$ inches in diameter. The fine heckles contain no fewer than 1,109 teeth. Instead of making the points of the teeth round, it is better to make them quadrangular, in a rhombus form, in which case the edges serve to separate or dissect the fibres.

The operation of manual heckling is simple in principle, although it requires much experience to acquire dexterity.

The workman having first divided the flax into handfuls or stricks, of which there are 300 to 400 to the cwt., proceeds to grasp one as flatly spread as possible between his forefinger and thumb, by about its middle and wind the top end round his hand in order the better to prevent the slipping of the fibres; he then begins by a circular swing of his arm to lash the root end into the heckle, taking care to commence as near the extremity as possible, now and then collecting the fibres by holding his left hand in front of the tool, turning the strick from time to time, he thus gradually works up as near as possible to his right hand, when he seizes the ruffed part of the strick and holds it in the same manner as at first, and proceeds by similar treatment to "ruff" the top end; when this is finished the "ruffed" work is taken to the tool called a "common 8," the pins of which are much closer placed than those of the ruffer, and are only 4 or 5 inches long. This "8" is always used after the ruffer, but from it the work can be taken to any of the finer tools, viz. 8, 10, 12, and sometimes 18. It is usual and better to dress both ends over each tool before taking the work to the next. The pins of all these tools are 4 inches long, in order, as was supposed, to have sufficient spring. The flax is not lashed into them as into the ruffers, neither are the ends required to be wound round the hand. But the root end of the flax is always the one to be first worked, and the heckling begun at nearly the extremity of the strick, which on being drawn through the heckle is received by the left hand of the workman, and by it carried back and laid upon the back board and over the point of the pins, for the angle of inclination of the heckles and a slight lowering of the right hand causes it to enter sufficiently on being drawn forward. As it is impossible to ruff or dress entirely up to the hand, when the hold is changed in either operation, there must of necessity be left a certain space to be repassed through the tools; this is called the "shift," but the less length that is required for this purpose the better for the yield of line. The numerous long fibres that slip from the strick in ruffing must be collected and drawn from the mass of tow attached to them, when they can be relaid in the strick, or kept to be dressed separately under the name of "shorts," and from time to time the short fibres or tow sticking to the teeth of the finer tools are removed. Whenever one-half of the length of the strake of flax is heckled, it is turned round to heckle the other half. This process is repeated upon each heckle. From 100 pounds of well-cleaned flax, about 45 or 50 pounds of heckled line may be obtained by the hand labour of 12 hours; the rest being tow, with a small waste in boony particles of dust. The process is continued, till by careful handling little more tow is formed.

To aid the heckle in splitting the filaments, three methods have been had recourse to; beating, brushing, and boiling with soap-water, or an alkaline lye.

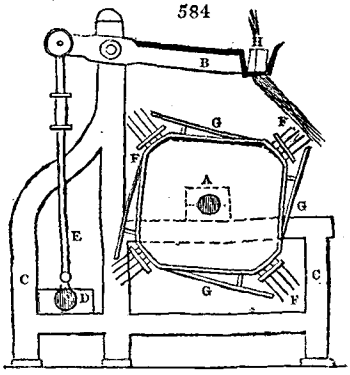
Beating flax either after it is completely heckled, or between the first and second

heckling, is practised in Bohemia and Silesia. Each heckled tress of flax is folded in the middle, twisted once round, its ends being wound about with flaxen threads; and this head, as it is called, is then beat by a wooden mallet upon a block and repeatedly turned round till it has become hot. It is next loosened out, and rubbed well between the hands. The brushing is no less a very proper operation for parting the flax into fine filaments, softening and strengthening it without risk of tearing the fibres. This process requires in tools, merely a stiff brush made of swines' bristles, and a smooth board, 3 feet long and 1 foot broad, in which a wooden pin is made fast. The end of the flax is twisted two or three times round this pin to hold it, and then brushed through its whole length. Well heckled flax suffers no loss in this operation; unheckled, only a little tow; which is of no consequence, as the waste is thereby diminished in the following process. A cylindrical brush turned by machinery might be employed here to advantage. These have been tried in establishments for machine spinning, but not found advantageous.

The boiling of flax with potash lye alone, or with lye and soap, dissolves that portion of the glutinous cement which had resisted the retting, completes the separation of the fibres, and was therefore supposed a good practical means of improving flax. When it is performed upon the heckled fibres, a supplementary brushing is requisite to free it from the dust, soapy particles, &c., but this also is now abandoned.

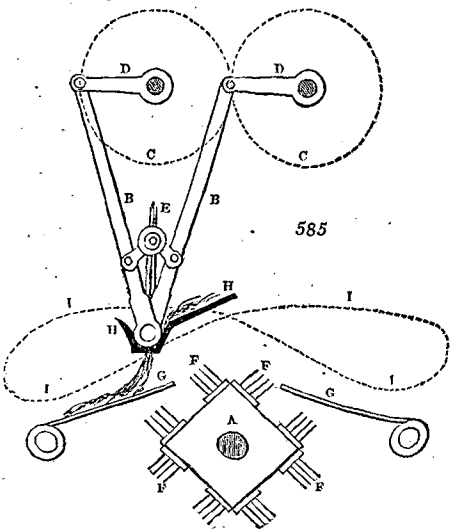
Machine heckling. — As intimated above, the object of all heckling was that of producing a good yield of line with tows of good quality, that is to say, free from broken unsplit fibres, lumps and knots: the care and attention to do this, together with the expense and uncertain results of the individual skill of workmen, urged manufacturers some time since to attempt the establishment of machines for dressing flax mechanically. Therefore many contrivances have been made with this view, but it was long doubted whether any of them made such good work with so little loss as hand labour. In heckling by the hand, it was supposed the operative would feel at once the degree of resistance, and be able to accommodate the traction to it, or throw the flax more or less deeply among the teeth, according to circumstances, and draw it with suitable force and velocity. For a considerable period these ideas, or rather prejudices as they may now be called, seemed to be confirmed; for the earlier attempts to supersede hand heckling, like those in many other undertakings, though partially favourable, were upon the whole somewhat discouraging: in attaining one point desired another was lost, for too much still depended upon the care and attention, if not upon the actual skill, of the attendants. Therefore, a review of those machines that really came into operation, to a more or less limited extent, as well as a slight mention of some of those patented, but never publicly shown, may not be useless as a lesson for preventing a repetition of things already known, as well also for illustrating the steps by which these first prejudices have been gradually overcome. The first heckling machine invented, or at least published, was called the "Peter," and was intended to imitate as closely as possible the movements of the hand heckler. In commencing the work, the flax was first divided into small convenient portions or handfuls, of about 4 ounces each, called "stricks," and which, before being taken to the machine, were slightly straightened and dressed over the ordinary hand "ruffer." Each of these stricks was then placed between a pair of short iron bars, one of these bars having an indentation along its middle, and the other a corresponding projection; thus, when tightened together by screws $4\frac{1}{2}$ inches apart (such a length being equal to a hand-heckler's grasp), the flax was firmly held while exposed to the action of the heckles, (this pair of bars with screws being called a "holder"). This holder was then suspended from movable levers over a truncated rectangular cylinder, upon the truncated angles of which were fixed, at a certain angle, heckles similar to those used in the manual operation. The levers supporting the holders received from a crank a short up and down motion, so timed in their oscillations as to strike the holder nearly against the points of the pins at the time they were passing under, coming thus as nearly as possible to the effect of a man striking in and drawing through the heckles, with the exception that the flax remained nearly stationary and the heckle was drawn through it by the rotation of the cylinder; such machine carried two holders. The tow made and collected in the heckles, was seized and taken off by boys stationed for that purpose, while another at the ringing of a bell took out and changed the sides of the stricks to be presented to the action of the heckles, and subsequently withdrew them from the first machine to another similar but with finer heckles, and thus continued till the root end (always the first to be operated upon) was dressed to the desired degree of fineness, when they would be taken to a table where another set of boys, previously to removing the first holder, put on a second to the already heckled part, leaving a short length of $2\frac{1}{2}$ or 3 inches to be reheckled. This operation is termed shifting, and the space left the "shift," and is thus performed and so called at the present day; the only change in the holder now in use being, that one screw is used for two stricks instead of two screws for one strick. *Fig.* 584. will more clearly show the construction of this machine.

584



A square truncated cylinder carrying the heckles; B oscillating arm or lever for supporting the holder; C C C framing; D crank and shaft; E connecting rod from crank to oscillating arm; F, F, F, F heckles; G G G G back board; H holder. The first motion was given by pulleys on the shaft D, which revolved 4 times to 1 of the heckle cylinder, by the intervention of suitable wheels. The worm and wheels for the bell-motion were attached in the usual manner to the shaft of the cylinder.

Machines of this construction continued in rather limited use without any change or competition till about the year 1825, when a patent was taken for a machine known as the pendulum machine. The flax in the holder being suspended and swung backwards and forwards while the heckle remained fixed, thus the flax was heckled, stroke for stroke, on each of its sides. The boys as in the last described, snatching off the tow as it was formed, and at certain times, that is at each rise of the pendulum, for it had a rising and falling motion to imitate the hand workers in commencing at the extreme end of the flax, passing the holder from one recess to another of the pendulous table, so as to arrive at the progressively finer tools when ranged along the machine, but sometimes the different tools were fixed upon the angles of a square cylinder that presented a finer range, the whole length of the machine, by turning up a new angle at each rise of the pendulum, when the labour of the boys was simply to put in the tow and take out from it the flax. The adjoining diagram, (*fig. 585.*) without entering on any details of a machine that was so little used, will make the theory of its action quite clear.

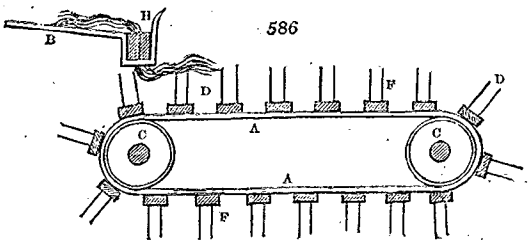


A heckle bench sometimes revolving so as to present different degrees of heckles at its various angles, sometimes stationary with the gradations of heckles upon its length; B B, pendulum arms; C C, equal wheels working into each other; D D, crank arms; E radial slide-bars to preserve the holder table vertical; H, holder table; F, F, F, F, heckles; G, G, back boards; I I, direction in which the holders swing; there were the same wheels, &c., at each end of the machine, and the holder table H reached from one to the other. The wheels C, C, with all attached to them, were made to rise and lower upon the heckles, and the back-boards G to rise when the heckle bench turned.

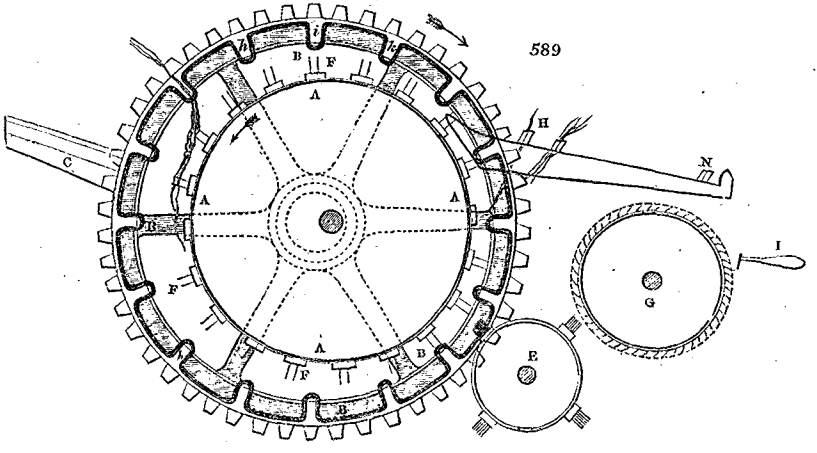
About the same time another patent was taken out for a machine, where the holders were suspended above one end of a travelling sheet of heckles. This machine also required hand labour to turn and transfer the stricks, though the tow was caused to fall clear from the heckles by mechanical means. The following sketch (*fig. 586.*) shows the principle upon which this machine works, and though never much employed at the time of its appearance, has subsequently served as a foundation for those that are now in the zenith of their prosperity.

A A (*fig. 586.*) sheet of heckles; B support for holders; C, C carrier pulleys for the sheet of heckles. *Fig. 587.*, a larger view of the heckle bar G G, in order better to show the faller D D D in the staples or grooves E, E, and *fig. 588.* at the end of the heckle-bar G G; F, F, pins of the heckles, between the rows of which the faller D D D acts to push the tow off the pins. There is a clearing faller D to each heckle, which is kept to the bottom of the heckles at that part of their course where they are in contact with the flax, but at the turn F D fly beyond the points, as shown by the effect of the centrifugal force.

All these machines, possessing great similarity of features in regard to the personal



attention required, never came into such general operation as to supersede entirely hand-dressing, either from their own defects or prejudices against their employment. About the year 1830, in consequence of the new mode of spinning, hereafter to be described, being carried on with considerable energy, it was found advantageous to cut the flax into 2, 3, or more lengths previously to heckling, which rendered it necessary to have machines peculiarly adapted for this new short description of material. This machine, known as the excentric or circular machine, deserves considerable attention for its own inherent merits, and the extensive utility it has proved to be of in suggesting the principal parts of those by which it has been supplanted. In its original form it was made of a breadth suitable for only one strick, and consisted of a cylinder 3 ft. diameter, upon the whole circumference of which at intervals of 3 or 4 inches were fixed the heckles. As each machine could only carry one description of heckle, it was necessary to employ a series of these machines, called a "class," when the flax required to be dressed over a succession of finer tools, each succeeding machine carrying a finer tool than its predecessor. The heckles were cleared of tow by coming in contact at one part of their revolution with a brush roller, which also revolved in contact with a cylinder covered with card clothing, the points of the pins being in such a direction as to clear the brush from tow, and allow itself to be in its turn cleared by the oscillations of a comb, whence by rollers the tow was brought into a sliver. In order to preserve the continuity of the supply of tow, and maintain the regularity of the sliver produced by it, the holders with the flax were presented to the heckle cylinder in a manner peculiar to this machine, and in endless succession by means of certain circular carriers placed at each end of the heckle cylinder, but excentric thereto, and at such a distance apart as each should bear one end of the holder as it extended across the cylinder parallel



to its axle. Thus, the holders introduced at that part of the circumference of these carriers furthest from the heckles were carried forward, while the flax was in operation, till they were brought almost into contact with the points of the pins, when by the intervention of a slide they were withdrawn from the machine, but with one side only of the flax dressed, and that but on one tool; therefore, the holder required replacing in the same machine, in order that the second side of the strick should be dressed as was the first. The holders then required to be carried by hand to each succeeding machine of the class.

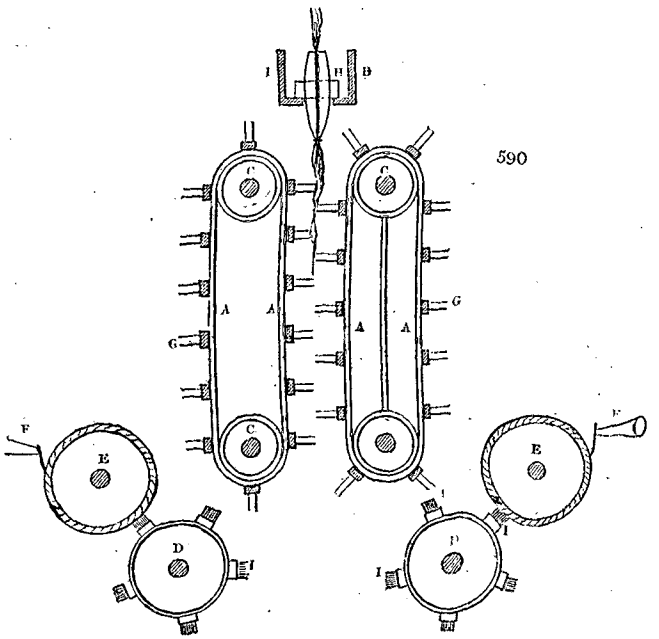
The preceding figure (589.) shows the leading features of these machines:

A A (*fig.* 589.) heckle cylinder; B B excentric wheel to carry holders in its recesses *h*, *h*, *h*, *h*, *h*; C slide upon which the holders were laid so as to fall into the recesses *h*, *h* of wheel B; D slide for taking out holders; E brush cylinder with brushes; G cylinder covered with card clothing; H holder come out; I doffing comb. The space of the holder carrying wheel was filled with holders, and so maintained in endless succession, and thus each served in some measure to keep the end of its preceding one down into the heckles.

About 1833, a machine was patented consisting of two parallel cylinders, over which the flax was carried, revolving in its progress so as to present the alternate sides of the strick to the heckles, the progressively finer tools being ranged along these cylinders, so that having passed the length of one cylinder one end was completely finished. When the holder was taken out, "shifted," and replaced, it was carried back along the second cylinder, and thus returned to where it commenced, finished. This machine, however, never was carried further than the experimental one for the patent.

Another machine the same year made its appearance, and which for some time enjoyed much celebrity. It consisted of two parallel vertical sheets of heckles running together, and so geared that the heckles of one intersected the interstices of the other. The flax suspended in its holder from a species of trough passed between these two sheets, and was thus heckled simultaneously on each side in its course through the progressively finer heckles from one end of the machine to the other.

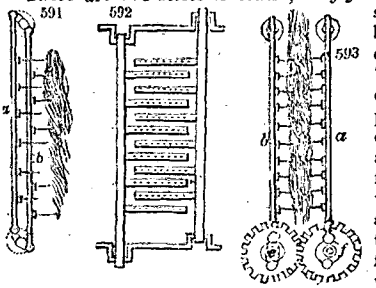
A, A (590.) heckle sheets; B B holder trough or slide; C, C, C, C, pulleys for carrying the



heckle sheets; D, D brush rollers; E, E rollers covered with card clothing to clear the brushes; F, F doffer combs; G, G, G, G heckles; H holder; I, I brushes.

At about the same period a foreign machine was patented, known as Evans's machine, of which the following description will give a correct idea of its principle of action, and also of its holders, which are different from those already described.

There are two series of combs, see *fig.* 591., attached to two movable frames represented at *a* and *b*. Each frame is formed by vertical bars *a b*, with lateral branches or arms, which carry the heckle points. The branches or arms are parallel, and at equal distances apart, but fixed in such positions in each frame that they may occupy the intervening space when the frames are brought together as *fig.* 592. The frames are put in motion by means of revolving cranks to which they are attached as shown in *fig.* 592., and when the cranks turn upon their axes, the branches of one frame pass between those of the other without touching. This forms what may be called a set of combs; the points of the combs of one set being opposed to the points of the combs in the other set.

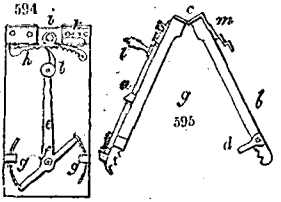


The way in which the series of combs that compose one set act upon the flax, is shown in the side view, *fig.* 591. When the cranks are nearly vertical, the points of both frames are away from the flax, but as the cranks move round in the direction of the arrows, the frames come into another position, and it is then that the points or heckles of one of the frames *a*, begin to penetrate the flax, and descending they comb or divide its fibres. The rotation of the cranks continuing, the two frames *a* and *b* come into the position shown at *fig.* 591., the points of the frame *a* withdrawing from the flax, and those of the frame *b* approaching and pushing the fibres off from the former, which are now combed by the descending stroke of the points.

It will hence be perceived that as the combs of the frame *a* and *b* respectively advance, they will push forward the whole of the strick of flax, and render it impossible for the fibres to be raised and entangled, as each frame in advancing clears the fibres from the points which preceded it.

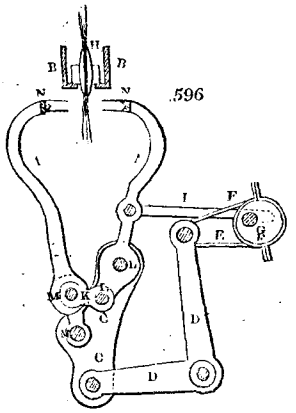
A single set, however, of such combs or heckles acting only on one side of the flax would but imperfectly perform the operation of opening its fibres; it is therefore necessary, in order to accomplish the desired object in the most effectual way, that two such sets of combs or heckles should be brought to act on opposite sides of the strick of flax, suspended in the position shown in the figures. The cranks of the two opposite sets of comb-frames or heckles *a*, *b*, and *c*, *d*, are connected by a pair of toothed wheels *e*, *f*, as *fig.* 593., or by four toothed wheels, by which the heckles are actuated at once, the two sets moving in opposite directions, but with similar speeds, and the combing or heckling of the material will go on in the way shown in the figure last indicated. The tow being collected as drawn off the lower end of the stricks on to a slowly revolving cylinder or brush roller, whence it is doffed by a comb and delivery rollers.

The clamps or holders differ considerably from the clamps which are commonly used. I shall therefore particularly describe their construction, before showing them in operation. *Figs.* 594. and 595. are views of the clamp in two different positions; *a* and *b* are two boards united together by a hinge *c*, at top, which of course allows them to shut and open. The lower parts, forming the jaws of the clamps, are made with teeth or indentations, between which parts the ends of the flax or hemp are securely held when the clamps are brought together; *d d*, are two pieces projecting from the board *b*, at the end of each of which is an eye shown by dots, and at the back of the board *a*, (see *fig.* 594.) there is a double armed lever *e*, turning upon a fixed pin *f*, which lever carries two circular wedges *g g*. These wedges pass into the eyes of the pieces *d d*, when the clamps are closed, and hold them fast. There is a segment ratchet *h*, at the upper part of the board *a*, which turns upon a stud *i*, and is pressed downward by a spring *k*. This ratchet receives the end of the lever *e*, and consequently keeps the circular wedges firm in the eyes, which hold the clamps securely together, and prevents their opening by the shaking of the machine.



When it is required to open the clamps, the ratchet *h* must be raised, and the lever *e* pushed aside by its handle *l*, which draws the circular wedge *f* from the eyes of the pieces *d d*, and the boards of the clamps immediately separate. For the convenience of suspending the holders in the machines, a piece of sheet iron *m*, is bent at right angles, and fastened to the back of the board *b*, as seen in *fig.* 595., forming a groove by means of which the holders are enabled to slide into the machine and hang there.

About the year 1840 an improvement took place in the excentric circular, by which one screw of the holder retained two stricks, and the machines made wide enough to take four stricks, and also a movement was made by which the holder was carried over two cylinders, so that each side of the strick was dressed before taking out. These improved machines had a very extensive sale, as wages and the necessity of attention were much reduced by them. Also the third machine, herein-before described, was revived, having a rising and falling motion for the holder support, and was known as the Belfast machine; and similar improvement was made in the double vertical sheet machine. But, as none of these sufficiently dressed the line for the finest yarns, a machine called the "crank machine" was invented for that purpose, but was in use for a very short time; its object was more to perfect the dressing after the excentric machine than to do the whole work itself. In this machine the flax was suspended, and then struck simultaneously on each side by heckles having an abrupt angular movement, first to strike into, and then draw down the line, in order to draw off the tow; the work was begun at the end and gradually advanced up to the holder.

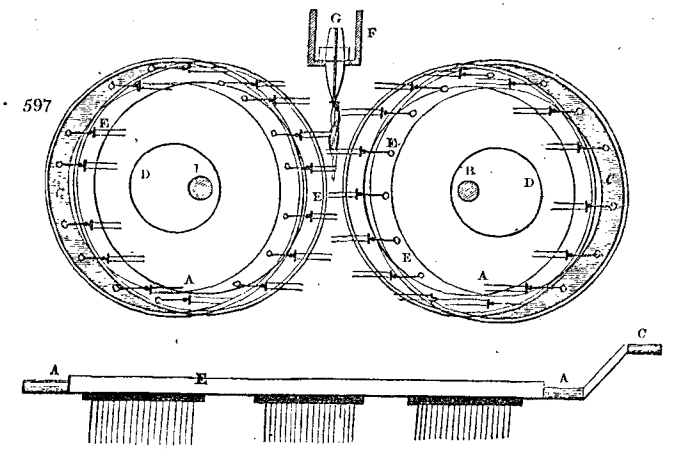


A, A (*fig.* 596.) arms for carrying the heckles; B, B, trough or slide for holders; C C sliding piece to carry pivots or the carriers A, A, so as to rise and fall by the motion of the bell crank D; E connection of bell-crank D with excentric F, to give the downward stroke when the heckles are closed upon the flax by the action of the crank, G, connected by arm I with the carrier A; H holder; K connecting rod for the carriers A, A; L and M pivots for the respective carriers A, A; N, N the heckles.

This machine, capable of doing the work but very slowly, and with great expense of heckles, was attempted to be improved upon by another made of two parallel cylinders constructed of a series of bars running at equal speeds in contrary directions. Upon these bars were fixed the heckles, which were kept in a horizontal position during their entire revolution by a crank at the end of each bar, guided in a circular path excentric to that of the bars themselves. The flax suspended passed with a rising and falling motion from one end of the machine to the other, each succeeding heckle being finer than its preceding.

A A (*fig.* 597.) circular discs keyed to the shafts B, B; C, C circular discs running upon the excentric bosses D, D; E, E heckle bars; F slide for holders; G holder.

The discs A, A are alike at each end of the machine, and have suitable bearings to



carry the heckle shafts E by their round necks A, A. The discs C, C have similar and equal number of bearings to carry the cranked ends of the heckle bars C, and are carried round by them from the movement communicated to A A. By this arrangement the

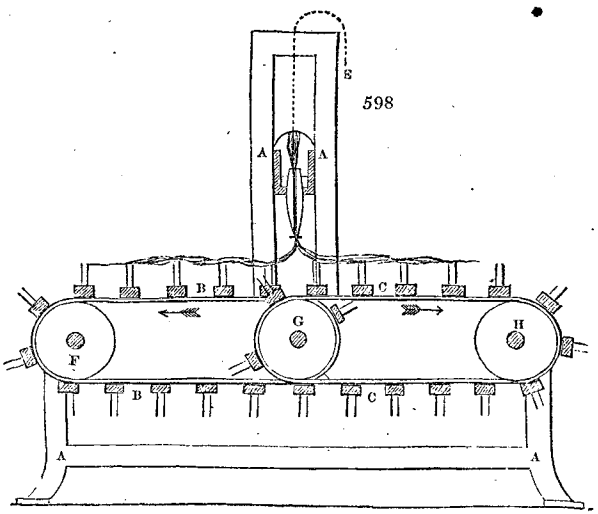
pins of the heckle are always in the position shown, and penetrate the flax at right angles to its length.

As all the preceding machines have now passed into oblivion, it may be as well to trace the reasons. The fault of the first was the great attention it required to turn the stricks and to carry them by hand from tool to tool; the want of the rising and falling motion caused the heckles to strike at once into the middle of the flax, thereby reducing the yield of line, and rendering the tow knotty and torn. Though some of these defects were remedied in the second, there still remained the transferring of the flax, the taking out of the tow, to be performed by the attendant, and the motion of the line through air was objectionable. In the third another step was gained, that of taking out the tow; but, for the want of the rising and falling, the work was too abruptly torn into. The fourth was suitable but for short flax; it was very expensive on account of the liability of the holders falling upon the heckles, and the turning and transferring the flax by hand, even when afterwards these expenses were slightly reduced by the improvement above alluded to. The fifth, never coming out of the workshop, was perhaps found deficient for want of the rising and falling, which, though partially obviated by the cylinder end being conical, might, even by this mode of palliation, lead to further difficulties of a practical nature, and by the turning movement being continued, a further inconvenience would no doubt have been found in the edges of the stricks being as long exposed to the heckles as the sides. The sixth, for a long time popular, was found, by heckling both sides at the same time, to tear away the flax, and from the impossibility of getting the pins to work near up to the holder, a long shift was required,—another reason by which the yield was reduced. Seventh; Evans' machine, though only put up for experiment in this country, has been more extensively tried abroad; but it made the tow so knotty for want of a clear stroke through, that it was immediately, and is now perhaps entirely, abandoned everywhere. Eighth; the crank machine was very troublesome and expensive, and could hardly ever be said to have got beyond its experimental state. It is now altogether laid aside. Ninth; the double cylinder machine answers well for very short line, but, for much the same reason as the above, makes but indifferent tow, and its use is now nearly discontinued.

Besides the above there have been several others patented; some have never been wholly constructed, and others never been used: neither appear to have suggested any principles or modes of action capable of being modified into a useful or practical state.

We now come to explain those heckling machines by which the flax-spinning trade is at present actually carried on, in which it will be seen that the best parts of all the preceding are combined, so as to form machines of the utmost efficiency, and capable of working with a closer approximation to the utmost degree of economy.

The first in order is the transverse sheet machine. This machine is on the same principle as the third, above described, having a horizontal sheet to each heckle, but each running in an opposite direction, and a rising and falling trough, along which the holders are impelled from one end of the machine to the other. It is so arranged, that when one side of the strick is heckled the slide or trough rises, and the holder being



suddenly pushed forward, the flax thereto attached comes in contact with the next sheet running in a reverse direction, and has thereby its other side dressed. This is repeated over as many tools as may be desired, generally three, but sometimes four. For the better elucidation refer to *fig.* 598., section of machine.

A A (*fig.* 598.) frame; B B heckle bearing sheet running in the direction of the arrow; C C another heckle sheet running in the opposite direction; D holder, and its rising and falling support in the form of a trough, along which it slides from one end of the machine to the other; E chain to which is attached the balance weight of slides, &c.; F, G, H the carriers of the sheets, of which F and H are keyed to their respective shafts, as it is by them the sheets B, B and C, C are driven, and drive their carriers G loose upon the shaft.

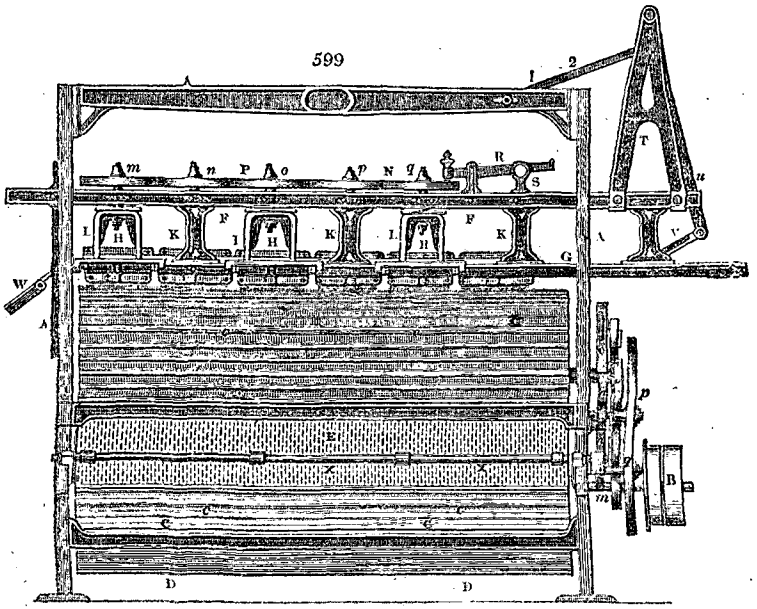
It is somewhat objectionable in the above machine, that the holder slide has to rise to a great height, so as to take the ends completely off the tool, otherwise the strick is liable to be crossed by one side being for the moment pulled in one direction, and the other in a contrary; and also that the tow and waste might be apt to collect in the spaces where the sheets cross each other, and thus occasion derangement.

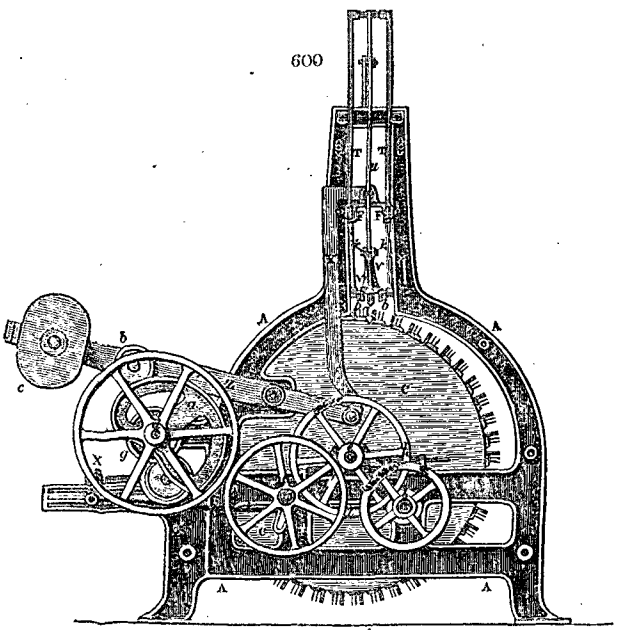
The following, known as Baxter's self-acting cylinder and sheet machines, (these appellations being given accordingly as cylinders or endless sheets were employed to carry the heckles), of which the distinctive feature is turning the holders, avoids this inconvenience.

The holders from which the flax is suspended are supported above the centre of the cylinder (when a cylinder is employed), or of the rotatory carrier of the endless sheet, when that method of applying the heckles is adopted; but instead of their supporting slide or trough being in one continuous piece, it is divided, according as the machine is intended for 3 or 4 gradations of tools, into 6 or 8 divisions, each equal to the length of the holder. Of these half the number always remain in a direction parallel to the axis of the cylinder, while the others, placed between or alternately with them, are connected together by gearing, so as to turn simultaneously in a horizontal direction, and the whole are combined to approach and recede to and from the heckles together by a falling and rising motion. The brushes, card-clothed cylinder, and comb, when employed, are similarly combined for clearing and delivering the tow as those already described for the same purpose in the excentric circular machine; but in general for the sheet machines a simple faller is found sufficient. Thus, the flax introduced into the first division when the slide is at the top of its course, is dressed during its descent, and "dwell" upon the first half length of the first tool; on being risen it is pushed forward by mechanism into the next division of the slide, which then by turning half round, or end for end, presents the second side of the strick to the second half of the same tool, upon which it thus becomes dressed, as was the first: on again rising, the flax is pushed into the third division of the slide, which presents the side of the strick that was second on the first tool to be first exposed to the action of the second, and thus, at each rise, is the flax advanced towards the finer tools, turning at each alternate advance, till the required number of tools is passed over. This is the construction generally employed, but it is sometimes necessary that each holder turns in its place, thus heckling each side of the strick on the same identical heckle; thus the flax is more worked, for it is exposed to 6 or 8 gradations of tools, instead of 3 or 4 by the other method, but a machine upon the former will do nearly double the weight of flax than upon the latter mode of working. Though the progress but of one holder has here been traced, it must be understood that there are necessarily 6 or 8 in simultaneous operation, according to the description of machine; for the propelling motion being at one end requires the full complement of holders to push one another forward. This machine and the last perform pretty nearly the same quantity of work, which, with 6 or 7 boys, amounts to about 1 cwt. per hour, and are applicable for long flax, and for cut as far as 60 or 70 leas; the latter is sometimes used with 4 gradations of tools as far as 100 leas. The construction of these machines, whether cylinder or sheet, is so similar, that the same letters and figures refer to the same parts of each. *Figs.* 599. and 600. front and profile views of cylinder machine, and *Figs.* 601. and 602. front and profile of sheet machine.

A A general framing; B driving pulley on the shaft of brush roller; C C main cylinder; D D brush roller; E E card-covered roller; F, F rails constituting part of the falling and rising head, and to which are fixed the movable parts for turning the holder; G G the first part of the slides along which the holders pass; H, H the alternate turning parts; I, I the holders, those No. 1. are with the side as put in, and those No. 2. are when turned; K, K, K supports from the rail F to fixed parts of slides G; L the supports with pivots for the turning parts of the slide H H; to these pivots are fixed respectively the wheels *m*, *o*, *q*; the intermediate wheels *n*, *p* being loose upon their axis, serve to connect the motion of the series; R lever and lock to retain the wheels fixed during the fall and rise; S support for the lever R; T support for the pendulous lever U, which by the pusher V drives the holders forward when introduced into the slide; W slide inclined to conduct the holders on a table; X X doffing comb shaft; Y connector between the rails F and balance weight lever Z; *a a* excentric to give the up and down motion to moving head; *b*

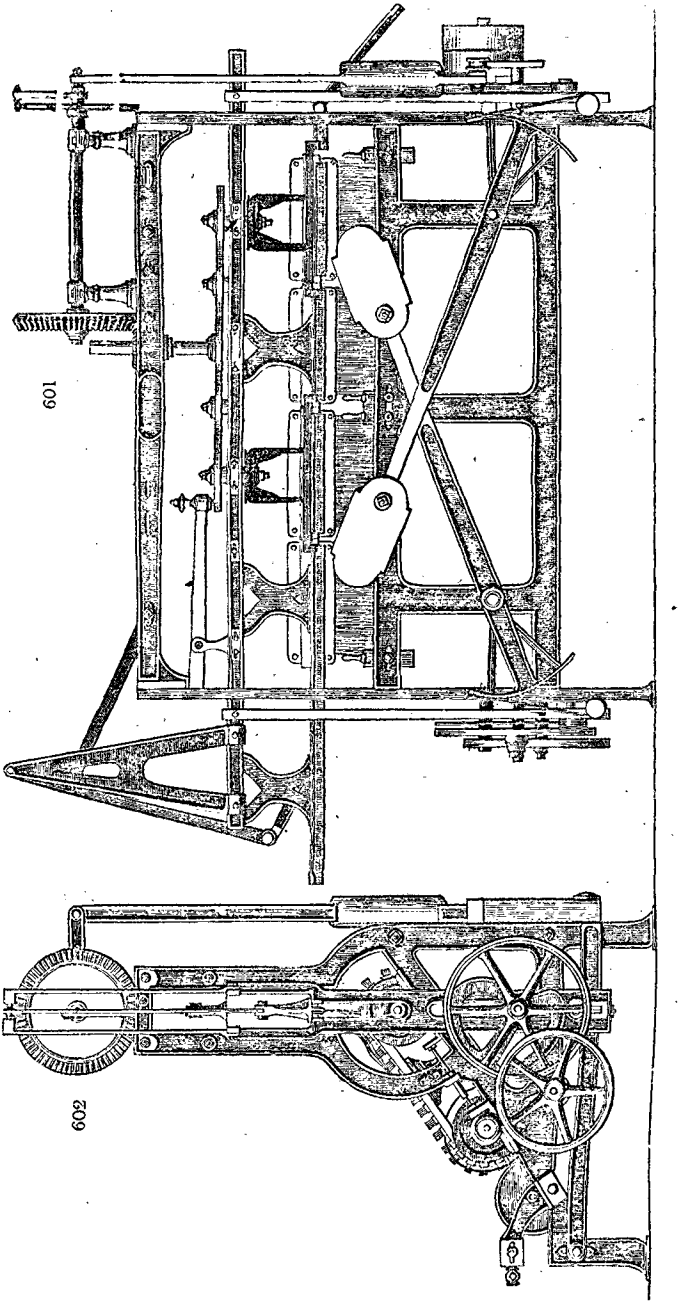
friction bowl; *c* balance weight: this arrangement of connector, lever weight and excentrics are the same at each end of the machine, as the shaft *d*, upon which the excentrics are fixed, extends the whole length of the machine; *e, f, g* train of wheels and pinions to reduce the speed of cylinder shaft *c* to the excentric shaft *d*; *h, i* wheel and pinions to drive the excentric by which the doffing comb is moved by the con-





necting rod *l*; *m, n, o, p, q* trains of wheels from driving pulley B to cylinder C and card roller E; the propulsion of the holders is caused by the radial movement of the lever *z*,

caused by the rise and fall of the head. The following figures show the form of the "sheet" machines, but which do not, from their similarity of principle and construction to the foregoing, require a detailed description; as the only differences are



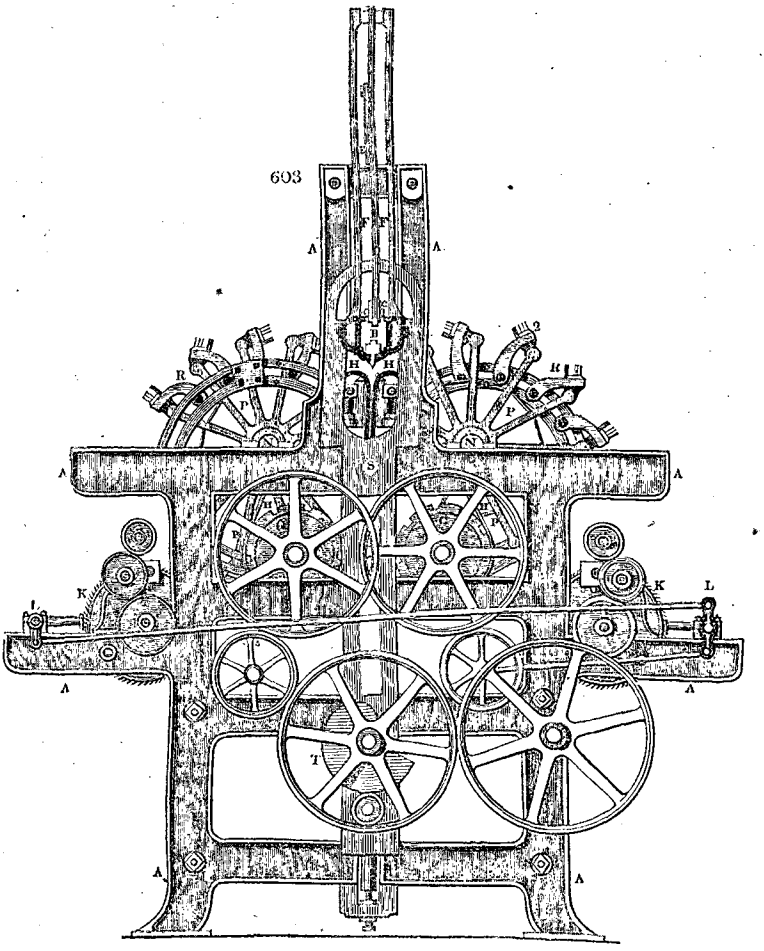
that a sheet is used to carry the heckles instead of a cylinder, and doffer bars for knocking out the tow instead of the more complicated arrangement of brush, comb, &c.

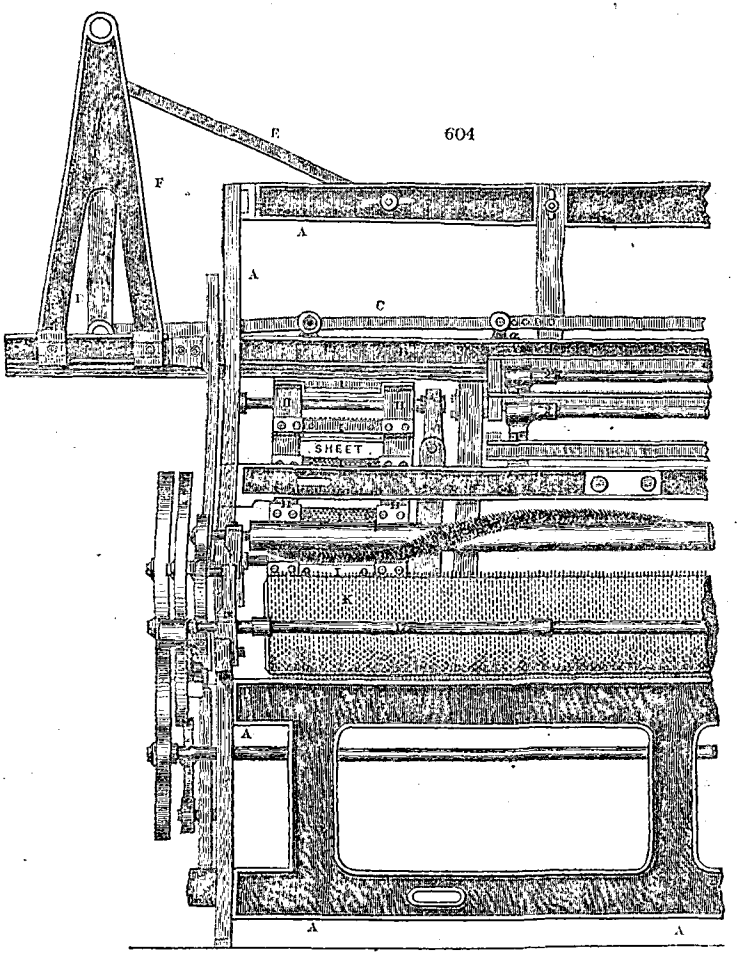
Those machines that are now employed for finest work are called *Marsden's intersecting machine*, and *combined intersecting*.

The *intersecting machine* is so called from the peculiarity of its construction, being somewhat similar in principle to that already described, of two cylinders of heckles carried on cranked bars, but instead of their being so closely placed together there are but six, eight, or more bars bearing the heckles, forming as it were a sort of a skeleton cylinder, of which there are two, parallel to each other in each machine: the flax passes along the machine between these two cylinders, and is struck by their heckles alternately, and in successive order on its opposite side. *Marsden's combined intersecting machine* has in addition to these cylinders a pair of sheets of heckles, by which the first tool work is performed previously to the flax arriving at the intersecting cylinders, and the flax is rather more severely heckled. In both of these machines the holder slide is provided with a rising and falling motion, as being absolutely necessary for the production of good work: these machines penetrate the flax better than the cylinder, as from its position between the heckles, the flax is rigorously exposed to their effect, but the tow thereby produced is rather more lumpy and uneven, and is, therefore, considered inferior to that from the cylinder machines, see *figs.* 603. 604. 605. of combined intersecting machine.

Fig. 603. end view; *fig.* 604. side view; *fig.* 605. sheets; *fig.* 606. holder; AAA framing; BB holder trough or slide; C jointed rod, having a horizontal motion to push forward the holders by the clicks *a*, *a*, which catch the holders in one direction only; D pendulous

603

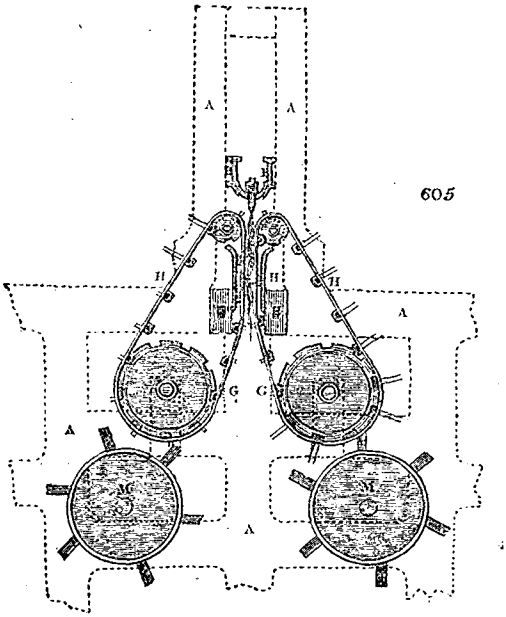




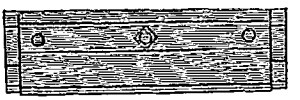
ever receiving a reciprocity motion from the radial arm E, at thean rising and falling of the sliding head; F support for the pendulous lever D; G, G carriers of the heckle bearing sheets, H, H; I, I heckles fixed to the sheets or straps H; K K card-clothed cylinder for receiving the tow from the brush cylinder; L doffing comb; M brush cylinder; N N, *o o* slide shafts, upon which are keyed the carrier arms P, P of the intersecting heckle bars Q, Q; R, R crank arms fixed to the heckle bars, and guided by their extremities in the slides *o*, *o*, by which the peculiar position of the heckles is maintained; S connector between sliding head and lifter excentric, or cam; T, U the friction bowl for pulling downwards the slide head, to which a tendency is given to rise by balance weights, not necessary to be shown; V wheel commanding excentric to give the oscillations to the doffing combs.

In all heckling machines, whether those of sheets or cylinders running in opposite directions, and not therefore requiring the turning motion for the holder, or those with the turning motion, and having therefore but one sheet or cylinder; or again those called the intersecting and combined intersecting, the hand labour required, and the number of holders or work turned out in a given time, are nearly the same for similar degrees of dressing, and all these machines are provided with change pinions, to increase or diminish the quantity of heckling in any required degree.

The hand labour consists, first, of dividing the flax into stricks, for long flax, of 4 or 5 ozs. each, and for cut, 1½ to 2 ozs. Then screwing these into the holders, and when one end is worked, taking out the holders, performing the "shift," and replacing them,



605



606

by which it is evident that the manual work is reduced to nearly the lowest possible point; for the taking out the holder and performing the shift are the only operations that can by possibility be done mechanically; and it is desirable that this should be so effected, not only with a view of saving the expense in wages, but to avoid the waste and entanglement, and consequent reduction of yield, to which by handling the flax is exposed, and at the same time reduce to the utmost degree all need for reliance upon the care and attention of the workers employed. A holder with this intention was patented about three years since, which, from its novelty of construction, deserves a record, for though not yet in active operation, it only requires time to remove the groundless prejudices opposed alike to this as to all other innovations.

Previously, however, to entering upon a description of this holder, it will be necessary, in order to make our account of heckling machines now actually in use complete, to describe one much used in France, and patented for that country, January, 1846. It is there known as the *peigneuse mechanique system Busk*, from the name of its inventor, an English machinist, (whose transferring excentric and double cylinder machines have already been described).

Flax heckle, called *Peigneuse Mécanique, on the system of Busk*, as described in a French *publication industriel*. — It has been found in practice that to obtain the best results, it is absolutely necessary to attack the flax by the end of the strick, and to continue it slowly and gradually till the points of the heckle act on the middle; then to obtain the greatest product in long line and the best quality of tow, it is necessary to heckle it alternately on each side of the strick, continuing thus on the first, second, third, and fourth heckle, &c.

The machine which we offer to the public as the invention of Mr. Busk, the author of many ameliorations in flax-spinning machines, unites in itself all the different points of perfection indicated, without any of the inconveniences of the rival systems. The force requisite to drive it is hardly one half of a horse-power; is capable of heckling on any number of heckles, and without increase of hand-work, about 500 kilogrammes (½ ton) daily, more or less, according to the nature of the flax. It is applied with equal advantage to the long or the cut line. It may be conducted or managed by

4 or 5 children merely, employed to screw and unscrew the clamps (presses), an easy operation.

Description of the machine. — *Fig.* 607. longitudinal elevation of the mechanical heckle.

607

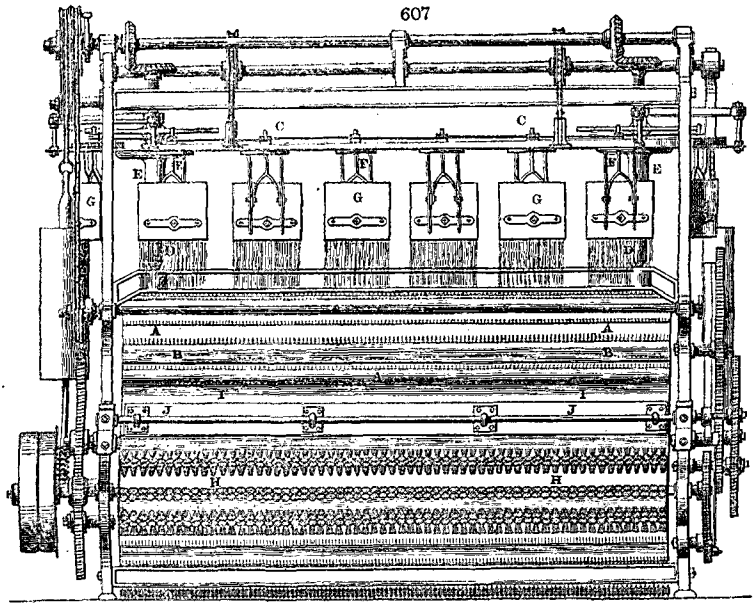


Fig. 608. Elevation of one of the sides, or as seen from the end.

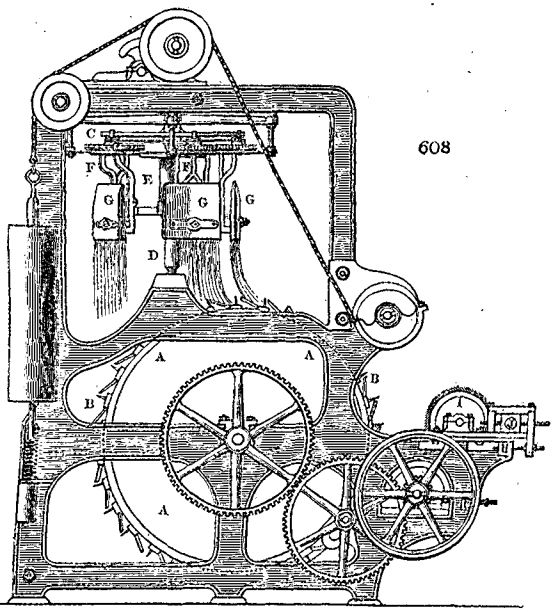
608



A. Large cylinder, in whose circumference the heckle teeth are fixed. The distance between the points varies according to the perfection which is desired in the heckling,

and the quality of the flax. The length of the cylinder (2 metres 40 cents) admits of multiplying the heckle points, and varying their distances.

B. Small plates (*planchettes*) fixed between the heckles, to determine the depth to which the points shall act in heckling. These plates are moveable, so as to be arranged at pleasure.

C. Carriage bearing the pincers in which the stricks are fixed. D. Upright arbours on which the carriage rises and falls by means of the sockets, E, fixed to the carriage, to guide its ascent and descent, effected by aid of an excentric placed on the side of the machine. This carriage is balanced by counterweights. One of its sides is furnished throughout all its length with a cast-iron rack, in which all the pincer bearers (which are toothed on their upper part) work.

F. The pincer carriers, whose upper part is a toothed wheel, and whose lower part terminates in hooks (*crochets*) that receive the pincers in wood. Rigid bars connect the pincers in the upper part; so that they all work at the same time.

G. Wooden pincers clasping the stricks of flax by means of a screw.

H. Cylinder with brushes for removing the tow, which had been retained by the heckle points, and carrying them to the cylinder I, furnished with cards.

J. Heckle which deposits its tow into a box placed to receive it. All the pincers G being furnished with flax are fixed in the hooks of the pincer bearers. On setting the machine in motion, the carriage C, commanded by an excentric intended to give it a progressive velocity, calculated proportionally to the thickness of the strick, descends and puts the flax in contact with the heckle teeth fixed round the large cylinder A, actuated by a continuous movement. When this operation is terminated, all the stricks of flax submitted to the action of the cylinder having been heckled on one side, the excentric, which had caused the carriage to descend, makes it mount again; at which moment the other excentric acts, destined to communicate to all the pincers the horizontal motion; and, as the pincer bearers are in toothed geer with their carriage, the consequence is that in advancing the pincer bearers pivot on themselves, so that the carriage descending anew, presents to the action of the heckle points the other face of the flax.

This action in being thus repeated even to the extremity of the carriage, works on the flax by heckle teeth closer and closer together. When they have arrived at this point, the pincer carriers continue to advance, passing by the back of the machine: but this side of the carriage having no rackwork, the pincer bearers do not pivot (turn round) and proceed without changing position, at which point the heckled flax is replaced by the unheckled.

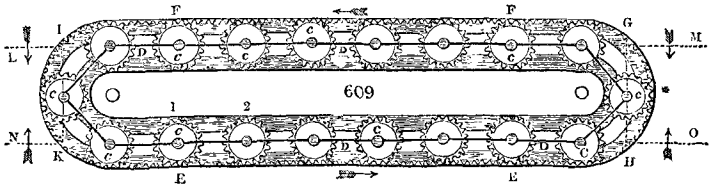
The tow is disengaged by the brush-cylinder, and transmitted to the cylinder mounted with cards: a heckle then detaches it and drops it into a box.

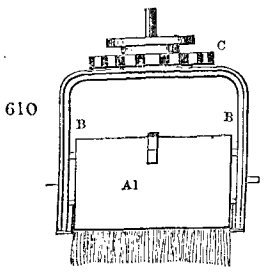
Such was the state of heckling machines when the holder above alluded to was first contrived with a view of being applied to this machine, for which it is peculiarly adapted.

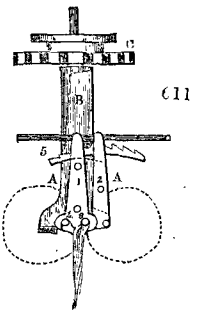
All the holders that have hitherto been used are similar to those described at the beginning of the article, consisting of two clamps of wood or iron pressed together by screws, except in Evans's machine, where an inclined plane was used for that purpose. But the holders now referred to are on an entirely different principle; the holding pressure being produced by the effect of leverage of the clamps or jaws themselves, which are for this reason, and also for better supporting the end of flax out of operation, made from 7 to 9 inches broad; and while one of their edges are hooked or fastened together by a pair of double-acting hinges, similar to those used at the bottom of turnpike-gates, the others are held together by a clasp, and thus the flax is very firmly grasped or held by the pressure at the joint or hinge, and the end of the flax not exposed to the heckle is held vertical and straight by the breadth of the clamps. These holders do not slide of themselves along a trough, as do the other description, but there are "carriers" for them attached to the sliding and turning apparatus, by which they are carried forward and turned as desired. These carriers are so constructed as to retain the holder by one of its clamps or jaws always vertical, but leaves the other free to fold from one side to the other; when this folding takes place, which is during the dwell of the other holders upon the heckles, that end of the flax which was contained between the clamp becomes liberated, and the previously pendant one is lapped up and enclosed between them, when the rise of the head taking place, the catch replaces itself, and the holder is carried forward to return along the second cylinder of the machine, and ultimately arrives at the place where it was first put in with the line completely dressed. As all these movements are performed automatically by the machine itself, the whole of the wages necessary, when the other holders are used, for taking out, and screwing and unscrewing, and replacing them, amounting to nearly half of the whole expense, is saved, besides much indirect trouble and confusion.

A 1, A 2, jaws of the holder; B B carriage or frame for supporting the holder; C C, a toothed wheel, having a groove on one side to allow it to be carried by the rails of the

moving head of the machine, of which *fig.* 609. is a plan or bird's-eye view; D, D, links or bars connecting the series of wheels c, c. These wheels are of such a diameter, that



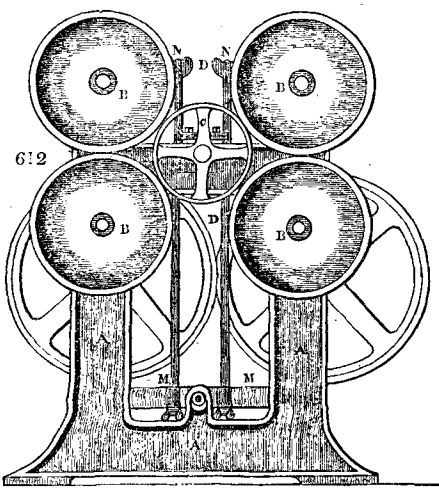


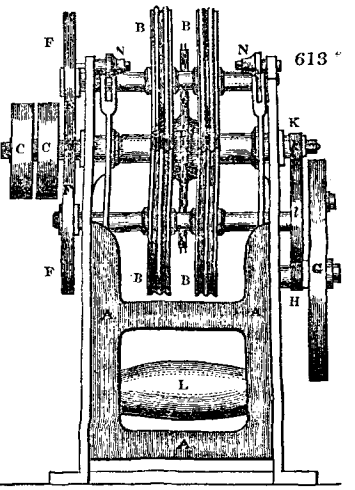


when propelled from 1 to 2, they will at the same time make one exact half revolution; and thus the holder attached to each presents its opposite side to the heckles at each advance similar to other machines. To cause this half revolution, the teeth of the wheels c, c engage those of the racks E, E and F, F; but the slides are so made as to maintain the wheels in one position from E to F at one end of the machine, and from F to E at the other; G H the position and place where the holder stands to be shifted; and I K when first put in or to be taken out of the machine; L M, axis of heckle cylinder to dress the flax after "shifting;" therefore its coarser tools are at end M; N O axis of cylinder for dressing the root ends; therefore, its coarser tools are at end N. The arrows show the direction of movement of all these parts. The mode of action of the holder is as follows. The jaw A 2 is first laid upon a table, and the flax placed upon it, when the jaw A 1 is caused to engage the pin 3, which are similar at each end of the holder, when it is folded down upon A 2, and the catch fixed to 2 engages the rack fixed to A 2 at *5*, and the whole is firmly combined together and placed into the carrier, and maintained by the pins projecting for the purpose from A 1 entering into vertical grooves in the carrier, when, having passed over the heckles on cylinder N O, it ultimately arrives at G H, when, during the descent of the sliding head, the lever attached to the catch *5* strikes against a fixed point, and is thereby lifted out of the rack, thus leaving at liberty the jaw A 2 to turn. This is effected by a projecting pin 2, being actuated by a crank having a suitable intermitting motion, which carries it in the direction of the dotted line, while the hinge pins quit recess 3, and the other enters the recess 4, and the rack engages the catch opposite to the one it has quitted; and thus the shift is completed with a length equal to the thickness of the holder at 3, 4.

The cutting of flax, which is done in order the better to select and separate its various qualities, is an operation of some delicacy, and requires a peculiar machine for the purpose, which, though not complicated, requires great nicety in its making and arrangement; for the flax must not be cut too abruptly, but be gradually reduced to a taper and somewhat natural end. The cutting should be done before the flax is heckled. The machine for the purpose consists of a species of circular saw about 20 in. diameter; but, instead of a single blade, is constructed of 3 or 4 plates of steel, each about $\frac{1}{4}$ in. thick, and having angular projections from their circumference. This revolves at a considerable velocity, while the flax firmly grasped in each hand by its ends, is still further held and slowly carried against the saw by two pair of grooved pulleys pressed together by a considerable weight. It is thus partly sawn and partly broken through. Flax may be cut into 2, 3, and sometimes 4 divisions: and sometimes the dead harsh fibres that are frequently found at each of its ends only are cut off and used as tow; but more generally the different portions are heckled and used for the purposes they are sorted for.

Description of flax cutting machine. (*figs.* 612, 613.) A A, framing; B, the grooved pulleys for holding and carrying the flax; c c, the driving pulley; D, saw or cutter;





E, F, wheels for geering together the pair of holding pulleys; G, H, I, K, pinions and wheels for producing the proper relative speeds between the cutter and pulleys; L, weight, which by levers M and N, causes the pressure of the holding pulleys.

4th. *Preparing.* — By this term is understood those preliminary operations through which both line and tow must pass after the heckling and before the spinning process.

The mechanism and modes of proceeding for this purpose, which consist of repeated drawings, are similar for "long" line or "cut;" though the dimensions and fineness of the machinery must be made suitable for their various lengths and qualities. But in the preparation of tow a peculiar additional operation is demanded, as a consequence of the different state of the fibres of which the material is composed; this operation, termed "carding," has for object to bring the highly irregular and entangled mass into a somewhat more homogeneous and uniform state, previously to its being afterwards drawn and equalised in a manner similar to line.

In the preparation of line the first operation is called "spreading," and the machine employed a "spreader," or first drawing: those subsequently are the second and third "drawings," (sometimes a fourth is used), and lastly the "roving." It is upon the spreader that the separate stricks of line are first combined and drawn into long uniform bands or ribbons, called "slivers," of determinate lengths. This is effected by subdividing the stricks into two or three portions, and then placing them consecutively slightly elongated; and overlaying each other about $\frac{3}{4}$ths of their length upon and in the direction of an endless creeping sheet or apron. The machines are generally made with two of these creeping sheets or aprons, and upon each sheet are thus laid two distinct lines of stricks; each of which forms a thick uniform body of line, and capable of being maintained to an indefinite length. These endless creeping sheets supply continuously another part of the machine, where the body of "line" is drawn out to between 20 and 60 times its original length, according to whether it is composed of cut or long flax. This part of the machine comprises a pair of holding or back rollers; an endless succession of bars called fallers, bearing combs of closely ranged steel pins, through which the slivers are drawn; a pair of drawing rollers; an arrangement of diagonal or doubling bars; and a pair of delivering rollers; is generally termed the "gill frame," or "gill head," probably from the French word "aiguilles" (needles), as descriptive of the combs, and to distinguish this machine from those formerly used for the same purpose, which simply consisted of a series of rollers under and over which the line was passed.

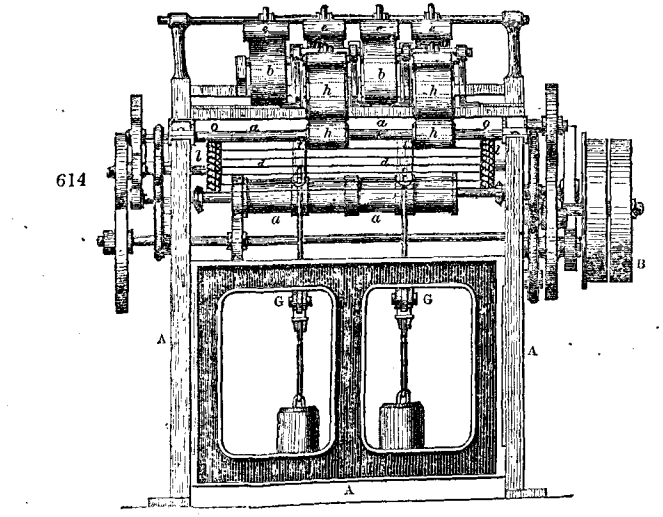
The following figures 614, 615. show the outline of the present most approved gill spreader or first drawing.

A A, general frame of the machine; B, driving pulleys; C, auxiliary frame for endless sheets; D, D, D, D, rollers for carrying the endless sheets or aprons; E, E, conductors to guide and slightly condense the four bodies or slivers of line; F, can for receiving the sliver; G, lever for weight on front or drawing roller; H, lever for weight on back roller; K, delivering roller shaft, spring and bell, which, by the intervention of geering between it and the front roller, is caused to ring when any desired length of sliver is delivered.

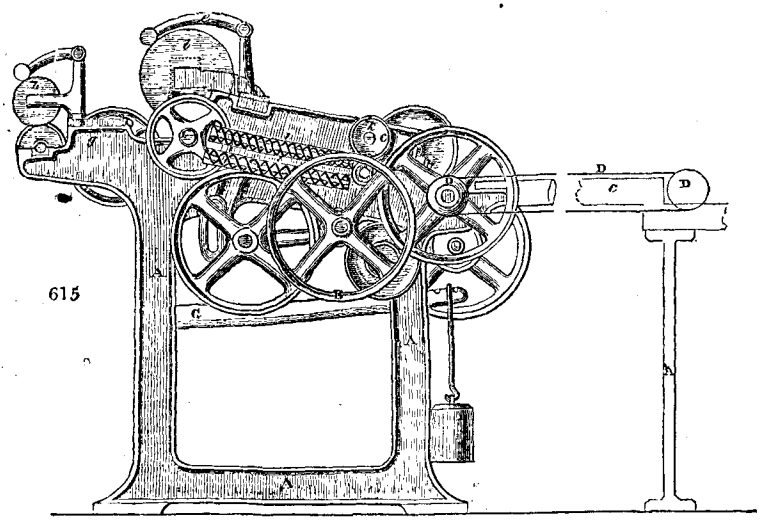
a a, the iron drawing roller or boss; *b b b*, the wooden or pressing roller, by the pressure

of which upon *aa* the sliver is held during the greater velocity of these rollers over that of *c*; the holding or back rollers elongate in exact proportion of its augmentation; the holding roller *c* is in like manner pressed against another in order to assist the "gills" in retaining the fibres; *k, k,* hooked rods to connect the weighted lever *h* with the holding roller *c*, and by the pressure thus caused insure its effect; *dd*, the sheet or surface of "gills" composed of separate bars, as seen at *fig.* 614*, 615.*; *e*, rubber or cleaner of pressing roller *b*; *f, f,* conductors to contract laterally the sliver at the moment of drawing; *g*, plate of metal having diagonal openings at an angle of 45° (this plate is sometimes called the "doubling bars," having been first made of separate bars) to the original course of the sliver, in order to enable it to be turned in a rectangular direction and guided to the delivering rollers *h, h*; this direction of the sliver is more distinctly seen at *fig.* 617.; *i*, hanger or connector of pressing roller *b* to its weight lever *c*; *l, l,* the screws or worm shaft for carrying the gill bar *dd*; *mm*, the shaft with bevel wheels by which the screws

614

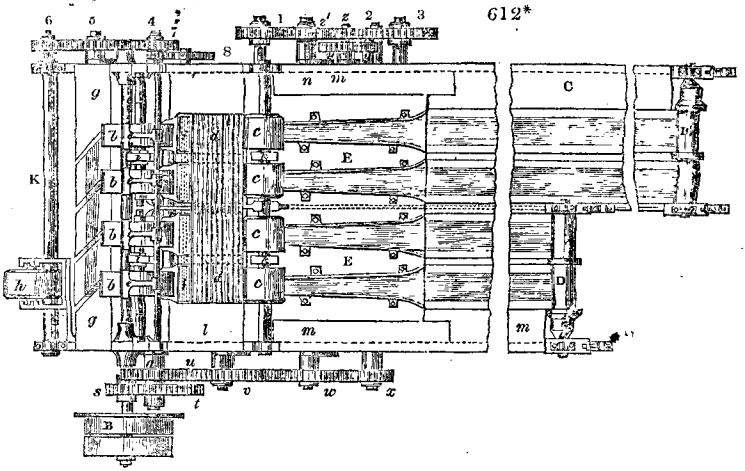


615

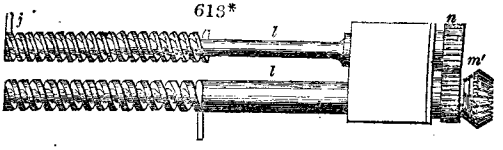


at opposite sides of the frame are caused to move simultaneously; *n, n,* pinions for connecting the upper and lower spirals of each pair; *oo*, the cams or excentrics for lowering and raising the gill bars; *pp*, weighted guide lever or bell cranks for guiding the faller

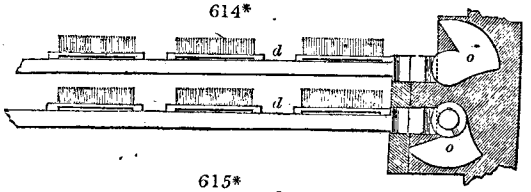
612*



613*

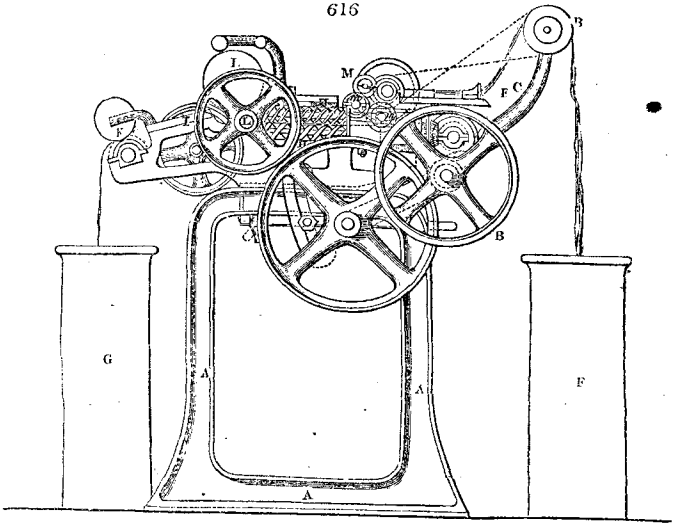


614*



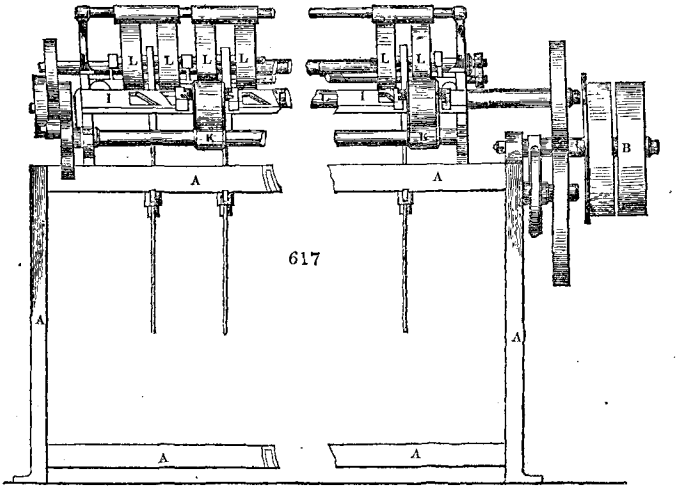
615*

616



in its descent, and moderating the shock caused by its weight when coming in contact with the lower slide or support; *q* and *r*, worm and wheel for bell motion; *s*, *t*, *u*, *v*, *w*, *x*, line of wheels from pulley to front roller and from front roller to back; 1, 2, 3, line of geering from back roller to sheet; 4, 5, 6, 7, line of geering from roller to delivering roller; 8, front roller to brush; *y y*, from back shaft to back roller.

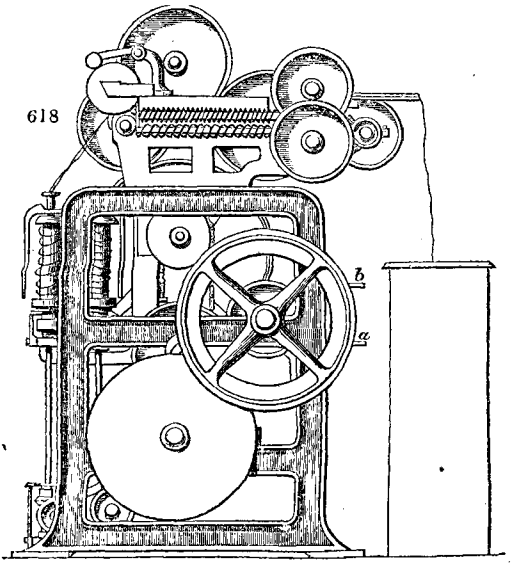
The machines for the second, third, and fourth drawings, though in principle essentially the same, yet differ in some of their minor details from the foregoing, as they do not require the feeding sheet to supply them, the "sliver," from the spreader having sufficient coherence as to allow itself to be drawn from the cans direct by the back rollers of these machines — neither is a bell motion requisite to determine the length of slivers produced by them. The subjoined sketches show the general parts requisite (*figs.* 616, 617.)



617

A A (*fig.* 616. 617.), framing; B, driving pulley; C, support of sliver carrier; D, roller for carrying sliver; E, conductors; F, can containing the slivers from the first drawing; G, receiving can; H H, the heckle carrying spirals; I, the diagonal or doubling bars; K, delivering rollers; L, the drawing rollers; *m*, *m*, *m*, the retaining rollers.

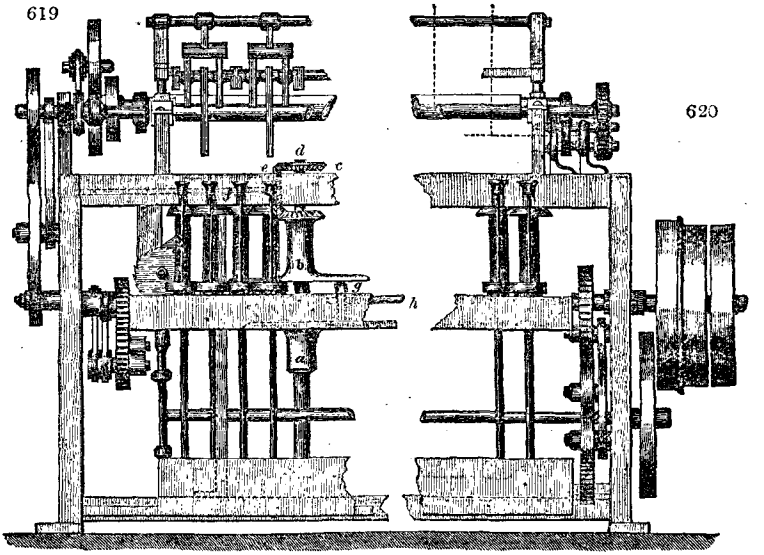
The roving frame is the same in regard to the arrangement of its back and front



618

rollers and gills, as the drawing frames; and as the position and manner of regulating the spoles are generally the same as adopted for cotton, the description of these parts therefore does not require to be repeated; but an improvement patented a few years since by Mr. P. Fairbairn, of Leeds, of that part of these frames which relates to regulating the taking up movement of the bobbin merits particular attention, as by it the inconveniences of the older method of a weighted belt and cone, and those of the more recent disc frames, are entirely overcome. The principle of this improvement consists of driving a pulley by pressure between two discs running at equal speeds in opposite directions, as seen at *figs.* 618, 619, 620.

Figs. 618, 619. To obtain the variable speed, instead of using a cone and belt as in some frames, or the pulley and single disc as in others, *a b*, the horizontal driving discs, the lower one *a* is keyed to the shaft *d*, while the upper *b* is free to turn upon it; *i*, bevel

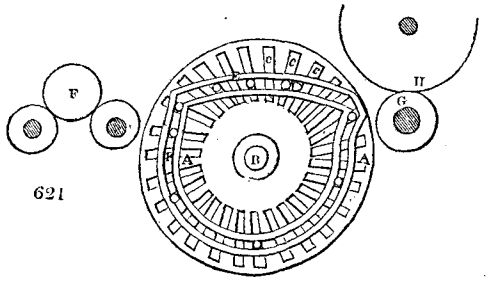


wheel fitted to or forming one piece with the upper disc *b*; *c* bevel wheel keyed to shaft *d*; *e* intermediate bevel wheel geering in the bevel wheels *c* and *i*, so as to turn them in opposite directions, and consequently the discs to which they are directly or indirectly attached; *g* the variable pulley covered with leather and resting upon the lower disc *a*, and itself pressed upon by the weight of disc *b*; it is thus driven at speeds varying according to its approach to or from the shaft *d*, thus answering the purpose of the traversing leather belt of the cone movement; *h* shaft keyed in the pulley *g*, from which the variable motion is transferred to the bobbins.

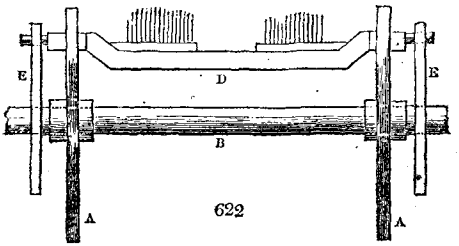
A series of preparing machines, termed a "system," consists in general of 1 spreading of 4 slivers at the drawing rollers, united into one by the doubling bars at the delivering roller, 2 frames of second drawing, in all 24 bosses 2 frames, third drawing containing together 36 bosses: if a fourth drawing is required, 2 frames of 24 bosses each, or 48 bosses in all. 180 spindles of roving in 3 frames will well supply 3000 spindles of medium spinning. The mode of using this "system" is, as has already been said, first to spread the stacks of line upon the feeding-sheet of the "spreader," then to receive the sliver or slivers there produced into cans capable of holding 1,000 to 1,200 yards of slivers. Those cans specially intended to receive the slivers from this machine are all made to one regular weight; thus, when filled, the weight of line each contains is correctly ascertained, and by the bell motion the length is also known. Upon this basis is founded the method of producing any desired number of yarn, and by doubling the slivers, a degree of equalisation that the simple spreading would be unable to effect, for at each drawing and at the roving several of the slivers from the preceding drawing are put together, to be again reduced to one for this object alone. Hence, the weight of a determinate length in yards of the desired yarn being known, a calculation is made, combined of the drafts and number of doublings the material has to undergo, to determine what the weight should be of that length of slivers contained in the cans from the spreader. It is ordinary to put 10 or 15 of these "cans" together, to form what is called a "set," the slivers of which are united at the second drawing with the subsequent drawings and rovings: the combination of two or three slivers at each boss is sufficient.

Though the above is descriptive of the "gill" frames now in use, yet it should be understood they are by no means the first or only results of the attempts made to correct the defective principle of the original roller machines, which were incapable of holding or retaining the flax with a sufficient degree of regularity, owing to its unequal lengths and unadhesive nature. The consequences were that the yarns produced were "lumpy" and unlevel, making it evident that some improved means were necessary for more completely restraining and regulating the drawing of the fibres. The most obvious way to do this was to introduce some mode of partial detention by creating a friction among the fibres to imitate the action of the fingers in hand-spinning. This led to causing the slivers to pass through and among several ranks of serrated pins, which was found very nearly to attain the object, and certainly greatly improved the levelness and uniformity of the slivers. Thus the use of "gills" became general about thirty years since.

Those first brought into general use were constructed with circular discs or plates for carrying the faller or gill bar, which at the same time were guided by their ends passing in fixed slides so as to bring the gill in as vertical a position and as near the



621

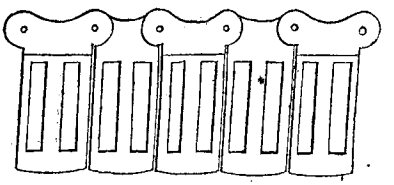


622

drawing roller as possible. The figures (621, 622.) are profile and front views of the working parts of one of these gills:—A, slotted plate or disc, of which a pair were keyed upon a shaft B, so as to carry each end of the faller D, passing through the slots c, c; E the fixed excentric slide; G, H the drawing rollers; F the holding rollers.

This was succeeded by the "chain gill," in which the fallers were carried forward by an endless series of connected links, or jointed together "slotted plates," instead of the simple circular. The object of this was to increase the flat surface of gill bars between the holding and drawing rollers, making it more suitable for the longer descriptions of material. The slides and rollers, being similar in these machines to those in the former, are not repeated, but the sketch of five slotted plates is given in *fig.* 623.

623



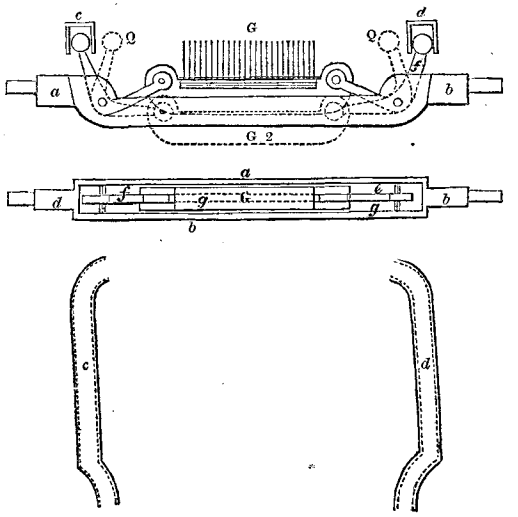
From the evident importance of bringing the retaining effects of the gills as closely as possible to the point where the movement of the drawing fibres is greatest, several attempts have been made to improve the above described gills in this respect. With

this view Messrs. Taylors & Wordsworth patented a gill of considerable ingenuity, (*fig.* 624.) which therefore deserves mention, though it never came into use. Its description is as follows: —

a b the faller or "gill bar" in one piece, which were carried forward by an endless chain; *c, d* slides placed horizontally over the gill sheet guiding the ends of certain bell-cranks *e, f*, jointed at their angle in the recess *f g e* of the gill bar, and at their other end to the gill or comb *g*. By this arrangement, as long as the bell-cranks are in the parallel parts of the slides *c, d*, the gill teeth will be above the faller *a b*, but when they arrive at the contracted part the guided ends will be brought into the position Q Q, and consequently the gill depressed is G 2; this is so timed as to cause them to clear the drawing roller, when, on again continuing their course, they are again caused to rise and penetrate the sliver by the reversed inclination of the slides *c, d* at the back roller.

The objection to this ingenious machine was the largeness of the space suddenly

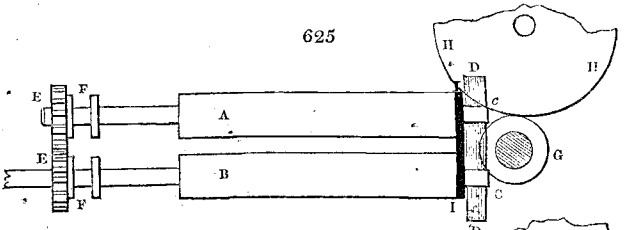
624



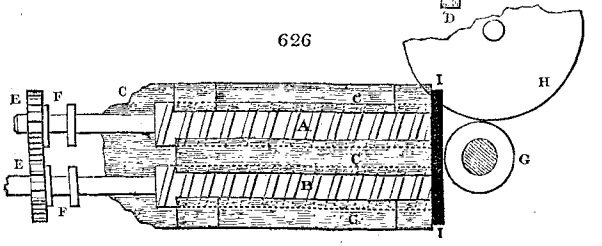
left open by the descent of the gill, as the double faller, bell-crank, and gill necessarily occupied a great width.

The screw or spiral movement of the fallers, which was soon afterwards invented, quickly superseded all others in use, as by these means the faller was caused, even in the

625

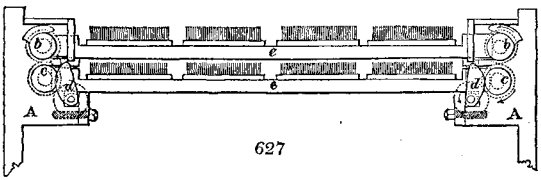


626



manner they were first constructed, to approach closer than even in the most perfected construction of the others, to the side of the drawing roller, and still maintain the pins in a vertical position. Recently this object has been more perfectly attained by a patented improved construction adopted by Messrs. P. Fairbairn & Co., whereby the obstacle to the faller wholly touching the roller has been removed, and thus producing the full holding effect of the gill to the latest possible moment. This is effected by employing a method of supporting the spirals by their working in tubular recesses in the side plate of the machine; along these recesses are longitudinal openings through which the faller end passes to enter between the threads of the spiral, and which serve also as slides to support the faller. As by this means the supports or plummet blocks that intervened between the end of the spirals and the roller are suppressed, the faller is enabled to advance to the place they formerly occupied. *Fig.* 625. and 626. show this comparison of the older and more recent methods. A, B spirals; C, C the parts by which they are supported, being in *fig.* 625. small pivots in plummet block D D, and in *fig.*.626. hollow tube-like recesses in frame plate C C; E, E pinions to work the upper and lower spiral together; F bearings; G drawing-rollers; H pressing rollers; I I passage of the faller's descent.

Here it may be as well to observe that the same parties have still more lately introduced another important amelioration in these machines for remedying the noise and wear and tear which ordinarily attend them by the abrupt and violent descent of the faller. *Fig.* 627. shows a sectional front view of a head having this improvement



627

applied. A A supports for screws; *b*, *c* top and bottom screws; *d*, *d*, the new cams fixed on shafts parallel with the screws, and revolving at the same speed. Thus, these cams *d*, *d* receive the faller *e e* at their largest diameter, at the moment they are free to descend, and guide them gradually down to the lower slide.

Thus constructed the "screw gill" continues to be the most esteemed in principle, though not without some serious objections in practice. For the abrupt and angular movements of the "faller" even here not only liberates too suddenly a portion of the fibres that should be but gradually relaxed at the moment of being drawn, but causes considerable wear and tear to itself, the slides, and the gills attached to it; to which cause of destruction must be added the great friction of the worm movement; these, however, in "line" preparing, where the fibres are long and straight, and the drafts employed large, and where, consequently, a comparatively slow movement of the gills is required, are not so much felt as in the preparation of tow, where they become serious.

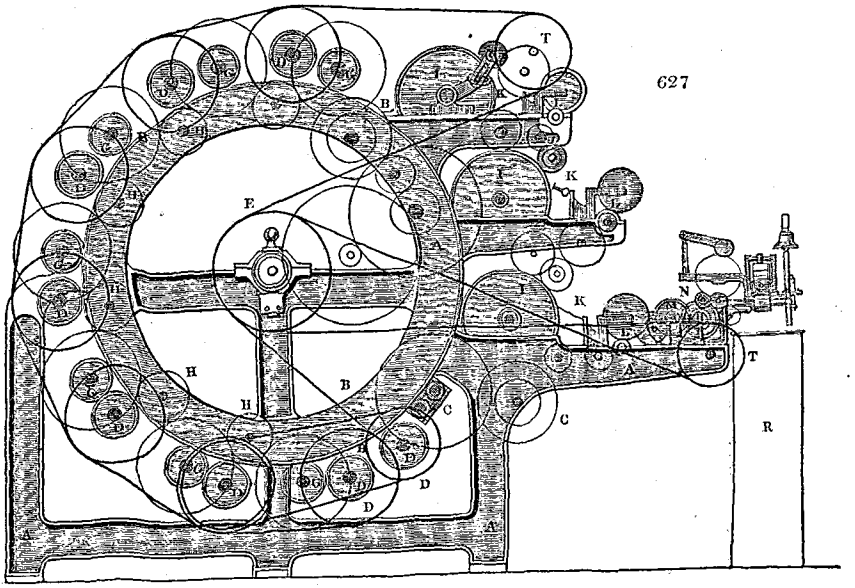
In "tow preparing" the first operation, as before stated, consists of "carding," which is generally repeated over two separate machines, which are respectively called the "breaker" and the "finisher" cards. They are essentially the same in principle, and vary but little in construction, the only difference being that the "breaker" is fed or supplied by the disjointed parcels of tow from a creeping sheet (as the spreader with "line,") and delivers its slivers into a can, whereas the finisher is fed from a bobbin upon which several of the slivers from the "breaker" are united by a machine expressly for that purpose, called a "lap frame"; this card thus receives its supply of work in a very regular form, and previously to delivering it in the form of slivers causes them to pass over a gill, to consolidate and strengthen them before delivering them into the receiving can; it is also generally clothed with a finer description of wire filleting than the breaker. Though it is the better method to card thus the tow twice, yet this second carding is sometimes dispensed with; in that case this auxiliary "gill" is similarly fixed to the first card or breaker. The cards employed for tow are machines of considerable weight and importance, the main cylinder, or, as it is sometimes called, "swift," being from 4 to 5 feet diameter and 4 to 8 feet long; those most generally employed are 6 feet long. Previously to entering upon the detailed description of a card, it may be as well first to trace in general terms the progress of its operations, as tending to elucidate the explanation of the machine itself.

The tow is first divided by weighing into small parcels of 10 to 20 drams; these are then shaken out and spread so as to cover certain definite portions of the creeping feeding sheet, by which they are conducted to the first pair of rollers, called the feeders. These rollers are covered with a leather band, in which are fixed in close array a number of wire points about $\frac{1}{2}$ an inch long, and having a tangential inclination to the

circumference of the rollers, which are about 2½ inches diameter. The tow, passing at a slow rate of progression between these rollers, is by them gradually presented to the points with which the swift is likewise covered, also set in leather bands, but which are about 2 inches wide; these points, the same length as those of the feeders, have an inclined direction pointing to that in which the cylinder turns. The much greater velocity of the "cylinder" combs and somewhat opens and breaks the tow as it slowly arrives in contact, and the inclination of the pins at the same time carries it forward. All such lumps and fibres as are not sufficiently opened and straightened by this first contact, remaining prominent on the surface of points on the cylinder, are carried by it against another roller, whose axis is parallel, and whose wire-covered circumference is brought as near as possible, without absolute contact, in order to catch and retain these prominent lumps and fibres; the points of this roller (called a "worker") are inclined in a direction opposed to the movement of the swift, and, therefore, hold the "tow" to be again combed and straightened as at first it was by the feeders: this is repeated eight or nine times, by having that number of workers to the card; each of these workers has its attendant roller, also covered with wire points, by whose inclination in a contrary direction, and by the greater velocity of the roller, the tow is stripped from the workers, to be again laid on to the cylinder. The strippers, though running at a greater velocity than the workers, are still slower than the cylinder. The tow thus carried forward gradually improving in openness and regularity as it passes each pair of "workers and strippers," finally arrives at the roller called a doffer, of which there are two or three upon a card, the wire points of which are in such a direction as to hook or catch the "tow" "as it flies." The use of these several doffers is, that by placing each succeeding one progressively nearer the swift, the longer and shorter fibres are successively and separately taken off. Each doffer is cleared by an oscillating comb, and the slivers conducted, if intended for the lap machine, into a can by delivering rollers; but if finished, these delivering rollers are as it were the back rollers of the auxiliary gill, patented for this application by Messrs. Fairbairn and Co.; whereby the slivers are not only saved from all danger of derangement in their loose and porous state as direct from a card, but the hitherto double expense of carding and first drawing is reduced to that of carding alone.

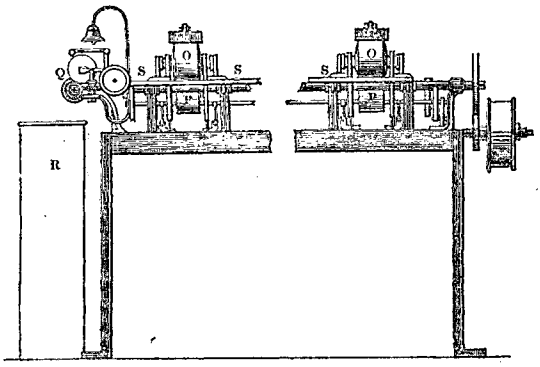
A A A, (*fig.* 627.) framing; B, swift or main cylinder; C, feed rollers, D, D, D, strippers to feed rollers and workers driven by one belt from pulley E, and maintained tight by the

627



movable pulley F; G, G, G, workers; I, I, I, the three doffers; H, H, H, intermediate wheels to connect the movement of the doffers with one another; K, K, K, oscillating combs for their respective doffers; L, delivering rollers; M, back roller of auxiliary gill; N, gill surface; *o*, *p*, drawing rollers; Q, delivering rollers and bell motion for measuring the

628



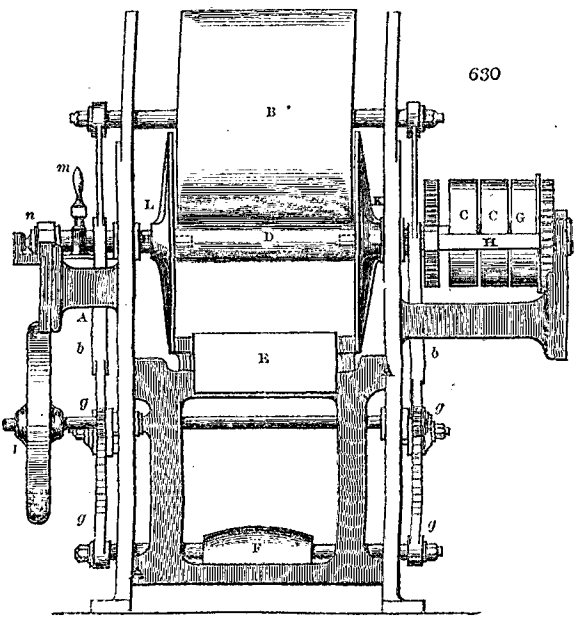
629

slivers into the cans R; S S, doubling plate; T, pulley for driving auxiliary gills by bell from the pulley E.

The lap frame, to which allusion has already been made as the necessary adjunct to the cards when double carding is to be performed, is employed to collect together a number of slivers from the "breaker" by winding or lapping them upon a cylindrical piece of wood, which may be described as a bobbin shank, thus producing an equalisation of the slivers of tow as the making up of sets effected in line preparing; from 50 to 60lbs. of tow is the usual complement of one of these bobbins, the length and the diameter, when full, about 22 inches; thus, a 6 feet wide finisher card will take off these bobbins at once; from 15 to 20 is the number of slivers usually wound together, and the completion of a bobbin by the ringing of a bell, connected with the measuring cylinder of the machine. The following is a descriptive drawing of the lap machine.

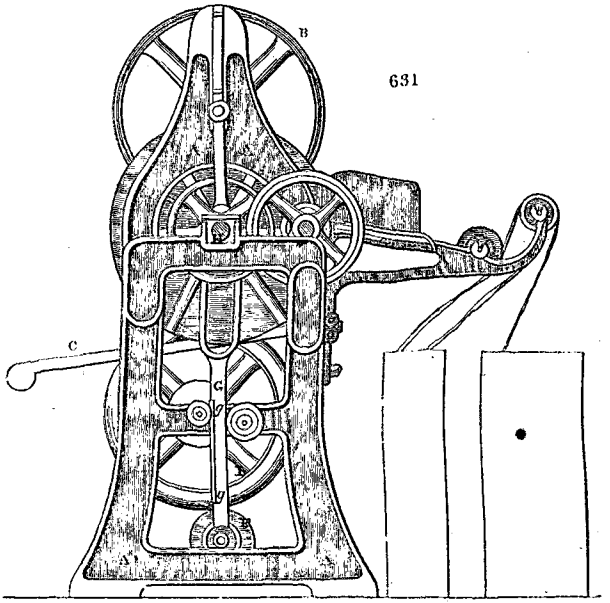
A A A, (*fig.* 630. & 631.) framing; B, measuring and pressing cylinder; C, C, C, driving pulleys connected with different geering to change the speed as the bobbins fill; D, bobbin or shank intended to be filled; E, table to receive the bobbin when about to be taken from the machine; F, weight to increase the effect of pressure of the measuring cylinder by the connecting rods G, G, G, which are split for part of their length in order to pass the shaft H, and at another *g g* have racks into which work pinions keyed on the shaft of

630



the hand wheel I, for the convenience of raising and lowering the cylinder and weight. The shaft H is divided at the plates K and L, and provided with sockets to receive the end of the bobbin shank B, which is introduced by sliding back the piece H *n*, and returning it by lever *m*, and thus is coupled and turns together with two pieces of shaft H, as also the disc plates K and L, which are to serve as temporary ends to the bobbin during the time of its filling, and thus by turning with it avoid that rubbing and felting effect upon the edges of the tow so injurious in the machines formerly constructed,

631



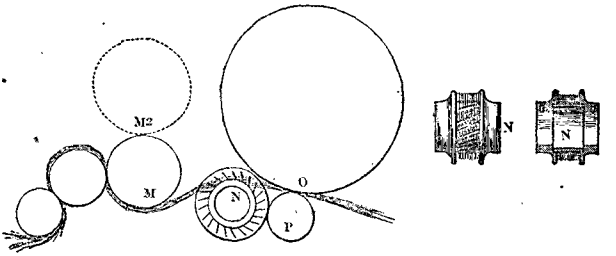
and by the bobbin acting as the driver to the cylinder the slivers are drawn tighter, and thereby avoid those plaites that the other machines were so liable to produce.

As before mentioned, some objections were found to the working of the screw-gill, of a nature detrimental to the machines themselves, which, though not of great importance in "line," were much aggravated in tow preparing, as the lesser drafts there employed cause a greater wear and tear of the fallers and gills. The objection to these machines, however, is not confined to this point only, but extends also to their effect upon the material itself. The fibres of the tow sliver, as coming from the card, are in a light and much confused state, which renders them liable to be easily separated; so that the faller, by its sudden descent, has a tendency to draw some down, and become lapped by them, as well as to make so marked a difference in the thickness of the sliver, by the withdrawal of the retaining comb, so as materially to injure the quality of the yarn. Thus this "gill" was not enabled to hold its place in tow spinning, when other circumstances led to greater attention being paid to this important branch of the flax business, and it became a desideratum to have a machine free from these defects, and capable of working without derangement, at much greater velocity than was safe with the "screw-gill." These desiderata the "rotary" gill, patented by Messrs. Fairbairn & Co., amply supplies. For in this gill the circular form of the gill sheet obviates the necessity of having several fallers, and the simple motion creates neither friction nor abruptness of effect, while the retention of the fibres being continuous, the slivers produced are perfectly level and uniform, consequently these gills are extensively applied, as the auxiliary gill explained in carding, as well as for the subsequent drawings and rovings of tow, and sometimes, as will be afterwards seen, to coarse spinning. The theoretical construction of these rotary gills will be seen by the annexed sketch.

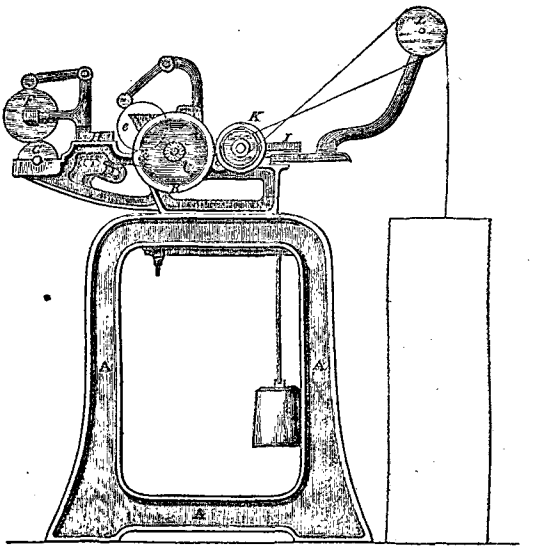
M, (*fig.* 632.) back rollers, but when applied to a card a top and bottom holding rollers are again employed; N, the rotary gill sheet having the pins inclined backwards, so as to insure the impalement of the sliver when the fibres begin to draw; P and O, the drawing and pressing rollers; the doubling bars or plates are the same to these gills as to the 'screw-gills."

Subsequently to the carding the preparation of tow is completed by making up sets

632



633



of cans for the second drawing, as explained for line; these slivers are doubled and drawn once or twice more, and then roved. The drafts used in tow preparing are from 6 to 8, for as the fibres are shorter, it necessitates the employment of less draft. In both line and tow preparing, lesser drafts are employed as the stages advance, the gills finer, and the conductors narrower; also for both materials much attention is requisite to keep the various parts of the machines in good order, free from bent or broken pins, and chipped or indented rollers, for no subsequent operation can cure the defects that may be produced by negligence in these particulars. The drawing and roving frames for tow are shown in *figs.* 633, 634, 635.

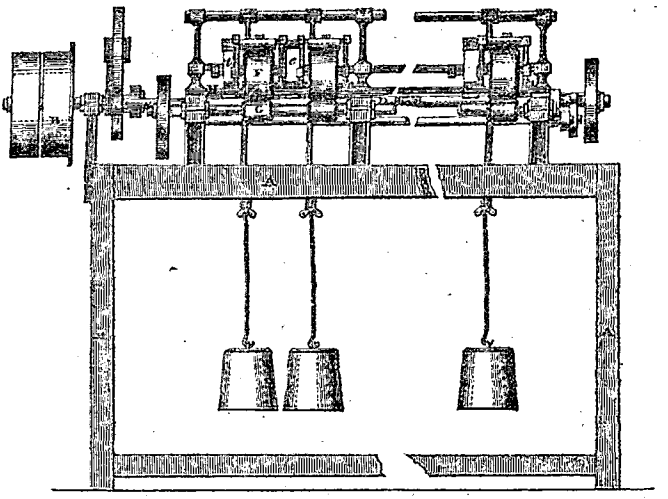
A A, (*fig.* 634.) drawing framing; B, driving pulleys; C, rotary gill sheet; D, drawing roller; E pressing; F, G, pairs of delivering rollers; H, doubling plate; I, back conductor; K back roller wheel with pulley to turn the sliver rail L.

A A, (*fig.* 634 & 635.) roving frame; B, pulley and fly wheel combined; C, drawing roller; D, rotary gill; *a a*, stand for gill movement. The regulation of the bobbins is effected in the same manner as already described for line roving.

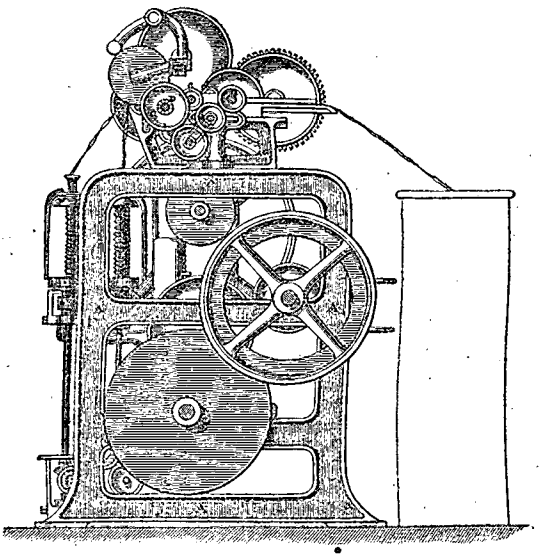
5th. *Spinning.*—This operation consists in drawing the "rovings" down to the last degree of tenuity desired, and twisting them into hard cylindrical cords, which are called "yarns."

There are three modes of performing this operation; the first, and perhaps oldest, is that where the drawing and twisting are performed altogether, with the material preserved dry, and without breaking or shortening the fibre; the second is that which likewise, without changing the length of the fibres, draws them while dry, but wets them just at the moment before twisting. This method is the nearest imitation of hand spinning, and makes the yarn more solid and wiry than the first; as the fibres of flax losing their elasticity while wet, unite and incorporate better with one another. The third mode of spinning has been much more recently introduced than either of the others, and by it

634



635



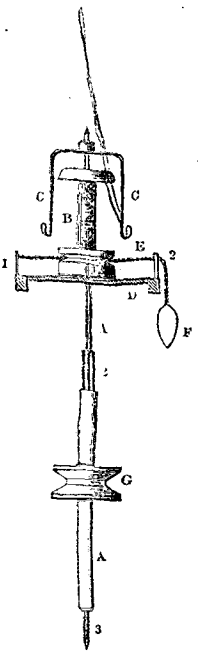
the fibres are wetted to saturation previously to being drawn, whereby they are not only much reduced in length, but their degree of fineness is increased by the partial solution of the gummy matter, inherent in the flaxen material: owing to these circumstances equally good yarns can be produced by this mode of spinning from line and tow of inferior quality, to what could be employed upon either of the others, and not only that, but much finer yarns can be now spun than were possible previous to its introduction. It has therefore not only nearly superseded all other methods of spinning for yarns from 20's to the finest, but has much increased the extent and importance of the flax manufacture.

The only difference in spinning frames for "line or tow," when employed for the older methods, consists in the length of reach, which generally involves the necessity of having separate machines for each material, though sometimes they are made with a capacity to be adapted to either purpose. In the third method the same machines are used promiscuously for "line or tow."

The yarns spun wholly dry are used for the coarse description of woven goods, as packing canvass, corn sacks, and when partially bleached for sheetings and towellings,

as from its greater elasticity and openness it fills up better in weaving. Those spun partially wetted are employed for a somewhat superior description of linen goods, and the solid silky appearance qualifies them for drills, damasks, &c., as well as for sewing and shoe threads: a somewhat inferior material, by this manner of treatment, makes an equally good yarn as a better material spun dry. The yarn produced from this wet principle is rather inclined to have a cottony appearance, and from the comparative ease with which an inferior material can be made to present an apparently fine good yarn, the application of yarns thus produced is exceedingly various and sometimes deceptive, though when good materials are used, these yarns afford durable and handsome drills, shirtings, lawns, and cambrics, as well as fine sewing threads.

636



The mechanical arrangements for twisting, and then winding the yarn upon a bobbin, is called the "throstle" principle, supposed to be so called from the whistling noise they create when working at full speed, which is from 2,500 to 4,000 revolutions a minute. The following diagram will explain the principle, which is applied alike to all the modes of spinning above described.

A A, (*fig.* 636.) the spindle; B, the bobbin, loose and independent of the spindle in regard to turning, and rising, and lowering, but through which the spindle passes; C C, the flyer screwed to the spindle top; D, table called bobbin lifter, as while at work it rises and lowers to lay the yarn on the whole bobbin equally; E, a small cord to press on the bobbin by the weight F; G, pulley by which the spindle is driven.

Many attempts have been made to improve upon this principle, in order to avoid or lessen the strain upon the thread in its passage from the drawing rollers to the flyer eye; but, till recently, without any degree of success. The only improvement at present known, and which promises to become general, is that where the necessity to have a top to the bobbin is avoided. It will be seen from the above diagram, that the yarn is compelled to rub the top of the bobbin, and the friction thereby created quickly causes it to become rough; and therefore it has a tendency to catch and break the thread. The desirableness, therefore, of having a clear course for the yarn was evident, and this improvement that we are about to explain produces the effect by employing what is called a coping motion, which, like that used in mule spinning, preserve the layers of thread upon the bobbin ever in a pointed or conical state, and therefore self-supporting without the aid of the wooden end of the bobbin. See Cotton Spinning.

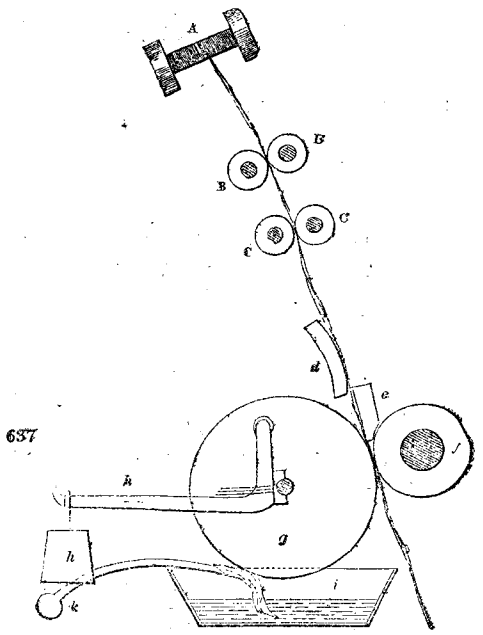
The arrangement of the rollers for holding and drawing the slivers or rovings, as well as the plates and rollers for aiding to retain the twist of the rovings, in order to render their elongation more equable when to be drawn dry and spun upon the older methods, will be seen in *fig.* 637.

A, (*fig.* 637) roving bobbin; B, back or holding roller; C, carrying roller, *d* flat plate with a slightly curved face; the carrying roller and plate are so placed as to cause a degree of friction to the roving when passing over them, so as to retain the twist, and thus act as the pins in the "gill frames;" *e*, tin conductor for contracting the roving at the moment of being drawn; *f*, metal roller; *g*, wooden roller pressed against the drawing roller in order to pinch the roving; *h*, lever and weight. When it is intended to wet the yarn previously to twisting, the trough *i* is used, in which is water, which is supplied to the roller *g* by the capillary attraction of a piece of cloth immersed therein, and bearing against the roller by lever *h*.

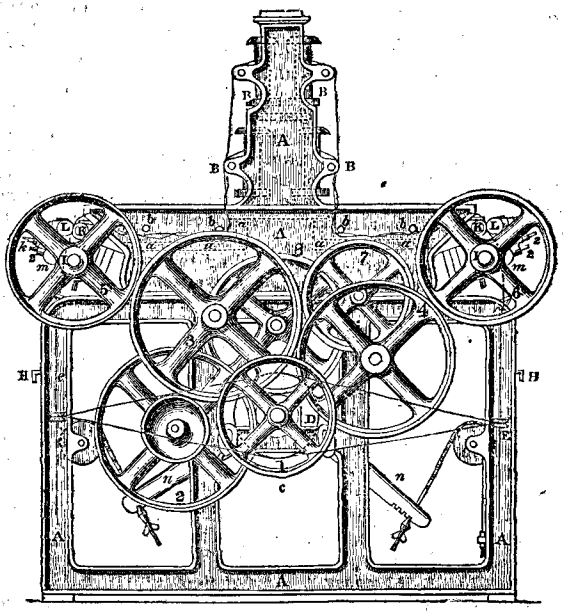
The machines for "wet" spinning are of a very different construction and appearance; as the close proximity of the holding and drawing rollers prevents the intervention of holding rollers or friction bars, while the force requisite to draw the rovings at the short reaches used, varying from 2⅜ to 4 inches, requires each pair to be deeply and accurately fluted into one another. The water used is heated, in order by the expulsion of the fixed air more rapidly and completely to saturate the rovings while passing through it. The following drawings and description will be sufficient to give an accurate idea of the principle of these machines, which are generally 20 to 30 feet in length, and contain 200 to nearly 300 spindles; that is, 100 to 150 on each side.

A A A A, (*fig.* 638. & 639) framing; B B, stand for roving bobbins; C, driving pulleys fixed upon the axle of cylinder D, from which pass endless cords to drive the spindles

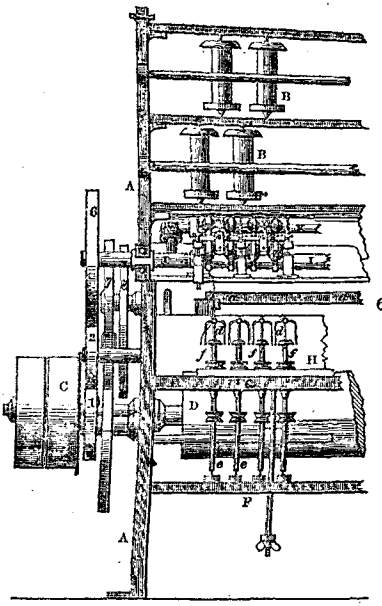
637



638



e e; F, step-rail of spindles; G, collar-rail for ditto; H, bobbin lifter; I I, front roller; K K, back roller; L, back pressing roller; M, top pressing roller (these are generally made of box wood, but sometimes of gutta percha); N, N, levers in connection with the excentric to produce the rise and fall of the bobbin lifter; O O, thread-plate; Q, Q, saddles or transverse bars resting on the axles of the back and front pressing rollers, so that one lever and weight acts for both by the connecting rod to lever *r r*, which, in order to cause more pressure on the drawing than on the back roller, is placed on the saddle nearer the former than the latter. 1, 2, 3, 4, 5, 6, 7, 8, train of wheelwork, by which the movements are dis-



tributed. *a*, *a*, *a*, the trough of hot water maintained by steam-pipes at the desired temperature; *b*, *b*, guide rods or pipes to cause the roving to pass under the water. In order to avoid the rollers becoming indented by the roving always passing on the same place, they are caused to traverse the breadth of the rollers by a traversing guide rail, moved by an excentric at the worm and wheel *c*; *d*, flyers, and *f*, spindles.

Here it may be proper to introduce a description of the machines for twisting the yarns when spun into "threads" used for sewing, &c. The yarns spun for this purpose should always be made of a somewhat superior description of line to that employed for the same number of yarns for weaving, and have rather less twist. They are generally taken while wet on the spinning bobbins to the twisting frame, and, when combined together, the union is effected by a torsion in the opposite direction to the original twist of the separate yarns.

6. *Reeling.* — This operation consists in winding the yarn off the bobbins of the spinning or twisting frames, and forming it into hanks or skeins. The various denominations of the skeins into which yarn is reeled, and then the forms or combinations they are made up into, are as follows: —

The lea containing 300 yards	
10 leas making	1 hank
20 hanks „	1 bundle
6 bundles „	1 packet.

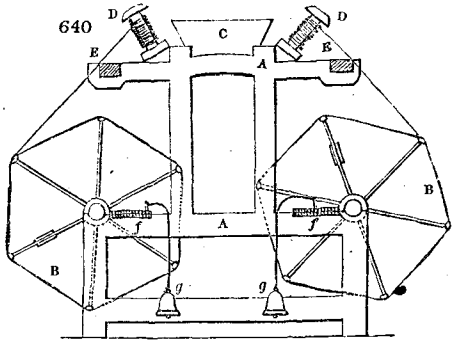
It is by the standard lea of 300 yards that the description of yarn is known from the number contained in 1 lb. weight; thus No. 20. contains 20 leas or 6000 yards for 1 lb. weight. In Scotland, the subdivisions are rather different from the foregoing, which are employed in England and Ireland; the lea, however, remaining the same: —

38 leas make	1 spindle
6 „	1 rand
12 rands „	1 dozen.

The reeling is performed upon exceedingly simple machines, generally put in motion by the hand of the person attending them, though sometimes they are driven by the motive power of the factory. The reel is made sufficiently long to receive twenty bobbins, and the barrel upon the yarn is wound in one length; the diameter, however, varies so as to suit the different sized yarns to be reeled. For the coarsest yarns and down to 16. and 20., the largest circumference is used of 3 yards, from that to about No. 100. 2½ yards, and for the finest yarn 1½ yards is found most convenient. These various circumferences are compensated either by putting a great number of threads

into each "tye," or increasing the number of tyes, so that opposite to each one of the 20 bobbins an entire hank should be formed before taking the yarn off; thus at each "stripping," one bundle is turned off. To facilitate the stripping, one of the rails of the barrel is made to fall in, and thus slacken the hanks; care is taken to leave the leas bands very loose, in order to allow the yarn to be spread out in drying and bleaching. The determinate lengths of yarn, when wound on the reel, are notified by the ringing of a bell connected with the axle of the barrel. Figure below shows the form of an ordinary hand-reel.

640



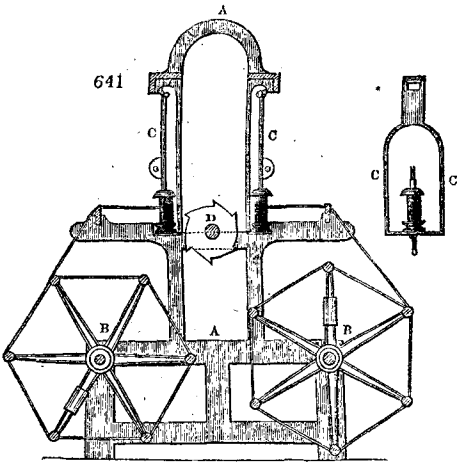
A A (*fig.* 640.) framing; B B reel barrels; C box or trough to receive empty bobbins &c.; D D bobbins in position of being reeled; E E guide rails moveable so as to place the leas side by side on the reel; *f f* bell wheels; *g g* bells for each reel barrel suspended on springs.

To these hand-reels there are many objections; for it is evident that the correctness of measure depends entirely upon the attention of the reeler, and the stoppages arising from the breaking of a thread or the finishing of a bobbin interrupts the work of all the others. These objections rendered it necessary to attempt some ameliorations of the system by the introduction of a reel that should automatically prevent these causes of error. Such a reel was patented a few years since, and is now in general use in Scotland; it is so contrived as to have the capacity of stopping itself when a thread breaks, when a bobbin finishes, and leas and hanks completed; and having but four or five bobbins in one compartment, the stoppages affect but few at a time; and as this machine can be worked by less skilful persons without possibility of error, much saving is effected both in wages and material. The annexed figure (641.) shows the principle of this improved reel.

A A (*fig.* 641.) framing; B reels; C, C pendulums on which are hung the bobbins to be wound off; D driving shaft with ratchet wheels opposite to each pendulum, so that when a thread breaks, the pendulum to which it was attached falls into the ratchet wheel, and thus stops it.

The drying of wet spun yarns should always, when possible, be done in the open air

641



by spreading the hanks upon horizontal poles through them, with another similar pole resting inside upon their lower extremities, in order to keep them straight. If artificial heat is employed, that from steam or hot water is preferable, and it should never exceed 90° Fahr., as otherwise the yarn is apt to become harsh.

7. *Making up.* — By this operation is first produced upon the yarns a certain softness and suppleness, and then the hanks are folded and tied up in conveniently-sized packages.

In order to give the yarns that soft and mellow feel so agreeable and characteristic of flax yarns, the hanks, when brought from the drying, are what is called shaken down and pin-worked. This is done by separating a few at a time, and passing them on to a strong arm of wood fixed to a wall or pillar, when with a heavy baton put through them, the workman proceeds to stretch the hanks with a sudden check or jerk, which operation he repeats in two or three places so as to thoroughly straighten and shake them loose; he then, using the same baton as a lever, twists them lightly backwards and forwards till the desired degree of suppleness is obtained. A brush is sometimes used to aid the straightening and separating, as well as to increase the gloss on the yarn. The hank or hanks will then be found to have assumed a flat shape, as on the reel, which facilitates their folding with a dexterous twist by their middle, when they are laid in square piles upon a table with their twisted folds one upon another. They are maintained in the perpendicular by a few supports fixed in the table. Sometimes these packages, which, according to the sizes of the yarn, consist of from $\frac{1}{4}$ of a bundle to 5 or 6 bundles, are bound together by some of their own hanks, but sometimes by cords in three or four places of their length. It is, however, better to employ a bundling press than an ordinary table, as the yarn can then be made up more solidly, thus both improving its appearance, and causing it to occupy less space for packing and stowage. The bundling presses are made upon the same principle, but on a smaller scale, for making up the small packets, in which sewing threads are generally presented for sale, and are upon the following construction, (*figs.* 642, 643.)

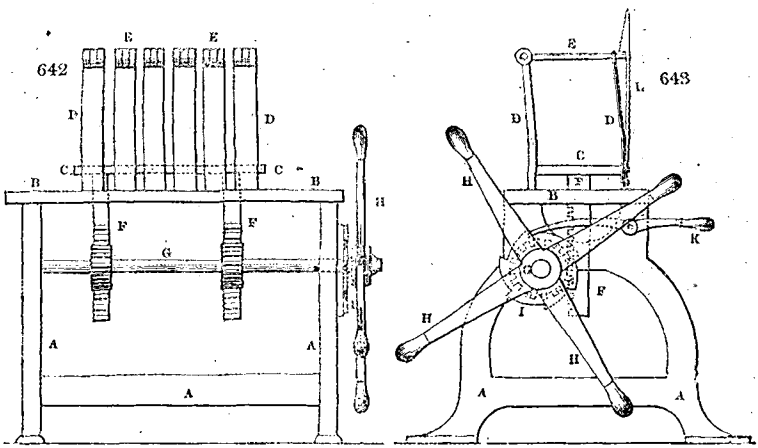


Fig. 642. front view; *Fig.* 643. profile. A A A frame; B table or flat top of frame; C rising table; D D iron uprights fixed to B; E E bars hinged at one end to uprights D D, to shut across the press, and be caught and latched down by the spring catch L fixed to the upright D along one side of the press; F F racks for lifting the table C by the pinions on shaft G; H crossed levers for turning the shaft G; I ratchet wheel engaging the detent K, and thus retain the shaft G in any required position, and thus of course maintaining the pressure of table C against the top cross-bars E.

8. *Weaving*, is the operation by which the yarns are combined into textile fabrics, such as canvas, linen, drills, damasks, &c., and a great variety of other denominations of article for use and ornament.

Hitherto the weaving of linens has been carried on by the ancient and well known hand process, so ancient and so well known as to place the operative practising it among the worst paid of any other art. Now, however, there are several extensive and thriving establishments, where machinery has taken the place of much squalid misery, and at much cheaper rates produce to consumers superior articles, and still afford good payment to the operative. The improvements in power weaving which have led to this result are not founded upon one or even a few successful inventions or contrivances, but are the combination of a great many that have occupied much time to mature. Many difficulties had to be overcome in the weaving of flax that did not exist in that of other materials; and for a considerable period the expense of linens rendered their

consumption so limited, as to make their production by power weaving but a very secondary object. The greatest obstacle of a practical nature to the introduction of the automatic weaving of linens was, the stubbornness or want of elasticity in the yarn, which caused frequent breakages, and much confusion. In woollen or cotton goods, if a thread or yarn should chance to be a little tighter than the others in the warp, its elasticity will allow it to come up to the general bearing of the others when the weft is struck up by the reed; but in linen, from the want of that elasticity, a thread so situated would break, and by crossing some others cause them, if not to be broken direct by that circumstance, at all events cause an obstruction to the shuttle that would lead to further mischief. Hence it was most material in linens to have such a method of winding the yarns upon the warp beams that should insure the greatest regularity; but strange to say, that point, though now attained, was at first wholly lost sight of. That circumstance, as well as the great mistake of attempting to use the same looms as are found suitable for cotton, produced so much discouragement in the earlier attempts as to give rise to a high degree of prejudice against the possibility of success in this undertaking, which may account for the backwardness in which this branch of the flax manufacture was found till quite recently. See article FLAX WEAVING LOOM.

The new roving machine, called by the ingenious inventor, Mr. W. K. Westley, of Leeds, the SLIVER ROVING FRAME, seems to be a *philosophical induction* happily drawn from the nature of the material itself, and accommodated to its peculiar constitution. It is remarkable for the simplicity of its construction, and, at the same time, for its comprehensiveness; requiring no nicety of adjustment in its application, and no tedious apprenticeship to be able to work it.

It is known, that the glutinous matter of the plant may be softened by water, and hardened again by heat; of this fact advantage is taken, in order to produce a roving wholly without twist; that is, in the form of a ribbon or sliver, in which the fibres are held together by the glutinous matter which may be natural to them; or which may, for that purpose, be artificially applied. The sliver roving, as long as it remains dry, possesses all requisite tenacity, and freely unwinds from the bobbin, but on becoming again wetted in the spinning frame, it readily admits, with a slight force, of being drawn into yarn, preserving the fibres quite parallel.

The diagram, *fig.* 644., shows in explanation, that

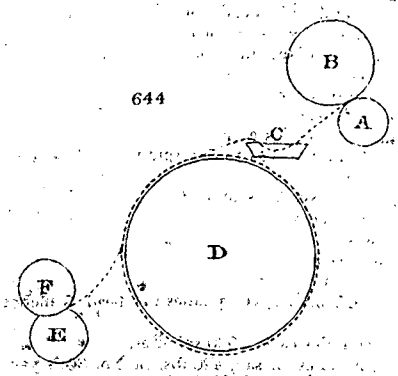
A, is the drawing roller of the roving frame in front of the usual comb.

B, the pressing drawing roller.

C, a shallow trough of water.

D, a cylinder heated by steam.

E, a plain iron roller for winding.



F, a bobbin lying loose upon the winding roller, and revolving upon it, by the friction of its own weight.

The roving, or sliver, as shown by the dotted line, after leaving the drawing rollers, A, B, passes through the water, in the trough C, which softens the gluten of the fibres; and then it is carried round by the steam cylinder D, which dries it, and delivers it hard and tenacious to the bobbin F, on which it is wound by the action of the roller E.

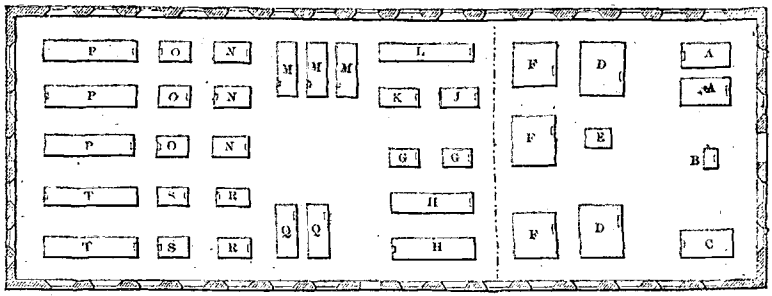
This is the whole of the mechanism required in producing the sliver roving. All the complex arrangements of the common cone roving are superseded, and the machine at once becomes incomparably more durable, and easier to manage; requiring only half the motive power, and occupying only half the room. A frame of 48 bobbins is only 6 feet long, and affords rovings sufficient to supply 1200 spinning spindles.

This machine, though here described, is but little used, being capable of but very limited application.

The following sketch shows the arrangement of the machinery in the most important rooms in a modern flax mill of 7000 to 8000 spindles, capable of producing, weekly, about 1900 bundles of line yarn, No. 25.'s to 120.'s; and about 700 bundles of tow yarn, No. 10.'s to 40.'s.

There are three systems of long line machinery for No. 25.'s to 70.'s; two systems of

645



cut line machinery for No. 10.'s to 120.'s; and three systems of tow machinery for No. 10.'s to 40.'s.

The building is 56 feet wide and 162 feet long; which is a very suitable and convenient size, and which admits of the most economical arrangement of the machinery.

The following is a description of the machines shown in the preparing room:—

A, A, two of Baxter's patent sheet hackling machines for long tow.

B, a flax-cutting machine.

C, one of P. Fairbairn & Co.'s patent double line of holder hackling machines for cut line.

D, D, are two breaker cards 4 feet diameter x 6 feet wide.

E, lap machine.

F, F, F, are three finisher cards 4 feet diameter x 6 feet wide, with P. Fairbairn & Co.'s patent rotary gill drawing heads attached.

G, G, are two patent rotary gill drawing frames for long tow, 12 slivers each.

H, H, two ditto regulating roving frames 48 spindles each for long tow.

I, is a screw gill second drawing frame of 3 heads for cut line tow.

K, is a screw gill third drawing frame of 3 heads for cut line tow.

L, a screw gill regulating roving frame of 72 spindles for cut line tow.

M, M, M, are three long line first drawing frames or spreaders of 4 bosses each.

N, N, N, are three long line second drawing frames of 2 heads each.

O, O, O, are three long line third drawing frames of 2 heads each.

P, P, P, three long line regulating roving frames 60 spindles each.

Q, Q, are two cut line spreaders of 4 bosses each.

R, R, two cut line second drawing frames 2 heads each.

S, S, two cut line third drawing frames 2 heads each.

T, T, two cut line regulating roving frames 72 spindles each.

The spinning room contains 34 spinning frames of 184 to 244 spindles each, apportioned to the several systems as described below.

I. System of long line machinery for spinning No. 25.'s to 40.'s.

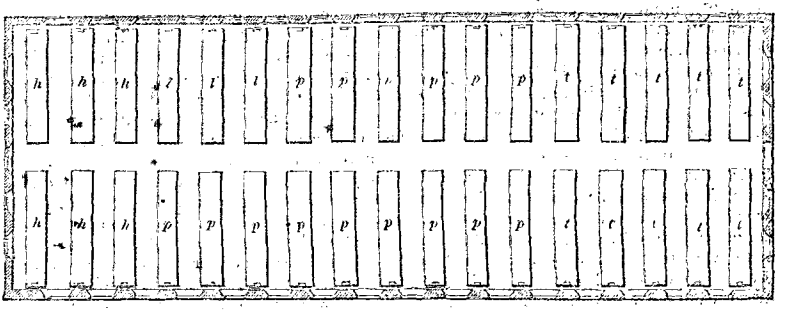
1 Baxter's patent sheet hackling machine, 6 tools.
1 spreader or first drawing frame, 4 bosses.
1 second drawing frame, 2 heads 4 bosses each.
1 third drawing frame, 2 heads 6 bosses each.
1 patent disc regulating roving frame 60 spindles, 10 spindles per head, 8 inches x 4 inches bobbin.
5 spinning frames $2\frac{3}{4}$ inches pitch, 200 spindles each, 1000 spindles.

The production of this system is about 66 bundles, or say, 420 lbs. of No. 30.'s yarn per day.

II. Two systems of long line machinery for No. 40's. to 70's.

1 Baxter's patent sheet hackling machine, 8 tools.
2 spreaders or first drawing frames 4 bosses each.
2 second drawing frames, 2 heads of 6 bosses each.
2 third drawing frames, 2 heads of 8 bosses each.
2 patent disc regulating roving frames, 60 spindles each, 12 spindles per head, 6 inches x $3\frac{1}{2}$ inches bobbin.
10 spinning frames, 220 spindles each, $2\frac{1}{2}$ inches pitch, 2200 spindles. Production about 130 bundles, or 472 lbs. of No. 55.'s yarn per day.

646.



III. Two systems of three cut line machinery for No. 40.'s to 120.'s (one for 40.'s to 70.'s, and one for 70.'s to 120.'s).

1 flax cutting machine.
1 P. Fairbairn & Co.'s patent double line of holder hackling machine.
2 spreaders or first drawing frames 4 bosses each.
2 second drawing frames, 2 heads each, 6 slivers per head.
2 third drawing frames, 2 heads each, 8 slivers per head.
2 patent disc regulating roving frames, 72 spindles each, 12 spindles per head, 6 × 3½ inches bobbin.
5 spinning frames 220 spindles each, 2½ inches pitch, = 1100 spindles.
5 spinning frames 244 spindles each, 2¼ inches pitch, = 1220 spindles.
Production about 65 bundles or 236 lbs. of No. 53.'s yarn per day, and about 50 bundles or 105 lbs. of No. 95.'s yarn per day.

IV. Two systems of long tow machinery for No. 10.'s to 25.'s.

1 breaker card 4 feet diameter 6 feet wide, doffed by rollers.
1 lap machine.
2 finisher cards 4 feet × 6 feet with P. Fairbairn & Co.'s patent rotary gill drawing frames attached.
2 patent rotary gill drawing frames 12 slivers each.
2 patent rotary gill disc regulating roving frames, 48 spindles each, 8 inches × 4 inches bobbin.
3 spinning frames, 184 spindles each, 3 inches pitch for No. 10.'s to 18.'s = 552 spindles.
3 spinning frames, 200 spindles each, 2¾ inches pitch for No. 16.'s to 25.'s = 600 spindles.
Production about 39 bundles, or 488 lbs. No. 16.'s per day, and about 39 bundles, or 312 lbs., No. 25.'s per day.

V. One system of cut tow machinery for No. 25.'s to 40.'s.

1 Breaker card 4 feet diameter 6 feet wide, doffed by combs.
1 Finisher card with P. Fairbairn & Co.'s patent rotary gill drawing frame attached.
1 Screw gill second drawing frame 3 heads each, 4 bosses per head.
1 Screw gill third drawing frame 3 heads each, 6 bosses per head.
1 Screw gill patent disc regulating roving frame 72 spindles, 12 spindles per head, 6 × 3½ inches bobbins.
3 spinning frames of 220 spindles each; 2½ inches pitch, = 660 spindles.
Production about 36 bundles, or 240 lbs. of No. 30.'s per day.

The reeling is generally carried on in the attic above the spinning room, and the number of reels required is about the same as the number of spinning frames.

Summary view.

There are 3200 spindles long line, producing 196 bundles, or, 890 lbs. of yarn per day.

1152	„	long tow,	„	78	„	800	„
2320	„	3 cut line,	„	115	„	340	„
660	„	cut tow,	„	36	„	240	„
7332 spindles				425 bundles		2270 lbs. of yarn per day.	

The waste in line spinning is generally about 10 per cent., and in tow spinning about 25 per cent., so that the quantity of raw flax required to produce the above stated quantity of yarn would be about 20 cwts. of flax for long line and long tow spinning, and about 6 cwts of flax for cut line and cut tow spinning.

Claussen's Patent Process. — The great interest which has of late been excited in the public mind with respect to flax, in part by the enlarged sphere of application which is supposed to be opened out to it by the discoveries of Mr. Claussen, and more particularly from the fact, that it is a material of home growth, and capable of production in unlimited quantities in Ireland, would seem to demand from us special comment. We are not the less inclined to this course, as the public is ever ready to take upon trust the practicableness of any new projects, when their promised results chime in with any feeling of sympathy which happens to pervade the community; thus, where the interest of Ireland is concerned, we find that commercial schemes for aiding its advancement are eagerly seized upon, and confided in almost without inquiry; but this is far from a prudent course. There can be no question that the flax trade is the growing manufacture of Ireland, and, as such, too much attention cannot be given to the production of the raw material; it has therefore been encouraged in every legitimate way, but it may be questioned whether the late announcements which have been made of its almost universal applicability to textile fabrics, will not tend to direct capital to too great an extent into this now thriving branch of industry, and thereby quickly induce a false and ruinous competition between manufacturers.

Flax, though apparently, from its fibrous character, better suited by nature than either cotton or wool to be formed into thread, nevertheless presents many difficulties to manufacturers, which are quite foreign to the working of these short staples, and which can only be in part remedied by the adoption of a somewhat different process of manufacture. In contradistinction to cotton, which may be considered the fruit of the plant, flax is the filamentous substance contained in the stalk of the plant. It has therefore to be obtained from stripping off the bark or woody coating, termed the "boon." But, in order to effect this, as well as to detach the fibres from each other, it is necessary to dissolve the gum or resinous sap, which pervades the plant, and binds the several parts together. Various plans have been suggested for attaining this end; and it is upon the efficiency of the process adopted that the ultimate success of the flax trade mainly depends. When it is understood that the growth of the flax plant is principally in the hands of small farmers without capital, and that the bulk of the flax, when reaped, is so disproportionate to the yield for manufacturing purposes as to preclude the removal of the article to any great distances in the state of straw, it will readily be seen, that no process of dissolving the gum, or of "retting" as it is termed — requiring the purchase of expensive apparatus, or demanding the exercise of scientific knowledge — can be brought into general use, however efficient that process may prove to be. It cannot, therefore, be wondered at that the old plans of water-retting and dew-retting still prevail, although a far superior method, which we shall presently explain, has been introduced.

Retting is simply bringing the plant to a certain stage of decay, which causes a perfect loosening or separation of its fibres. In carrying out the water-retting process pits are dug in the ground and filled with water, and the flax is thrown in in bundles and pressed down by weighted boards, to keep it under water. After a short time fermentation commences, and in about ten days (more or less according to the mean temperature) the decaying process will have proceeded sufficiently far; the flax is then taken out and dried, and the boon is removed by hand. The retting may be carried on in either running or stagnant water; but the latter, although the more expeditious method, requires closer watching, to prevent the flax from losing its strength of fibre by over decay. It will be obvious that large masses of vegetable matter exposed to putrefaction must generate such exhalations as are very injurious to the health of the community. Yet this practice not only prevails, but will, as we think, necessarily increase in proportion to the increase in the growth of the plant, unless some energetic means are adopted to put down the practice. Dew-retting is a process that is less objectionable, but its operation is far slower, and it is altogether beyond the means of many farmers to adopt. In this instance the flax is strewn thinly over meadow or grass land, and then submitted to the action of the air, dews, and rain, which, in a period varying (according to the mean temperature) between three and six weeks, will effect the required disunion of the plant. This plan has an advantage over the water-retting, inasmuch as the flax is yielded of a brighter colour, — the latter process being very apt to impart a deep stain to the fibres, as well as to destroy their tenacity.

The improved plan of retting, above alluded to, was introduced into Ireland from the United States in 1847, by Mr. Schenck of New York. It had been tried there successfully on hemp; the strength of the fibre, when made into cables, having been proved in some of the government navy yards to exceed any that had been retted on the old system. The process was patented in the United Kingdom in 1846, and is now in profitable work near Belfast. A recent inspection of the factory will enable us to state in detail the manner of proceeding to separate the long fine fibres of the flax from the boon. The principal apartment in the building contains a number of large circular

vats, in which the flax is steeped, and these are provided with steam-pipes connected to the steam engine boiler. The flax to be operated upon is placed in these vats and piled up to a given height; strong cross-bars of wood, forming a kind of framework, are then laid above the flax and secured to the respective vats, — the object of this framing being to keep the flax down in the vat, as otherwise it would rise as it swelled in fermenting, and protrude above the water. When a mass of flax is thus secured, water is run into the vats, and as it becomes absorbed, more water is added. Steam is now admitted into and made to circulate through the steam-pipe at the bottom of the vat, so as to raise the water to about 90° Fahr., and maintain it at that temperature. In a few hours acetous fermentation is established in the vat, and the decomposition of the resinous or gummy matter in the stalk proceeds with rapidity. After about sixty hours the decomposition is completed, and that without the exudation of any inodorous or noxious effluvium. The water surcharged with the mucilage is then drawn off, the framing is removed, and the flax is taken out of the vat to be dried, either in the open air or by artificial means. Thus, not only is the objection to the old plan, on the score of injury to health, removed, but a considerable economy in point of time is effected; the flax also is less liable to deterioration in colour and strength of fibre, if ordinary care is used in conducting the operation. When the weather is favourable for drying in the open air, the flax, tied up, in tufts or handfuls, is suspended in rows tier above tier, in an open framing, covered in at top by a penthouse roof. This mode of packing admits of a large quantity of flax being stowed in a small compass, and yet allows of a free access of air through the whole mass. When it has hung a sufficient time to dry, it is next submitted to the scutching operation. Or, instead of open air drying, the flax, in damp weather, is piled loosely in a drying chamber, into which a current of air, heated after Messrs. Davison & Symington's method, is passed, and the moisture is quickly expelled. The cost of this operation, as carried on at the works, must be very trifling, as the waste steam from the engine, which works on the high-pressure principle, is found amply sufficient for heating the air; an advantage consequent on this mode of heating is, that no carelessness on the part of the attendants will render the air liable to be heated to an extent that would injure the flax. The flax having been retted and dried, is next carried to the rolling or crushing mill, and there passed, by hand, between rotating horizontal rollers, which crack the boon already loosened by the retting process, and spread, or partially separate, the long fibres. The flax, as it is delivered out of the machine, is gathered up by boys, and handed to others, who submit it by handfuls to the action of rotating knives. These knives are attached to the face of a vertical wheel, several of which are mounted on one and the same shaft, at about three feet apart, and receive motion from the engine. There is an attendant stationed at every wheel, whose duty is to submit the flax to the action of the knives, by holding it over a fixed bar, contiguous thereto, and allowing the rotating knives to strike the flax in the direction of its length. When the boon on the half length of the flax is broken away or knocked off, the flax is turned over and the other end is subjected to similar treatment. To further clear the flax of the woody particles, it is again submitted to a similar operation before another set of wheels, — the action of the knives being, in this instance, more thorough and searching, as the flax has now approached nearer to a stick of fine fibres. Having undergone this treatment, the flax is now ready for sale in the market; and it is in this state that it enters the flax mill, to be acted upon by the heckling-machine, for the removal of the tow or short staple, prior to undergoing the various operations of preparing and spinning, to convert it into yarn. From this description, it will be understood, that, so long as the cultivation of flax is in the hands of small farmers, Mr. Schenck's process is not likely to put the old practice out of use; for the water-retting is carried on at little or no outlay of money; and the cleaning of the flax by hand is made a sort of wet-day occupation: the bulk of the flax in the state of dry straw, — which, as we have before said, is so disproportionate to the amount of useful fibre as virtually to prevent its carriage to any distant part prior to undergoing the retting operation — scarcely exceeds, when carried to the market, 20 per cent. of its original weight.

M. Claussen's patented process (the merits of which have been so confidently paraded), does not seem to be in favour with the Irish flax spinners, although the specimens contained in the Exhibition appeared to the eye to realise everything that could be wished; but here, as in many other manufactures, it is not the attainment of a high degree of excellence that is the difficulty, but the cost at which such a result may be arrived at. Thus flax may be dressed from the straw, as, indeed, it was once proposed to be done, without being subjected to the retting process. The waste of material, however, soon showed the impracticability of the plan, although a good article was produced; it is possible, therefore, that M. Claussen's specimens may have been obtained without regard to cost. We do not assert this as a fact, but rather to show, that in commercial matters no just conclusions can be arrived at without the question of cost being taken into account. His mode of treating the flax will be readily understood from the following

description, which we have compiled from his specification. The straw, having been stripped of its seeds, is steeped in a solution of caustic alkali, of about the strength of 1° Twaddle's hydrometer, either in a boiling state, which renders an immersion of six hours sufficient, or at a temperature of 150° Fahr., which will necessitate the continuance of an immersion for about twelve hours. By this means the glutinous matters, which connect the fibres with the woody portions of the plant, are dissolved, and the colouring matters contained in the straw are discharged and prevented from staining the fibres. When the flax is required to be spun in long staple, the straw is next steeped for about two hours in dilute sulphuric acid, containing one part of acid to from two to five hundred parts of water, for the purpose of ridding it of the alkali which it has taken up; the straw is then removed from the acid-bath and well washed in water: this is one process. But the one which has raised the public curiosity, is that which purports to split the fibres into fine filaments, like those of cotton or wool. This operation is effected as follows: — The straw is put into a bath containing a strong solution of bicarbonate of soda, and allowed to remain there for three or four hours. When well saturated with the bicarbonate, it is immersed in water, acidulated with sulphuric acid, in the proportion of one part of acid to two hundred parts of water; the sulphuric acid will then combine with the soda and effect the disengagement of carbonic acid gas in the fibrous tubes, which gas, by its expansive force, will split the fibres into fine filaments, having the appearance of fine cotton wool, and capable of similar treatment. This splitting process may be applied to the plant either in the state of straw, or after it has been retted and brought to the state of long fibre; and it is therefore capable of general application, as far as the inconvenience arising from bulk is concerned. What manufacturers will eventually say to working up fibres that have been steeped in sulphuric acid, may depend upon the means taken to extract this corroding substance from the flax; but at present we think there is a strong feeling against its use.

Mr. Claussen's patent process for treating flax is described as follows, in his specification of March, 1851:—

"1. My said invention, in so far as respects improvement in bleaching, has reference to the bleaching of all kinds of vegetable productions, and of fabrics or articles composed of such productions, and consists of the following improved processes. In the usual methods of bleaching fabrics, such as calico, the goods are first immersed in a bleaching liquor (commonly the solution of hypochlorite of lime, 'the chloride of lime' of commerce), and then are steeped in a bath of water, acidulated with sulpheric acid. By this plan, the chlorine is set free, either in its simple form, or in combination with oxygen (as chlorous or hypochlorous acids), or in chemical union with the hydrogen of the water (as hydrochloric acid), and thus either is wasted, by its escape, or is rendered injurious to the fabric, by remaining too long in contact with it.

"Now instead of this I adopt the following process, whereby the whole, or a great portion of the chlorine, or chloro-compound, is kept in a combined state, and recovered for further use. By the term 'chloro-compound' I do not mean a salt containing 'chlorine,' but an acid having 'chlorine' for its base, such as chlorous or hypochlorous acid.

"In this process, then, of bleaching, I take the goods, after they have passed through the bleaching liquor (say a solution of the hypochlorite of lime), and then steep them in a strong solution of some salt, whose acid has a more powerful affinity for lime than hypochlorous acid; thus a strong solution of sulphate of magnesia may be employed, the sulphuric acid of which, having a strong affinity for lime, combines with the earthy base of the bleaching salt above mentioned, and forms sulphate of lime, and the chloro-compound being thus liberated unites with the magnesia of the sulphate of magnesia, and forms a new salt (hypochlorite of magnesia), having bleaching properties similar to the lime-salt first employed.

"This newly formed compound may be in the next instance, used as a primary bleaching agent, and may again be subjected to the process of double decomposition, as in the foregoing example. Thus, the goods having been exposed to the action of hypochlorite of magnesia in solution, may then be steeped in a liquid holding in solution some carbonate or other salt, for whose base the hypochlorous acid has a greater affinity than for the magnesia. In such a case, the carbonic acid having also a strong attraction for the magnesia, combines with it, to form a carbonate of that earth, and the liberated chloro-compound, instead of escaping, or remaining so long in contact with the goods as to injure them, combines with the base of the carbonate employed, to produce decomposition, and forms a new salt, having bleaching properties. This salt may also be brought under the same laws of double decomposition as exemplified before, and with similar results.

"Thus if the carbonate employed in the foregoing instance had been carbonate of barytes, and a solution of sulphate of magnesia or of lime were brought into contact with the resulting chloro-compound salt of barytes, a precipitate of the baryta as a

sulphate of barytes, will take place, and the chloro-compounds will unite with the lime or magnesia, to form a bleaching salt.

"I would mention, however, that, in bleaching flax, or other like vegetable material for making linen, no compounds should be used which are likely, during their decomposition, to evolve any gaseous matters, such as carbonic acid or chlorine, as, by their development and expansion in the fibrous tubes, the flax, or any similar material, would be rendered not so fit for spinning with the ordinary flax spinning machinery; but in bleaching flax, or any similar material, which is to be combined with other materials for spinning and felting, according to my invention, compounds evolving gas may be safely used, as I shall hereafter more fully specify and explain.

"For the purpose of bleaching by the method of double decomposition, I do not confine myself to the compounds already mentioned as examples, nor to any particular salts or class of salts; but I claim a right to use, which, when placed under the like circumstances, as before exemplified in the case of goods treated by the hypochlorite of lime and the sulphate of magnesia, will be subject to the same chemical law of decomposition, and will produce the same result. However, I may particularise as among the salts suitable for decomposing the chloro-compounds salts, or assisting themselves in the process of bleaching, the carbonates (such as the carbonate or bicarbonate of soda), sulphates (as sulphate of magnesia, &c.), nitrates (as nitrate of soda, &c.), acetates (as acetates of potash and of lead, &c.), prussiates (as prussiates of potash, &c.), chromates (as chromate and bichromate of potash, &c.), tartrates (as tartrate and bitartrate of potash, &c.); but I repeat, that I do not confine myself to these, which are merely given as examples.

"Another mode of bleaching which I sometimes employ, and which is especially applicable to goods composed of both animal and vegetable fibre, is as follows:—I take the goods, after they have been steeped in any of the ordinary bleaching liquors, such as the solution of hypochlorite of lime (chloride of lime), and while they are still wet, I expose them to the fumes of sulphur, slowly burning in a suitable chamber or stove. In this case, I have two powerful bleaching agents at work, viz.; the hypochlorite compound, and the sulphurous acid produced by the combustion of the sulphur. A portion of the sulphurous acid combines with the base of the chloro-compound salt, to form a sulphite of lime or magnesia, as the case may be, and a small portion of sulphuric acid may also in this case be formed, which, with the earth or base, would form a sulphate. In this way the chlorine, or chloro-compound, remaining in the wetted goods is liberated, and allowed to act freely upon the articles to be bleached. In this last method of bleaching I have ascertained that there may be occasionally substituted for the ordinary and known bleaching liquids certain chromates, manganates, and hypermanganates, &c.

"Secondly. My improvements in the preparation of materials for spinning and felting have special relation to flax and hemp, and other plants, to which the same may be applicable: and the processes I use to prepare the same, though possessed of some features common to the whole, vary according to the purposes to which the fibre obtained from the said materials is to be applied, that is to say, according as the fibre is required to be long or short, fine or coarse, and the machinery in which it is to be spun is adapted to the spinning of one or other sort of fibre. By the term 'fibre,' as used throughout the specification, I mean that portion of each plant which is capable of being spun or felted; and my invention applies to the 'fibre' surrounding the stems of dicotyledonous plants, and to that existing in the stems and leaves of monocotyledonous plants.

"In the following exemplifications of my improved modes of preparation, I shall throughout suppose flax or hemp to be the material operated upon.

"If I have to deal with the plant from the time of its being first cut down or pulled for use, I take it in the state of straw (after the seed had been stripped from it), and subject it to the following, which I call my 'primary process':—

"I first steep the straw in a solution of a caustic alkali of about 1° of Twaddle's hydrometer, and for such a length of time as may be most convenient. If despatch is required, I use the solution in a boiling state; in which case an immersion of about six hours is sufficient. If more time can be conveniently allowed, I employ a solution of a temperature of about 150° Fahr., and prolong the immersion for about twelve hours; and so in proportion to the degree of temperature. The solution may be even used at a lower temperature, with a corresponding prolongation of time, but in no case need the immersion exceed a couple of days at the utmost.

"The object of the preceding treatment is two-fold:—first, to decompose, dissolve, or remove (more or less, as required), the glutinous, gummy, or other matters, which connect the fibre with the woody portions of the plants; and second, to discharge or decompose any oleaginous, colouring, or extraneous matter contained in the straw, without allowing the matters so discharged to stain the fibre; and these results are obtained

by the action of the alkaline solution. In the preceding mode of preparing vegetable materials, I generally use a solution of caustic soda; but other alkaline liquors will answer the purpose,—such as a solution of caustic potash, or of lime dissolved in or diffused in water, or, indeed, any substance having the like power of removing, discharging, or decomposing the colouring, glutinous, gummy, or other foreign matters contained in the straw, and which would interfere with the whiteness of the fibre, or with its ready separation and manufacture.

"If the fibre is required to be long, like that now commonly spun in flax machinery, I subject the straw to a second process, for the purpose of getting rid of any of the alkali still adhering to the straw or fibre, and for the purpose of completing (if necessary) the removal of any glutinous, gummy colouring, or extraneous matters.

"To this end I will take the straw from the alkaline solution, and steep it for about two hours in water acidulated by sulphuric acid, in the proportion of about one part of the acid to from two to five hundred parts of water. Some other dilute acids will also answer this purpose, such as dilute muriatic acid, &c.; but sulphuric acid is to be preferred. Or, I transfer the straw, while yet wet with the alkaline solution, to a suitable chamber or stove, where I subject it to the action of sulphurous acid, or the fumes produced by the slow combustion of sulphur. In both cases, the acid combines with any free alkali remaining on the straw or fibre, to form a sulphite or sulphate, according to the acid employed; while an excess of either sulphuric or of sulphurous acid will complete the decomposition, discharge, or removal of the glutinous, colouring, and other matters.

"I next remove the straw from the acid bath, or sulphur chamber or stove, and wash or otherwise treat it with water, till all soluble matters are removed.

"If the fibre is required to be discolorised, the straw may now be exposed to one of the bleaching processes which I have already described, or to any of the other known bleaching processes. It may then be dried, and made ready for breaking and crushing, by the means ordinarily followed in the manufacture of long flax.

"I would mention here that, in some cases, it will be found advantageous to pass the straw between rollers, or to break it roughly or partially, before subjecting it to the process above described, for the purpose of facilitating the action of the chemical agents upon it.

"By the aforesaid method, I am enabled to remove from the straw certain matters, which water alone can discharge. The fibre thus prepared is also freer to heckle, and the straw more easy to scutch, than fibre and straw treated in the ordinary way. Much time and much material are also saved; while the noxious exhalations attendant upon the water-rotting system are wholly prevented.

"If the fibre is required to be short, so that it may be felted or carded, and adapted for spinning on cotton, silk, wool, worsted or tow-spinning machinery, either alone or in combination with cotton, hair, fur, silk, or shoddy, I take the fibre, after treating it by the processes just described, and divide it in proper lengths, by some suitable instrument or machine. I then transfer the straw or fibre to a bath, containing a strong solution of bicarbonate, or even carbonate of soda, or any other similar compound; but the first two of these are to be preferred, as most abounding in carbonic acid. In this bath I allow it to remain for about three or four hours, during which time the fibre becomes well saturated with the salt. I then immerse the materials, impregnated with the solution of the carbonates before named, for about a couple of hours in water acidulated by sulphuric acid, of about the strength of one part of acid to two hundred parts of water. Or, instead thereof, I expose the saturated materials, while wet, to the action of burning sulphur in a suitable chamber or stove.

"In this operation it appears that a certain portion of gas being developed in the fibrous tubes, splits and divides them by its expansive power into filaments, having the character and appearance of fine cotton wool; in which state they may be dyed and manufactured like cotton or wool.

"The same means of effecting the splitting of the fibre may of course be employed in the preparation of long fibre, and I do not limit myself to its use for the preparation of short fibres alone, but when the fibre is of its original length, the solution employed takes a longer time to penetrate the interior.

"The decomposition of the bicarbonate of soda or other suitable compound, with which the fibre is saturated, may be also effected by means of electric agency, when a like evolution of gas and splitting up of the fibre will take place.

"After the fibre has been subjected to the splitting process, it must be carefully washed to remove all soluble matters, and then dried.

"The splitting process may be applied to the plant, either in the straw (the wood of which is to be afterwards removed by proper means and machinery), or in the state of long fibre, whether prepared by my before-described process, or by any of the usual and known processes.

"Thirdly, my invention, in so far as it relates to improvements in yarns and felts, consists in composing the same of the following new combination of materials. I manufacture a yarn which I call 'flax cotton yarn,' composed partly of flax fibre prepared and cut into short lengths, as aforesaid, and partly of cotton, varying the proportions at pleasure. This yarn is much stronger than yarn composed of cotton alone, and also much whiter and more glossy, while it is equally capable of being spun in the ordinary cotton spinning machinery.

"I also manufacture yarns composed in like manner, partly of hemp fibre or of jute, or of *phormium tenax*, or of other like vegetable fibre (china grass excepted), prepared and cut into short lengths, as aforesaid, and partly of cotton, which yarns each possess the same properties (more or less) as the flax-cotton yarn.

"I manufacture also a yarn, which I call 'flax-wool yarn,' composed partly of flax prepared and cut into short lengths as aforesaid, or of any other like vegetable fibre, (cotton and china grass excepted) and partly of wool, or of that description of it called 'tschudy,' or partly of fur or hair, or partly of any two or more of the said materials; which yarn is stronger than any yarn composed of wool alone. Some wools also, which are too short to be spun by themselves, may, by being mixed with flax fibre, cut into short lengths, form a material very suitable for spinning.

"I manufacture also a yarn, composed partly of flax or other like vegetable fibre (china grass excepted), prepared and cut into short lengths, as aforesaid, and partly of waste silk, that is, silk of the short lengths in which it exists before reeling, or silk rags cut into short lengths and carded.

"Lastly, flax-felts, of a fineness and softness equal to the best felts composed wholly of wool, and superior to them in point of durability, are also produced by a mixture of flax fibre, prepared and cut into short lengths, as aforesaid, with wool, fur, hair or any other feltable material.

"And I declare that what I claim, as secured to me by the said letters patent, is as follows:—

"First,—I claim the method of bleaching by double decomposition, before described, whereby the various bleaching agents and compounds used may be recovered and economised.

"Second,—I claim the method of bleaching by the combined action of chlorides, or carbonates, or chromates, or any other bleaching agent, with fumes of sulphur, as before described.

"Third,—I claim the preparing of flax and hemp, and of all vegetable fibre capable of being spun or felted, from whatever description of plants obtainable, by steeping the plant from which the fibre is derived, while in the state of straw, stem, leaf, or fibre, first in a solution of caustic soda, or other solution of like properties, and then in a bath of dilute sulphuric or other acid, as before exemplified and described.

"Fourth,—I claim the preparing of the said vegetable fibre for spinning in cotton and silk machinery, and for being confined with cotton, wool, raw silk, or other materials of short staple, by firstly steeping the same in a solution of caustic soda, or other solution of like properties. Secondly, steeping them in a bath of dilute sulphuric or other suitable acid, or exposing them to the fumes of sulphur. Thirdly, saturating them with a solution of bicarbonate of soda or any other like agent, and then decomposing such salt, however such decomposition may be effected; and, fourthly, cutting them up into short lengths, all as before exemplified and described.

"Fifth,—I claim the employment generally in the preparation of flax, hemp, and other sorts of vegetable fibre, of the mode of splitting by gaseous expansion, as before described, whether the fibre is long or short, and whatever may be the purpose to which the same is to be applied.

"Sixth,—I claim the manufacture of yarns and felts from a combination of flax, or like vegetable fibre (china grass excepted), prepared and mixed, as aforesaid, with cotton wool, 'tschudy,' silk waste, fur, and hair, all or any of them as before exemplified and described."

Another process for treating flax is shortly to be introduced, which is said to surpass that of M. Claussen in its results. This is the patented invention of Mr. Bower, of Hunslet, but as his specification is not yet enrolled, we withhold, for obvious reasons, the details of his plan, and forbear to express any opinion of its practicability. The treatment of flax, in its early stages, is a matter of vast importance to this country; and perhaps there is no one problem throughout our manufactures whose solution would better repay the successful experimenter, than how the facilities for working cotton and wool are to be communicated to flax.—*Newton's Journal*, October, 1851.

Mr. D. F. Bower obtained in March, 1851, a patent for retting and preparing flax, in which he submits the flax, after steeping it for six days in cold or hot water, to the pressure of rollers once and again, with steeping, in order to expel the glutinous matter, and then dries it. Line is treated with dilute water of ammonia, or alkaline saline solution. He also avails himself of the air-pump, along with the above solvents, for the extraction of the gluten by means of hot water.

With the object of giving the flax grower the means of rendering his produce fit for the market, Mr. M'Pherson, of Edinburgh, has constructed a portable breaking and scutching machine, suitable for a farmstead. It consists of two rectangular wooden cases, of unequal size, connected together side by side, the smaller containing the breaking apparatus, and the larger the parts for scutching the flax. The small case is provided with a horizontal table, having a fluted surface, whereon the flax is laid; and over the table a fluted roller is caused to travel, for the purpose of cracking the boon, or woody portion of the flax plant. The axes or pivots of the roller move in horizontal guides, which can be lifted by depressing a treadle, for the purpose of raising the roller; and the traverse of the roller is effected by its connection, through a rod, with a crank on the end of a short horizontal shaft, which is caused to revolve by horse or other power. The shaft also carries a spur wheel, gearing into a pinion upon another horizontal shaft, that extends through the large case. Upon this second shaft (within the large case) are fixed two discs or bosses, to which four pairs of long radial arms are bolted; and to the outer ends of each pair of arms is fastened a wooden beater, of a L shape, in the transverse section. At the top of the large case two channels are made to receive the clamps, in which the stricks of flax to be scutched are held to receive the blows of the beaters. The flax is first laid upon the fluted table, and submitted to the action of the traversing roller until the boon is broken up and sufficiently loosened from the fibre; it is then removed, and secured in given quantities, between a pair of clamps, in such manner that one-half the length of the plant is pendent therefrom. Clamps or holders thus filled are successively passed into one of the channels in the large case, and as they are pushed forwards towards the other end of the machine, the stricks of flax are brought under the action of the rotating beater, whereby the pendent portion of the flax is cleared of its boon. When this is effected, the holders are removed from the channels and opened, to turn the end of the flax; the clamps are then again tightened and introduced into the other channel, to bring the other end, in like manner, under the action of the beaters. When the apparatus is in full operation, both channels will be full of holders; and the introduction of a fresh holder at one end is the means whereby a holder, containing a strick of scutched flax, is discharged at the opposite end. This machine, according to the statement of the inventor, is calculated, by the application of from three to four horse power, to clean half an acre of flax per diem.

Mr. Plummer, of Newcastle-upon-Tyne, has exhibited machinery, and of a new construction, for breaking and scutching flax, and for heckling what is technically known as "cut line." The breaker consists of a cast-iron framing, carrying five fluted rollers of similar diameters, and connected together by geering wheels, so that the driving of the axle of one by a band and pulley will cause the other to rotate at the same speed. This machine is provided with two platforms, the one for conducting the flax to the rollers, and the other for guiding it out of the machine. The rollers are so arranged as to bite the flax three times during its passage through the machine; and the top rollers are weighted, for insuring a proper amount of pressure being put upon the flax.

The scutching machine consists of a rotary vertical disc inclosed in a casing, and carried by an axle working in suitable bearing, supported by the frame of the machine. On each side of the disc radial beaters, or wooden knives, having a bevelled edge on their inner face, are fixed; but on one side of the disc the beaters are alternated by radial brushes, the object being to submit the flax, first to the action of the beaters only, and then to effect the more thorough separation of the boon from the fibre by the combined action of brushes and a second set of beaters. An opening is formed in the front of the case through which the flax is introduced by hand to the action of the beaters. When one end is cleaned, the operator turns ends, and again submits the flax to the scutching operation. By the use of a solid disc in place of radial arms (as hitherto used) for carrying the beaters, it would seem that greater speed than hitherto applied may be used without the risk of breaking the staple, as the objection presented by the arms, of causing the flax to lash round them, and thereby get broken when working at great speed, is necessarily avoided.

The next stage of treating flax is to subject it to the action of the heckling machine, whereby the flax is combed out, and its fibres are subdivided to the extent required; the short and entangled fibres being at the same time removed from the more valuable staple. The extent to which this separation is carried is to produce a yield of only from 50 to 80 lbs. of "dressed line," as the more valuable staple is termed, out of 112 lbs. of scutched flax, the remainder constituting the raw material known as tow, which in general goes to form an inferior description of yarn. If the flax is intended to be spun to a fine quality of yarn, or a "high number," it is cut into two, three, or more lengths, before being submitted to the heckling machine; the coarser parts of the staple, that is, the extremities, being separated from the others, to form a medium

quantity of yarn, while the middle portions are selected for conversion into fine yarn. The action of the heckling machine, as far as the operation itself is concerned, is the same whether the long or short staple be heckled; but, to effect the operation economically, that is, without making an undue amount of tow, different constructions of machines are preferred for dressing the long and the cut line. For heckling the latter kind of staple, Mr. Plummer exhibited a machine embracing some novel points deserving of notice. It is of that class of machines which have two heckle cylinders revolving in opposite directions, and dressing both sides of the strick of flax simultaneously, but which have hitherto met with very partial success, as the cost with which they work scarcely compensates for the waste of material they occasion, from the fact of two sets of heckles entering the strick simultaneously, and tearing through it without the power of yielding to the entangled or interlocked fibres. Now, in order to remedy this evil in part, one of the cylinders is mounted on sliding bearings; so that each strick of flax, on being first presented to the heckle-pins, will be partially combed by the cylinder, which is mounted in stationary bearings, before the traversing cylinder approaches to act upon the strick. These cylinders are furnished with three grades of heckle-pins, and the rows on the first, or coarsest set, are alternated by rows of brushes. The motion for traversing the holders, containing the stricks of flax through the machine, is somewhat novel and ingenious. Mounted near one end of the holder trough (which receives its up-and-down motion for bringing the length of stricks gradually under the operation of the heckle cylinders by the ordinary arrangements of mechanism) is a short axle, which carries three pinions, two of which take into vertical racks, attached to the end framing; and the central pinion geers into a rack formed on a horizontal reciprocating bar, carried by the trough, and provided with loose pendent fingers. As the trough ascends to take in a fresh holder, the pinions, working on the fixed vertical racks, are rotated, and thus the central pinion is made to draw forward its rack with the sliding rod; by which means the pendent fingers are brought in contact with the holders, and caused to propel them forward. On the descent of the trough, the reverse action takes place; and the reciprocating bar being slidden back, the fingers, which are hinged so as to pass back over the holders, are brought to a proper position for propelling them forward on the next ascent of the trough; this reciprocating bar is common to many heckling machines, but the mode of actuating it appears to us to be both new and simple. On the ascent of the trough to receive another holder, and discharge at the same time a holder of heckled flax, the traversing cylinder is caused to retire by a simple mechanical contrivance, and thus allow of the strick of flax just received into the machine, as well as those which, in consequence, have been shifted forward to a finer set of heckle pins, to be brought, first, under the action of the heckle cylinder, which works in stationary bearings, and then under the action of the pins of the traversing cylinder, as before explained; the ascent of the trough being made the means of driving back the cylinder, and its descent allowing of its moving forward to operate upon the flax. The heckle cylinders are cleaned as usual by rotating brushes; and an endless band of lattice-work is provided for gathering the tow into a proper receptacle. Whether or no this machine is destined to take a permanent place in our flax manufactories, a mere inspection of it in its quiescent state is not sufficient to enable us to judge: as regards compactness, it has greatly the advantage of the double cylinder machines of Messrs. Lawson & Sons, of Leeds, whose contribution we shall next notice; but we can give no opinion of their relative merits in other respects.

This firm has made by far the largest display of flax machinery; and, indeed, the credit is mainly due to them that the Great Exhibition has represented this important branch of our manufactures. Their contribution may be briefly stated to have included a complete set of machinery for heckling, spreading, drawing and roving long and cut flax; also for carding, drawing, and roving tow; for spinning coarse and fine flax yarn; and likewise for manufacturing thread. For treating short flax, a pair of cylinder heckling machines were exhibited. The cylinders, instead of being set abreast of each other, and acting simultaneously on the flax, are mounted in a line, and revolve in opposite directions, so that the flax is dressed, first on one side by one cylinder, and then on the opposite side by the other cylinder. The objection to this arrangement is, as before indicated, the want of compactness; as machines working on this principle are required to be double the length of those which turn the strick and heckle both sides on the same heckle-pins, or heckle it simultaneously on both sides. To remedy this objection, however, Messrs. Lawson apply two troughs to the machine, and are thus enabled to submit two rows of stricks to the action of the same rotating heckle cylinder. The mode of traversing the flax holders through the machine is analogous to that described in reference to Mr. Plummer's machine, and therefore need not to be repeated. The cylinders are furnished with two grades of heckle pins; and between each row, rising and falling plates (which take their motion from excentrics) are fitted for the purpose

of determining the depth that the heckle-pins shall enter the stricks. Between the rows of the finer grade of heckles, small flat brushes being set in one edge of the rising and falling plates form a sort of bed for the flax to lie on while under the action of the heckles. The stricks, in passing over one cylinder, are heckled on one side; they are then brought under the action of the second cylinder, which, revolving in an opposite direction, will finish the other side of the strick. The machine exhibited by this firm for operating upon long fibres is provided with two endless bands of heckles, set side by side, and arranged so as to present an inclined surface to the flax. These bands are set at opposite inclines, and revolve in different directions, for the purpose of operating upon different sides of the stricks of flax. These are the only arrangements of heckling and machinery which the Exhibition contained. It must, therefore, be considered as very deficient in this respect, as the rival inventions of Messrs. Marsden, of Manchester, and Messrs. Combe, of Belfast, for turning the stricks of flax, and causing them to be operated upon on both sides by the same cylinder (which have recently been the cause of so much litigation) are unrepresented. So also is a still more recent improvement of Messrs. Combe, for heckling both sides of the strick without turning, by the use of but one cylinder. In this machine (which we have had recently an opportunity of seeing in action at Belfast) the means of operating on both sides of the strick is obtained by merely reversing the direction of rotation of the cylinder, while the trough is ascending to take in a fresh holder. Another arrangement of a promising character, for passing once through the machine, has recently been devised by Messrs. Harding, Cocker, & Co., of Lille; but as this machine was not included in their contribution to the Exhibition, we conclude that it is not yet brought into the market. The flax, after leaving the heckling machine, is slightly combed by hand, and sorted into parcels, according to the quality of the staple; it is then packed away in a cool, dry, dark room, and by lying there for a few months its quality is said to improve. When the flax is taken from the "dressed line store," it is subjected to the action of the following machines, for the purpose of converting it into yarn, viz.; 1. The first drawing frame, or spreader, the use of which is to convert the flax, as delivered from the heckling machine, into a continuous sliver or band of filaments; 2. The second drawing frame, by which the sliver is attenuated; 3. The third drawing frame, whereby several slivers from the second drawing frame are united together and redrawn, to obtain a finer sliver, with greater regularity of fibre; 4. The roving frame, which further elongates the sliver, and converts it into a spongy cord or roving. 5. The throstle frame, which extends the spongy or loose roving, and spins it into yarn. The flax drawing frame is very different in construction to that formerly described as employed for drawing cotton, although the action is precisely analogous. Its construction and mode of operation may be thus briefly described: at the back of the machine is an endless travelling feed-cloth, on which the stricks of flax are laid, so as to overlap each other, and which carries the flax to what are termed the back holding rollers. In front of these rollers, and arranged parallel thereto, is a series of "gills" or straight bars furnished with heckle-pins, whose office is to receive the flax as it is delivered from between the holding-rollers, and carry it forward to the drawing-rollers. These gills are supported and traversed by their extremities, taken into the threads of two screw shafts, set at right angles to the holding rollers, which shafts, as they rotate, carry the gills forward. When they have arrived at the end of the shaft they severally fall, and are received by a pair of screw shafts below, having a quicker thread, which carry them back to the holding rollers, and a sweep, on the end of these shafts, lift the gills up again into geer with the upper screw shafts. Thus an endless chain, as it were, of gills is provided, which, having a somewhat greater speed than the holding rollers, combs the flax straight and delivers it with perfectly parallel fibres to the drawing rollers. By these the sliver is drawn to the requisite fineness, and then, passing between a pair of calendering rollers, it is delivered to a can. The cans of sliver, thus produced, are now set up behind the second drawing frame, to undergo the second operation. This frame, and also the third, are similar in construction to the first; the only difference being, that they are fed from cans instead of by a cloth; and as the progress of drawing out the sliver advances, the size of the working parts are required to be less, and the fineness of the gills to be increased. The operation of drawing is the same in all cases; but in the second and third frames, the sliver is doubled, to give it an evenness, or structural equality, as it is elongated.

Messrs. Lawson have exhibited screw gill spreaders (as the first drawing frame is termed) for both long and cut flax; also gill frames for completing the drawing of the long and short fibre, but further than being well made machines, they present no points for comment.

Messrs. Higgins & Sons have also exhibited a screw gill spreader and a second drawing frame for long lines. In the former of these machines the front top rollers are weighted by an arrangement of compound levers, which is said to have the advantage

of convenience over the ordinary plan; and in the latter, the roller and gills are driven at the middle instead of the side of the machine; thus relieving the rollers of a great portion of the strain to which they are ordinarily exposed, and permitting of the use of smaller rollers, which, for some descriptions of work, is considered of importance.

The sliver, as it is delivered into cans from the third drawing frame, is taken to the roving frame to be still further reduced and wrought into a loose thread; but as this operation is precisely similar, whether for long line, cut line, or tow, it may be well to explain briefly the means of bringing tow to a proper state for undergoing the first spinning process before speaking of the roving frame. The tow, which we have said is the short and irregular fibres combed out of the strick of flax by the heckling machine, is subjected to the action of a carding engine, somewhat similar in construction to that used for carding cotton. It consists principally of a large central cylinder, covered with wires, cards, and surrounded by card rollers termed "workers" and "strippers," revolving in contact therewith. The tow is carried into the machine by an endless travelling cloth, which delivers it to a pair of feed rollers, situate below the main cylinder, whereby it is transferred to the large cylinder. By this it is brought under the action of the workers, when combed or carded; and it is then stripped or "doffed" from the cylinder by card rollers, which in their return are relieved of the staple by doffer combs; these take it off in the form of a sliver, and it is eventually delivered from the machine by delivering rollers into cans. In order to prevent the liability of the sliver breaking by being pressed down into the cans, and also to avoid the necessity of using a separate machine for performing the first drawing operation, it has lately been the practice to apply one or more gill-drawing heads to the carding engine, according to the number of strippers employed and slivers produced, and to carry on the carding and the first drawing processes simultaneously. This arrangement, patented by Messrs. Fairbairn & Co., was applied to Messrs. Lawson & Son's carding engine. It is provided with three strippers, which are capable (by being set at different distances from the main cylinder) of taking off different lengths of staple from the card surface, and thereby sorting out or dividing the qualities of the tow. In this machine, however, there is but one gill-head; all the slivers, therefore, are united in the first drawing process, and form together a continuous sliver; the completion of the operation of drawing tow is precisely similar to that already described with reference to long and cut line.

To obtain a flax roving, it is usual, after drawing the sliver to the required amount, to put in its slight twist. Messrs. Higgins exhibited a roving frame with six heads and sixty spindles, for producing roving of this kind. This roving frame is, in fact, to describe it shortly, a drawing frame, with the addition of spindles; the gills and rollers being driven according to their improved plan, before noticed.

The roving frame for cut flax exhibited by Messrs. Lawson, is intended to produce a roving without twist, which, for obtaining fine qualities of yarn, is very desirable; the gummy matter in the flax is here taken advantage of to give the roving the necessary cohesive property. A correct notion of the construction of this roving frame may be best conveyed by tracing the progress of a sliver through the machine. The sliver passes from the can over a pulley through fixed guides over travelling gills, between a pair of drawing rollers, then into a trough containing hot water (for the purpose of dissolving the gummy matter in the flax), then over a heated cylinder which dries the staple, and finally it is wound on to a bobbin, which rests upon and turns in contact with a horizontal fluted roller. Rovings thus produced are capable, it is said, of being drawn to almost any degree of fineness, with little reference to the material; because one fibre can be glued to another; at any portion of its length a roving can be made. Messrs. Lawson also contributed machinery for wet and dry spinning, viz., a dry tow spinning frame, with 100 spindles; a fine spinning frame for spinning the roving through cold water; a double water frame, with 136 spindles; and a double twisting frame with 96 spindles. The only noticeable novelty in these machines (the construction of which will be understood from the description already given of cotton spinning machinery) is a new tape motion for driving the spindles. A spinning frame, by Messrs. Higgins, containing 144 spindles was also exhibited; but further than being a specimen of good design and workmanship, it calls for no special remark.

Retting of Flax.— Mr. Watt's system of flax retting may be briefly described as follows: — The flax straw is delivered at the works by the grower, in a dry state, with the seed on. The seed is separated by metal rollers, and afterwards cleaned by fanners. The straw is then placed in close chambers, with the exception of two doors, which serve the purpose of putting in and discharging the straw. The top, which is of cast iron, serves the double purpose of a top and condenser. The straw is then laid on a perforated false bottom of iron, and the doors being closed, and made tight by means of screws, steam is driven in by a pipe round the chambers, and between the bottoms; and, penetrating the mass, at first removes certain volatile oils contained in the plant, and afterwards is condensed on the bottom of the iron tank, and descends as a continuous shower of condensed water, saturating the straw. This water is a decoction of extractive matter, to which attach the fibrous and more porous portions. This liquor is run off from time to time, the more concentrated portions being used for feeding.

The process is shortened by using a pump, or such an arrangement as rapidly washes the mass, with the water allowed to accumulate. In about eight or twelve hours, varying with the nature of the straw, it is removed from the chambers, and, having been robbed of its extractive matter, it is then passed through the rollers for the purpose of removing the epidermis, or skin of the plant, and of discharging the greater part of the water contained in the saturated straw, and while in the wet and swollen state, splitting it up longitudinally. The straw then (being free of all products of decomposition) is easily dried, and in a few hours ready for scutching.

In the experimental trial, personally superintended, throughout all its details, by the Committee, a quantity of flax straw, of ordinary quality, was taken from the bulk of the stock at the works, weighing 13¾ cwts. with the seed on. After the removal of the seed, which, on being cleaned thoroughly from the chaff, measured 3¾ Imperial bush., the straw was reduced in weight to 10 cwt. 1 qr. 21 lbs. It was then placed in the vat, where it was subjected to the steaming process for about eleven hours. After steeping, wet-rolling, and drying, it weighed 7 cwt. 0 qrs. 11 lbs.; and, on being scutched, the yield was 187 lbs. of flax; and of scutching tow, 12 lbs. 6½ ozs. fine, and 35 lbs. 3 ozs. coarse. The yield of fibre, in the state of good flax, was, therefore, at the rate of 13½ lbs. from the cwt. of straw with seed on; 18 lbs. from the cwt. of straw without seed; 26¼ lbs. from the cwt. of steeped and dried straw.

The time occupied in actual labour, in the processes, from the seeding of the flax to the commencement of the scutching, was 13¼ hours, to which, if 11 hours be added for the time the flax was in the vat, 24 hours would be the time required up to this point. The scutching, by four stands, occupied six hours sixteen minutes. But, in this statement, the time required for drying is not included, as, owing to some derangement in the apparatus, no certain estimate could be made of the actual time required in that process. It would appear, however, that about thirty-six hours would include the time necessary, in a well-organized establishment, to convert flax straw into fibre for the spinner.

The cost of all these operations, in this experiment, leaving out the drying, for the reasons noted, appeared to be under 10*l.* per ton of clean fibre, for labour, exclusive of general expenses.

A portion of the fibre was sent to two spinning-mills to be hackled, and to have a value put upon it. The valuation of the samples varied from 56*l.* to 70*l.* per ton, according to the quality of the stricks of fibre sent, and the yield on the hackle was considered quite satisfactory.

On the results of this experiment, which was necessarily of a limited nature, the Committee think it best to offer no general remarks. They are sufficiently favourable to speak for themselves. It remains to be ascertained whether the qualities of flax fibre, prepared by this method, are such as to suit the spinner and manufacturer. They have been informed, by a spinner who has been trying some flax prepared by Mr. Watt's system, that the yarn made from it appears equal in all respects to what is ordinarily spun from good Irish flax, of the finer sorts. They believe that, before long, information will be given by several individuals who are about to carry out more extended trials on the spinning and manufacturing departments.

The Committee conceive that the most prominent and novel feature of this plan consists in the substitution of maceration, or softening, for fermentation. In the steeping of flax, both by cold and hot water, the fibre is freed from the substance termed gum, by the decomposition of the latter, while in Watt's system the maceration of the stems loosens the cuticle and gum, which are further separated mechanically in the crushing operation, and, after the drying of the straw, readily part with the wood, under the action of the scutch-mill.

Before concluding this statement, the Committee wish to call attention to a very curious feature in Mr. Watt's invention. The water from the vats, in place of being offensive and noxious, as is the case with ordinary steep water, contains a certain amount of nutritive matter. This arises from its being an infusion of the flax stems, in place of holding in suspension or solution the products of the decomposition of the gum, and other substances contained in the stems. The inventor is now employing this water, along with the chaff of the seed-bolls, for feeding pigs. It is of much interest, therefore, to note in how far this may be found practically to answer, as, between the seed, the chaff, and the water, by far the greatest portion of what the flax plant abstracts from the soil, would thus be returned in the shape of manure. However this may turn out, the avoidance of all nuisance in smell, and of the poisonous liquid which causes some damage among fish when let off into rivers, is a matter of some consequence.

Appended to this report is a note of the time occupied in the different processes during the experiment, and of the number of persons employed in each.

It is to be hoped that so promising a plan may, on more extended experience, be found fully to warrant the high anticipations formed from what is already known concerning it.

(Signed on behalf of the Committee),

RICHARD NIVEN, Chairman.

Belfast, 3d Nov. 1852.

APPENDIX.

Note of the time occupied, and of the number of persons employed in each of the processes witnessed by the Committee, on the experimental trial of Mr. Watt's system of preparing flax fibre: —

	No. of persons employed. Men.	Women and Boys.	Time occupied. Hours.	Minutes.
Seeding, ...	4	8	1	15
Placing in Vat, ...	3	4	0	15
Cleaning Seed, ...	1	0	3	0
Taking out of Vat, ...	2	3	0	30
Wet-rolling and putting in Drying-Room, ...	1	16	2	20
Rolling for Scutching, ...	0	11	1	8
Stricking for do., ...	0	7	4	47
Total,	11	49	13	15
Scutching, ...	4	0	6	16

Cultivation of Flax in Flanders. — There is a very fine long variety of flax which is cultivated in the neighbourhood of Courtray, in Flanders; it requires a very good soil to grow in, and the stem is so long and slender, that, if it were not supported, the least wind would break it and lay it flat, in which case, the quality of the flax would be much impaired and the quantity reduced. To prevent this, short stakes are driven into the ground in a straight line, at 8 or 10 feet from each other, and long slender rods are tied to them with oziers, about 1 foot or 18 inches from the ground, forming a slight railing to support the flax; a number of these are placed in the same manner at a short distance from each other in parallel lines all over the field, and the flax is thus prevented from being beat down. A better method, which is not commonly adopted, is to have stakes in regular rows, and thin ropes tied to them, instead of rods; by having these lengthwise and others across them at right angles, a kind of large net is spread over the whole field, and none of the flax can possibly be laid flat. By using cheap rope, or strong tar-twine from old cables, the expense is not very great, and much less room is taken up than by the rods. When the flax is pulled, the stakes are taken up, and removed to a dry place till they are wanted again.

The most common variety of flax is of a moderate length, with a stronger stem; if it is not sown very thick it will throw out branches at top and produce much seed; it is therefore a matter of calculation whether it will be most profitable to have finer flax with less seed, or an inferior quality with an abundance of seed.

There is a small variety which does not rise above a foot, grows fast, and ripens its seed sooner. When linseed is the principal object, this variety is preferred; but the flax is shorter, and also coarser.

Another variety of flax has a perennial root, and shoots out stems to a considerable height. It came originally from Siberia, and was much recommended at one time, but its cultivation did not spread. If it were sown in wide rows, and kept free from weeds by hoeing, it might, perhaps, be profitably cultivated for the seed; and if the flax is inferior in quality, it might still be of some value for coarse manufactures; it requires, however, to be renewed every three or four years and sown in fresh ground.

The soil best adapted to the growth of flax is a deep rich loam, in which there is much humus, or vegetable mould. It should be mellow and loose to a considerable depth, with a sound bottom, neither too dry nor too moist; either extreme infallibly destroys the flax; it is therefore not suited either to hot gravelly soils or cold wet clays, but any other soil may be so tilled and prepared as to produce good flax. It thrives well in the rich alluvial land of Zealand and the Polders, but it is also raised with great success in the light sands of Flanders, but much more careful tillage and manuring are required. The land on which flax is sown must be very free from weeds, the weeding of this crop being a very important part of the expense of cultivation. These circumstances suggest the best mode of preparing the land. A long fallow, such as is sometimes given to the land in Essex, including two winters and a summer, may be a good preparation on the heavier loams, which should be trenched, ploughed, and worked deep; the manure should be dung fully rotten, or a compost of earth and dung; it should be put on the land in autumn, and well incorporated before the seed is sown. If the land is sufficiently clean, a crop of potatoes well manured may be substituted with advantage for the fallow; but at least double the usual quantity of dung should be given to this crop, that enough may remain in the ground for the flax. Lime may be used if the soil contains a great portion of clay; but in the lighter loams there is some doubt of its advantage for flax. At all events it should not be used immediately before the flax is sown, but for some previous crop. Peat-ashes are excellent; they improve the soil and keep off insects, which are apt to injure the roots of the flax. For want of peat-ashes, those made by the burning of weeds and earth in a smothered fire are a good substitute. But the most effective manure is the sweepings of the streets in towns, mixed with the emptying of privies, and the cleaning out of the butchers' stalls and shambles. On light soils much manure is required; and where night-soil cannot be obtained in

sufficient quantities, rape-cakes, from which the oil has been expressed, dissolved in cow's urine, form the best manure. In many parts of Flanders, 500 rape-cakes are used for every acre of flax, besides the usual quantity of Dutch ashes and of liquid manure, which is the drainings of dunghills, and the urine of cattle collected in a cistern, and allowed to become putrid.

In southern climates flax is sown before winter, because too great heat would destroy it. It is then pulled before the heat of summer. In northern climates the frost, and especially the alternations of frost and thaw, in the early part of spring, would cause the flax to perish; it is, consequently, sown as early in spring as may be, so as to avoid the effect of hard frost. This is in March or April, in Great Britain and Ireland, and in Holland and Flanders. In no country is the ground better prepared for the growth of flax than in Flanders; and it may, therefore, be interesting to follow the whole process of Flemish cultivation for several crops, preparatory to that of flax, which is the most important produce in that country, and that which, when well managed, gives the greatest profit to the farmer. The best flax grows near Courtray. The soil is a good deep loam, rather light than heavy. It is not naturally so rich as the soil of the Polders in Flanders and Zealand, but the tillage and cultivation are far more perfect, and the produce, if not more abundant, is of a finer quality. Every preceding crop has a reference to the flax, and is so cultivated as to improve the texture of the soil, which is abundantly manured, in order to leave a considerable surplus in the ground. If the land has not been trenched all over with the spade, to the depth of 18 or 20 inches, it has been equally well stirred by the narrow open drains, which are dug out 12 or 15 inches deep every year, between the stitches, in which it is laid by the plough. These drains or water furrows are a foot wide, and from a foot to 18 inches deep. The earth taken out of them is spread evenly over the land after the corn is sown. When the ground is ploughed again, care is taken that the place of these water-furrows shall be shifted a foot on each side. Thus, in six years, the whole soil is deepened and thoroughly mixed with whatever manure has been put on. This produces the same effect as trenching, and even more perfectly. The whole of the land in which the best flax grows has been so treated for several generations, and may be looked upon as a species of compost 18 inches deep. Potatoes or colza are usually planted with a double portion of manure, after which wheat is sown, slightly manured; then rye with turnips sown the same year, after the rye. These are taken up in September or October, and stored for winter use. The land has been well weeded while the turnips were growing, and all the manure is decomposed and mixed with the soil. It is ploughed in stitches before winter, some manure having been previously spread over it if necessary; and it is left to the mellowing effects of frost and snow. As soon as the winter is over, and the snow is melted, the final preparation goes on. Deep ploughing and harrowing further divide and pulverize it; the surface is laid as level and smooth as possible; and if there is no fear of too much wet, which in this light loam soon disappears, the whole is laid flat and level as a bowling-green, or else divided into beds, with water-furrows between them. On this the liquid manure is poured out, and the Dutch ashes spread, if any are used, or the rape-cakes, as mentioned before. The harrows are drawn over the land, and it is left so a few days, that the manure may sink in. It is then again harrowed, and the linseed is sown broadcast by hand, very thick, and even about 1½ cwt. to the acre. A bush harrow or a hurdle is drawn over, merely to cover the seed, which would not vegetate were it buried half an inch deep. According to the state of the land, it is rolled or not, or the seed is trodden in by men, as is done with fine seeds in gardens. This is only in the lightest soils. Most commonly the traîneau is drawn over the land. This is a wooden frame with boards nailed closely over it, which is drawn flat over the ground, to level and gently press it. In a short time the plants of flax come up thick and evenly, and with them also some weeds. As soon as the flax is a few inches high, the weeds are carefully taken out by women and children, who do this work on their hands and knees, both to see the weeds better, and not to hurt the flax with their feet. They tie pieces of coarse flax round their knees, and creep on with their face to the wind if possible. This is done that the tender flax, which has been bent down by creeping over it, may be assisted by the wind in rising. This shows what minute circumstances are attended to by this industrious people. The weeding is repeated till the flax is too high to allow of it.

The seed which is used is generally obtained from Riga, it being found that the flax raised from home-grown seed is inferior after the first year. But many intelligent men maintain that if a piece of ground were sown thin with linseed, so that the flax could rise with a strong stem, and branch out, and if the seed were allowed to ripen, the Flemish seed would be as good as that from Riga; but it still remains to be proved whether it would be cheaper to raise it or to import it.

When the flax begins to get yellow at the bottom of the stem, it is time to pull it, if very fine flax is desired, such as is made into thread for lace or fine cambric; but then the seed will be of little or no value. It is therefore generally left standing until the capsules which contain the seed are fully grown, and the seed formed. Every flax-

grower judges for himself what is most profitable on the whole. The pulling then begins, which is done carefully by small handfuls at a time. These are laid upon the ground to dry, two and two obliquely across each other. Fine weather is essential to this part of the operation. Soon after this they are collected in the larger bundles, and placed with the root end to the ground, the bundles being slightly tied near the seed end; the other end is spread out that the air may not have access, and the rain may not damage the flax. When sufficiently dry they are tied more firmly in the middle, and stacked in long narrow stacks on the ground. These stacks are built as wide as the bundles are long, and about 8 or 9 feet high. The length depends on the crop: they are seldom made above 20 or 30 feet long. If the field is extensive, several of these stacks are formed at regular distances; they are carefully thatched at top, and the ends, which are quite perpendicular, are kept up by means of two strong poles driven perpendicularly into the ground. These stacks look from a distance like short mud walls, such as are seen in Devonshire. This is the method adopted by those who defer the steeping till another season. Some carry the flax as soon as it is dry under a shed, and take off the capsules with the seed by rippling, which is drawing the flax through an iron comb fixed in a block of wood; the capsules which are too large to pass between the teeth of the comb are thus broken off and fall into a basket or cloth below. Sometimes, if the capsules are brittle, the seed is beaten out by means of a flat wooden bat, like a small cricket bat. The bundles are held by the root end, and the other end is laid on a board and turned round with the left hand while the right with the bat breaks the capsules, and the linseed falls on a cloth below. The flax may then be immediately steeped: but the most experienced flax-steepers defer this operation till the next season. In this case it is put in barns, and the seed is beat out at leisure in winter. When flax is housed, care must be taken that it be thoroughly dry; and if the seed is left on, which is an advantage to it, mice must be guarded against, for they are very fond of linseed, and would soon take away a good share of the profits by their depredations.

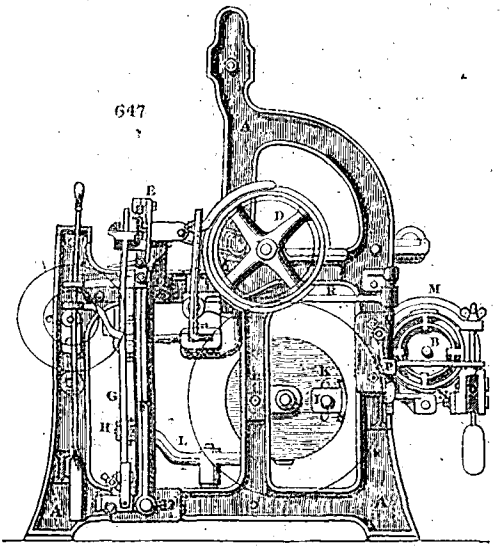
Steeping the flax is a very important process which requires experience and skill to do it properly. The quantity and colour depend much on the mode of steeping, and the strength of the fibre may be injured by an injurious mode of performing this operation. The object of steeping is to separate the bark from the woody part of the stem, by dissolving a glutinous matter which causes it to adhere, and also destroying some minute vessels which are interwoven with the longitudinal fibres, and keep them together in a kind of web. A certain fermentation or incipient putrefaction is excited by the steeping, which must be carefully watched and stopped at the right time. The usual mode of steeping is to place the bundles of flax horizontally in the shallow pool or ditches of stagnant water, keeping them under water by means of poles or boards with stones or weights laid upon them. Water nearly putrid was supposed the most efficacious; and the mud is often laid over the flax to accelerate the decomposition, but this has been found to stain the flax, so that it was very difficult to bleach it or the linen made from it afterwards. The method adopted by the steepers of Courtray, where steeping flax is a distinct trade, is different. The bundles of flax are placed alternately with the seed end of the one to the root end of the other, the latter projecting a few inches; as many of these are tied together near both ends as form a thick bundle about a foot in diameter. A frame made of oak-rails nailed to strong upright pieces in the form of a box 10 feet square and 4 deep, is filled with these bundles set upright and closely packed. The whole is then immersed in the river, boards loaded with stones being placed upon the flax till the whole is sunk a little under the surface of the water. The bottom does not reach the ground, so that the water flows over and under it. There are posts driven in the river, to keep the box in its place, and each steeper has a certain portion of the bank, which is a valuable property. The flax takes somewhat longer time in steeping in this manner than it does in stagnant or putrid water, and it is asserted by those who adhere to the old method that the flax loses more weight; but the colour is so much finer, that flax is sent to be steeped in the Lys from every part of Flanders. When it is supposed that the flax is nearly steeped sufficiently, which depends on the temperature of the air, the flax being sooner steeped in warm weather than in cold, it is examined carefully every day, and towards the latter part of the time several times in the day, in order to ascertain whether the fibres really separate from the wood the whole length of the stem. As soon as this is the case the flax is taken out of the water: even a few hours more or less than is necessary will make a difference in the value of the flax. If it is not steeped enough, it will not be easily scutched, and the wood will adhere to it. If it has been too long in the water, its strength is diminished and more of it breaks into tow. The bundles are now untied, and the flax is spread evenly in rows slightly overlapping each other on a piece of clean smooth grass which has been mown or fed off close. Fine weather is essential to this part of the process, as rain would now much injure the flax. It is occasionally turned over, which is done dexterously by pushing a long slender rod under the rows, and taking up the flax near the end which overlaps the next row and turning it quite over. Thus, when it is all turned, it overlaps as before, but in the contrary direction. It remains spread out upon the grass for a fortnight, more or less according to the season, till the woody part becomes brittle, and some of the finest fibres

separate from it of their own accord. It is then taken up, and as soon as it is quite dry it is tied up again in bundles, and carried into a barn to be broken and heckled at leisure during the winter.

The total annual production of flax in Belgium amounts, by a recent estimation, to about forty millions of pounds. Its total value is calculated at about two millions and a half sterling. This flax is of very superior quality, and is principally employed in the manufacture of the finest class of fabrics. Attempts are being now made on a large scale to cultivate this important plant in England and Ireland. Belgium exports about five millions of pounds of flax to England. That flax grown in the Courtray district is universally considered to be of the finest quality.

Flax Weaving Loom.—A A A, *Fig.* 648., frame of loom; B, beam on which the yarn for warp is wound; C cloth receiving beam; D driving pulleys and fly-wheel; E hand

647



rail for supporting the reed; F swords of supports of going part; G picking sticks for driving the shuttle; H leather straps for connecting the picking sticks with their actuating levers L; M, N, jaws of a clamp to cause the retaining friction on the collars of the beam B, by which friction the quantity of weft is regulated; O end of lever, bearing the weight by which the jaws are brought together; P, lever, keyed at one end to the upright shaft Q, and connected with the other to the fulcrum of the weighted lever O; R lever, one end of which is also keyed to the upright shaft Q, and the other is provided with a wood sole, and is pressed by a strong spring against the yarn wound upon the beam B. It will be seen that, as the yarn is taken off the beam B, and its diameter consequently reduced, the lever R moves the fulcrum of the weighted lever O, and thus regulates the pressure upon the clamps M and N, causing an equal tension upon the yarn from the full to the empty beam; *a* treddles, actuated by the cams *b*, driven by the wheels *c*, *d*, *e*, from the picking shaft *f*; *g*, *g* shuttle boxes at each end of the going part; *h*, *h*, arrangement of levers to conduct equally each end of the geers *i*, *i*. This loom has also, in addition to the ordinary stopping arrangement connected with the shuttle, one also for relaxing the reed in case the shuttle should be arrested in its course across the warp, whereby the danger, ordinarily incurred by that accident, of breaking many threads in the warp, is avoided; it will also be seen that the bands called picking bands are superseded by the ends of the picking levers striking the shuttle direct; thus, by these improvements, drills are currently woven in this loom at the rate of 120 to 130 picks per minute.

FLINT. (*Pierre à fusil*, Fr.; *Feuerstein*, Germ.) The fracture of this fossil is perfectly conchoidal, sometimes glossy, and sometimes dull on the surface. It is very hard, but breaks easily, and affords very sharp-edged splintery fragments; whence it is a stone which strikes most copious sparks with steel. It is feebly translucid, has so fine and homogeneous a texture as to bear polishing, but possesses little lustre. Its colours are very various, but never vivid. The blackish-brown flint is that usually found in the white chalk. It is nearly black and opaque, loses its colour in the fire, and becomes grayish-white, and perfectly opaque. Flints occur almost always in nodules or tubercular concretions of various and very irregular forms. These nodules, distributed in strata among the chalk, alongside of one another and almost in contact, form extensive beds; interrupted, indeed, by a multitude of void spaces, so as to present, if freed from the earthy matter in which they are imbedded, a species of network with meshes, very irregular both in form and dimension.

The nodules of silex, especially those found in the chalk, are not always homogeneous and solid. Sometimes there is remarked an organic form towards their centre, as a madrepore or a shell, which seems to have served as their nucleus; occasionally the centre is hollow, and its sides are studded over with crystals of quartz, carbonate of iron, pyrites, concretionary silex or calcedony, filled with pulverulent silica nearly pure, or silex mixed with sulphur; a very singular circumstance.

Flints are observed to be generally humid when broken immediately after being dug out of the ground; a property which disappears after a short exposure to the air. When dried they become more brittle and more splintery, and sometimes their surfaces get covered at old fractures with a thin film or crust of opaque silex.

Flints calcined and ground to a powder enter into the composition of all sorts of fine pottery ware.

The next important application of this siliceous substance is in the formation of gun-flints, for which purpose it must be cut in a peculiar manner. The following characters distinguish good flint nodules from such as are less fit for being manufactured. The best are somewhat convex, approaching to globular; those which are very irregular, knobbed, branched and tuberose, are generally full of imperfection. Good nodules seldom weigh more than 20 pounds; when less than 2, they are not worth the working. They should have a greasy lustre, and be particularly smooth and fine grained. The colour may vary from honey-yellow to blackish-brown, but it should be uniform throughout the lump, and the translucency should be so great as to render letters legible through a slice about one-fiftieth of an inch thick, laid down upon the paper. The

fracture should be perfectly smooth, uniform, and slightly conchoidal; the last property being essential to the cutting out of perfect gun-flints.

Four tools are employed by the gun-flint makers.

First, a hammer or mace of iron with a square head, from 1 to 2 pounds weight, with a handle 7 or 8 inches long. The tool is not made of steel, because so hard a metal would render the strokes too harsh, or dry, as the workmen say, and would shatter the nodules irregularly, instead of cutting them with a clean conchoidal fracture.

Second, a hammer with 2 points, made of good steel well hardened, and weighing from 10 to 16 ounces, with a handle 7 inches long passing through it in such a way that the points of the hammer are nearer the hand of the workman than the centre of gravity of the mass.

Third, the disc hammer or roller, a small solid wheel or flat segment of a cylinder, parallel to its base, only two inches and a third in diameter, and not more than 12 ounces in weight. It is formed of steel not hardened, and is fixed upon a handle 6 inches long, which passes through a square hole in its centre.

Fourth, a chisel tapering and bevelled at both extremities, 7 or 8 inches long, and 2 inches broad, made of steel not hardened; this is set on a block of wood, which serves also for a bench to the workmen. To these 4 tools a file must be added, for the purpose of restoring the edge of the chisel from time to time.

After selecting a good mass of flint, the workman executes the four following operations on it.

1. *He breaks the block.* Being seated upon the ground, he places the nodule of flint on his left thigh, and applies slight strokes with the square hammer to divide it into smaller pieces of about a pound and a half each, with broad surfaces and almost even fractures. The blows should be moderate, lest the lump crack and split in the wrong direction.

2. *He cleaves or chips the flint.* The principal point is to split the flint well, or to chip off scales of the length, thickness, and shape adapted for the subsequent formation of gun flints. Here the greatest dexterity and steadiness of manipulation are necessary; but the fracture of the flint is not restricted to any particular direction, for it may be chipped in all parts with equal facility.

The workman holds the lump of flint in his left hand, and strikes with the pointed hammer upon the edges of the great planes produced by the first breaking, whereby the white coating of the flint is removed in small scales, and the interior body of the flint is laid bare; after which he continues to detach similar scaly portions from the clean mass.

These scaly portions are nearly an inch and a half broad, two inches and a half long, and about one-sixth of an inch thick in the middle. They are slightly convex below, and consequently leave in the part of the lump from which they were separated a space slightly concave, longitudinally bordered by two somewhat projecting straight lines or ridges. The ridges produced by the separation of the first scales must naturally constitute nearly the middle of the subsequent pieces; and such scales alone as have their ridges thus placed in the middle are fit to be made into gun-flints. In this manner the workman continues to split or chip the mass of flint in various directions, until the defects usually found in the interior render it impossible to make the requisite fractures, or until the piece is too much reduced to sustain the smart blows by which the flint is divided.

3. *He fashions the gun-flints.* Five different parts may be distinguished in a gun-flint. 1. The sloping facet or bevel part, which is impelled against the hammer of the lock. Its thickness should be from two to three twelfths of an inch; for if it were thicker it would be too liable to break; and if more obtuse, the scintillations would be less vivid. 2. The sides, or lateral edges, which are always somewhat irregular. 3. The back or thick part opposite the tapering edge. 4. The under surface, which is smooth and rather concave. And, 5. The upper face, which has a small square plane between the tapering edge and the back, for entering into the upper claw of the cock.

In order to fashion the flint, those scales are selected which have at least one of the above-mentioned longitudinal ridges; the workman fixes on one of the two tapering borders to form the striking edge, after which the two sides of the stone that are to form the lateral edges, as well as the part that is to form the back, are successively placed on the edge of the chisel in such a manner that the convex surface of the flint, which rests on the forefinger of the left hand, is turned towards that tool. Then with the disc hammer he applies some slight strokes to the flint just opposite the edge of the chisel underneath, and thereby breaks it exactly along the edge of the chisel.

4. The finishing operation is the *trimming*, or the process of giving the flint a smooth and equal edge; this is done by turning up the stone and placing the edge of its tapering end upon the chisel, in which position it is completed by five or six slight strokes of the disc hammer. The whole operation of making a gun-flint, which I have used so many words to describe, is performed in less than one minute. A good workman is able to manufacture 1,000 good chips or scales in a day (if the flint-balls be of good quality),

or 500 gun-flints. Hence, in the space of three days, he can easily cleave and finish 1,000 gun-flints without any assistance.

A great quantity of refuse matter is left, for scarcely more than half the scales are good, and nearly half the mass in the best flints is incapable of being chipped out; so that it seldom happens that the largest nodules furnish more than 50 gun-flints.

Flints form excellent building materials; because they give a firm hold to the mortar by their irregularly rough surfaces, and resist, by their nature, every vicissitude of weather. The counties of Kent, Essex, Suffolk, and Norfolk contain many substantial specimens of flint-masonry.

FLOOKAN. The name given by the Cornish miners to a vein of clay-stone, often nearly vertical.

FLOOR CLOTH MANUFACTURE has become of late years a very large branch of trade. The cloth is a strong somewhat open canvas, woven of flax with a little hemp, and from 6 to 8 yards wide, being manufactured in appropriate looms, chiefly at Dundee. A piece of this canvas, from 60 to 100 feet in length, is secured tight in an upright open frame of oaken bars, in which position it receives the foundation coats of paint, 2 or 3 in number, first on the back side, and then on the front; but it is previously brushed over with glue-size, and rubbed smooth with pumice stones. The foundation paint made with linseed oil and ochre, or any cheap colouring matter, is too thick to be applied by the brush, and is therefore spread evenly by a long narrow trowel, held in the right hand, from a patch of it laid on just before with a brush in the left hand of the workman. Each foundation coat of the front surface is smoothed by pumice whenever it is hard enough to bear the operation. When both sides are dry, the painted cloth is detached from the frame, coiled round a roller, in this state transferred to the proper printing room, where it is spread flat on a table, and variously figured and coloured devices are given to it by wooden blocks, exactly as in the block printing of calicoes, and in the wood printing of books. The blocks of the floor cloth manufacture are formed of two layers of white deal and one of pear tree timber, placed with their grain crossing one another alternately. There is of course a block for each colour in the pattern, and in each block those parts are cut away that correspond to the impressions given by the others; a practice now well understood in the printing of two or more colours by the press. The faces of the blocks are so indented with fine lines, that they do not take up the paint in a heavy daub from the flat cushion on which it is spread with a brush, but in minute dots, so as to lay on the paint (somewhat thicker than that of the house painter) in a congeries of little dots or teeth, with minute interstices between. Applied in this way, the various pigments lie more evenly, are more sightly, and dry much sooner than if the prominent part of the block which takes up the colour were a smooth surface. The best kinds of floor cloth require from two to three months for their production.

FLOSS, of the puddling furnace, is the fluid glass floating upon the iron produced by the vitrification of the oxides and earths which are present.

FLOSS-SILK (*Filoselle, Bourre de soie,* or *fleuret,* Fr.), is the name given to the portions of ravelled silk broken off in the filature of the cocoons, which is carded like cotton or wool, and spun into a soft coarse yarn or thread, for making bands, shawls, socks, and other common silk fabrics. The floss or fleuret, as first obtained, must be steeped in water, and then subjected to pressure, in order to extract the gummy matter, which renders it too harsh and short for the spinning wheel. After being dried it is made still more pliant by working a little oil into it with the hands. It is now ready to be submitted to the carding engine. (See COTTON MANUFACTURE.) It is spun upon the flax wheel.

The female peasants of Lombardy generally wear clothes of homespun floss silk. Of late years, by improved processes, pretty fine fabrics of this material have been produced, both in England and France. M. Ajac, of Lyons, presented at one of the French national exhibitions of the objects of industry, a great variety of scarfs and square shawls, of *bourre de soie,* closely resembling those of *cachemire.*

FLOUR; the finely ground meal of wheat, and of any other corns or *cerealia.* See BREAD.

FLOUR OF WHEAT, *Adulterations of, to detect.*—The first method is by specific gravity. If potato flour be added, which is frequently done in France, since a vessel which contains one pound of wheat flour will contain one pound and a half of the fecula, the proportion of this adulteration may be easily estimated. If gypsum or ground bones be mixed with the flour, they will not only increase its density still more; but they will remain after burning away the meal.

The second method is by ascertaining the quantity of gluten which the suspected sample will afford, by the process prescribed under the article BREAD. The two following chemical criteria may also be employed.

1st. Nitric acid has the property of colouring wheat flour of a fine orange yellow, whereas it affects the colour neither of fecula nor starch.

2nd. Pure muriatic acid colours good wheat flour of a deep violet, but dissolves fecula or starch, and forms with it a light, colourless, viscous fluid, decomposable by alkalis. It may also be observed, that as fecula absorbs less water than flour, this affords a ready means of detection.

The adulteration with bean or pea flour may be detected by pouring boiling water upon it, which developes the peculiar smell of these two substances.

FLOWERS (*Fleurs*, Fr.; *Blumen*, Germ.) of benzoin, of sulphur, of zinc, &c., is the appellation given by the older chemists to such substances as were obtained in a pulverulent or rather minutely crystalline form by the process of sublimation.

FLOWERS, ARTIFICIAL, MANUFACTURE OF. The art of representing by flowers, leaves, plants, &c., vegetable nature in her ornamental productions, constitutes the business of the artificial florist. The Italians appear to have been the first people in Europe who excelled in the art of making artificial flowers; but of late years the French have been most ingenious in this branch of industry.

Ribbons folded in different forms and of different colours were originally employed for imitating flowers, by being attached to wire stems. This imitation soon gave way to that by feathers, which are more delicate in texture, and more capable of assuming a variety of flower-like figures. But a great difficulty was encountered in dyeing them with due vivacity. The savages of South America manufacture perfect feather flowers, derived from the brilliant plumage of their birds, which closely resemble the products of vegetation. The blossoms and leaves are admirable, while the colours never fade.

The Italians employ frequently the coccoons of the silk-worm for this purpose; these take a brilliant dye, preserve their colour, and possess a transparent velvety appearance, suitable for petals. Of late years, the French have adopted the finest cambric for making petals, and the taffeta of Florence for the leaves. M. de Bernardiere employs whalebone in very thin leaves for artificial flowers; and by bleaching and dyeing them of various hues, he has succeeded in making his imitations of nature to be very remarkable.

The colouring matters used in flower dyeing are the following:—

For red; carmine dissolved in a solution of carbonate of potash.

For blue; indigo dissolved in sulphuric acid, diluted and neutralised in part by Spanish whitening.

For bright yellow; a solution of turmeric in spirit of wine. Cream of tartar brightens all these colours.

For violet; archil, and a blue bath.

For lilac; archil.

Some petals are made of velvet, and are coloured merely by the application of the finger dipped in the dye.

FLUATES, more properly *fluorides* (Eng. and Fr.; *Flussäure*, Germ.); compounds of fluorine and the metals; as fluor spar, for example, which consists of fluorine and calcium.

FLUOR SPAR. (*Chaux fluatée*, Fr.; *Spath fluor*, Germ.) This mineral often exhibits a variety of vivid colours. It crystallizes in the cubic system; with regular octahedral and tetrahedral cleavages; spec. grav. 3·1 to 3·2; scratches calc spar, but is scratched by a steel point; usually phosphorescent with heat; fusible at the blowpipe into an opaque bead; acted on by the acids, with disengagement of a vapour which corrodes glass; its solution affords precipitates with the oxalates, but not with ammonia. Its constituents are, fluorine, 48·13; calcium, 51·87 in 100.

Fluor spar occurs subordinate to metallic veins; as to those of lead, in Derbyshire; of tin, in Saxony and Bohemia; but it is found also in masses or veins, either in crystalline rocks, associated with quartz, heavy spar, &c., as in Auvergne, Forez, Vosges, Norberg in Sweden; Norway; Petersburg; near Hall; Gourock, in Scotland, &c.; or among secondary limestones, slates, and sandstones, in Derbyshire, Cumberland, Cornwall, and New Jersey. It exists also in the amygdaloids of Scotland, and in the volcanic products of Monte Somma at Vesuvius. The variously coloured specimens, called Derbyshire spar, are worked upon the turning lathe into vases and other ornamental objects.

FLUX, (Eng. and Fr.; *Fluss*, Germ.) signifies any substance capable of promoting the fusion of earths or metallic ores by heat. White flux is the residuum of the deflagration in a red hot crucible, of a mixture of two parts of nitre, and one of cream of tartar. It is in fact merely a carbonate of potash. Black flux is obtained when equal parts of nitre and tartar are deflagrated. It owes its colour to the carbonaceous matter of the tartaric acid, which remains unconsumed; the quantity of nitre being too small for that purpose. The presence of the charcoal renders this preparation a convenient flux for reducing calcined or oxidized ores to the metallic state. Limestone, fluor-spar, borax, and several earthy or metallic oxides are employed as fluxes in metallurgy.

FLY POWDER; the black coloured powder obtained by the spontaneous oxidize ment of metallic arsenic in the air.

FODDER; is the name of a weight by which lead and some other metals are sold in this country. It varies in its amount in different parts of the kingdom; being in Northumberland estimated at 21 cwts., and in other counties 22, 23 or even more cwts.

FONDUS; is the name given by the French to a particular style of calico printing resembling the rainbow, in which the colours are graduated or melted (*fondus*) into one another, as in the prismatic spectrum. See PAPER HANGING, for a description of the process.

FORGE; (Eng. and Fr.; *Feuer*, Germ.) is the name either of the furnace, where wrought iron is hammered and fashioned with the aid of heat, or the great workshop where iron is made malleable. The former is called a smith's forge, the latter a shingling mill. See IRON.

649

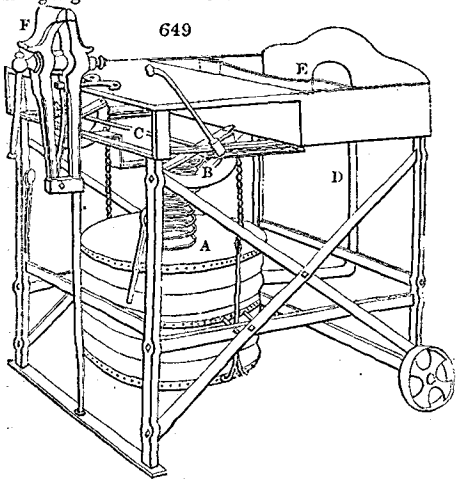

Fig. 649. represents a portable truck forge of a very commodious construction. A is the cylindric leather bellows, pressed down by a helical spring, and worked by means of the handle at B, which moves the horizontal shaft C, with its two attached semicircular levers and chains. D, is the pipe which conducts the blast to the nozzle at E. The hearth may be covered with a thin fire-tile or with cinders. F is a vice fixed to the strong rectangular frame. This apparatus answers all the ordinary purposes of a smith's forge; and is peculiarly adapted to ships, and to the execution of engineering jobs upon railways, or in the country. The height is 2 feet 6 inches; the length is 2 feet 9 inches; the width 2 feet. Weight about 2 cwt.

FORGERY, PREVENTION. — Forgeries of Bank cheques and other cash documents are proposed to be prevented under the patent recently granted to Messrs. Henry Glynn and Rudolph Appel. They prepare paper by mixing its pulp with solution of nitrate or sulphate of copper, to which mixture alkaline saline matter is added, to produce a cupreous precipitate (phosphate of soda being preferred), so that reddened litmus paper will be rendered blue by it. One ounce of nitrate of copper is sufficient for two gallons of the pulp, or even more if the cupreous colour is objectionable. The pulp is to be then washed with water. A mixture of equal parts of white soft soap and old palm oil is to be dissolved in boiling water, using half a pound of soap to one gallon of water. Into this saponaceous solution, the paper impregnated with the said pulp is to be dipped, and then sized. They also prevent a transfer being taken with paper, by washing it with solution of sulphate of copper, drying it, and dipping it in phosphate of soda strong enough to convert the sulphate into a phosphate.

FORMIATES; are compounds of formic acid, with the salifiable bases. Many of them are susceptible of crystallization.

FORMIC ACID; (*Acide Formique*, Fr.; *Ameisansaure*, Germ.) exists in the bodies of wood ants, associated with the malic or acid of apples. The artificial formation of this animal secretion, is one of the most remarkable triumphs of modern chemistry. If 10 parts of tartaric acid, 14 of black oxide of manganese, 15 of concentrated sulphuric acid, and from 20 to 30 of water be mixed and distilled in a retort, formic acid will be the liquid product; while carbonic acid will be disengaged. It may also be generated from other mixtures. This acid is transparent and colourless, of a pungent sour smell, a strongly acid taste, of specific gravity 1·1168 at 60° F., and may be re-distilled without suffering any change. It contains in its most concentrated form 19¾ per cent. of water. The dry acid, as it exists in the *formiates*, is composed of 32·54 carbon, 2·68 hydrogen, and 64·78 oxygen: or of two volumes carbonic oxide gas, and one volume of vapour of water. It reduces the oxides of mercury and silver to the metallic state. It has not hitherto been applied to any use in the arts.

FORMULÆ, CHEMICAL, are symbols representing the different substances, simple and compound.

FOUNDING *of metals, chiefly of Iron.* The operations of an iron foundry consist in re-melting the pig-iron of the blast furnaces, and giving it an endless variety of forms, by casting it in moulds of different kinds, prepared in appropriate manners. Coke is the only kind of fuel employed to effect the fusion of the cast iron.

The essential parts of a well-mounted iron foundry, are,

1. Magazines for pig irons of different qualities, which are to be mixed in certain proportions, for producing castings of peculiar qualities; as also for coal, coke, sands, clay, powdered charcoal, and cow-hair for giving tenacity to the loam mouldings.

2. One or more coke ovens.

3. A workshop for preparing the patterns and materials of the moulds. It should contain small edge millstones for grinding and mixing the loam, and another mill for grinding coal and charcoal.

4. A vast area, called properly the foundry, in which the moulds are made and filled with the melted metal. These moulds are in general very heavy, consisting of two parts at least, which must be separated, turned upside down several times, and replaced very exactly upon one another. The casting is generally effected by means of large ladles or pots, in which the melted iron is transported from the cupola, where it is fused. Hence the foundry ought to be provided with cranes, having jibs movable in every direction.

5. A stove in which such moulds may be readily introduced, as require to be entirely deprived of humidity, and where a strong heat may be uniformly maintained.

6. Both blast and air furnaces, capable of melting speedily the quantity of cast-iron to be employed each day.

7. A blowing machine to urge the fusion in the furnaces.

Fig. 467. represents the general plan of a well-mounted foundry.

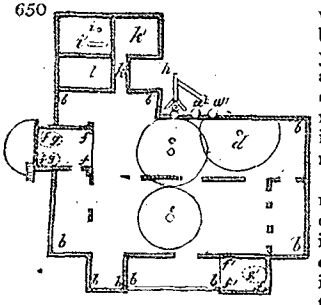
a, is a cupola furnace of which the section and view will be afterwards given; it is capable of containing 5 tons of cast-iron.

à, is a similar furnace, but of smaller dimensions, for bringing down 1¾ tons.

a'', is a furnace like the first, in reserve for great castings.

b, b, b, b, a vast foundry apartment, whose floor to a yard in depth, is formed of sand and charcoal powder, which have already been used for castings, and are ready for heaping up into a substratum, or to be scooped out when depth is wanted for the moulds. There are besides several cylindrical pits, from five to seven yards in depth, placed near the furnaces. They are lined with brick work, and are usually left full of moulding sand. They are emptied in order to receive large moulds, care being had that their top is always below the orifice from which the melted metal is tapped.

650



These moulds, and the ladles full of melted metal are lifted and transported by the arm of one or more men, when their weight is moderate; but if it be considerable, they are moved about by cranes whose vertical shafts are placed at *c, d, e*, in correspondence, so that they may upon occasion transfer the load from one to another. Each crane is composed principally of an upright shaft, embraced at top by a collet, and turning below upon a pivot in a step; next of a horizontal beam, stretched out from nearly the top of the former, with an oblique stay running downwards, like that of a gallows. The horizontal beam supports a movable carriage, to which the tackle is suspended for raising the weights. This carriage is made to glide backwards or forwards along the beam by means of a simple rack and pinion mechanism, whose long handle descends within reach of the workman's hand.

By these arrangements in the play of the three cranes, masses weighing five tons may be transported and laid down with the greatest precision upon any point whatever in the interior of the three circles traced upon *fig.* 650. with the points *c, d, e*, as centres.

c, d, e, are the steps, upon which the upright shafts of the three cranes rest and turn. Each shaft is 16 feet high.

f, f, is the drying stove, having its floor upon a level with that of the foundry.

f', f', is a supplementary stove for small articles.

g, g, g, are the coaking ovens.

h, is the blowing machine or fan.

i, is the steam-engine, for driving the fan, the loam-edge stones,

k, and the charcoal mill.

i'', are the boiler and the furnace of the engine.

k', workshop for preparing the loam and other materials of moulding.

l, is the apartment for the patterns.

The pig-iron, coals, &c. are placed either under sheds or in the open air, round the above buildings; where are also a smith's forge, a carpenter's shop, and an apartment mounted with vices for chipping and rough cleaning the castings by chisels and files.

Such a foundry may be erected upon a square surface of about 80 yards in each side, and will be capable, by casting in the afternoon and evening of each day, partly in large and partly in small pieces, of turning out from 700 to 800 tons per annum, with an establishment of 100 operatives, including some moulding boys.

Of making the Moulds. — 1. Each mould ought to present the exact form of its object.

2. It should have such solidity that the melted metal may be poured into it, and fill it entirely without altering its shape in any point.

3. The air which occupies the vacant spaces in it, as well as the carburetted gases generated by the heat, must have a ready vent; for if they are but partially confined, they expand by the heat, and may crack, even blow up the moulds, or at any rate become dispersed through the metal, making it vesicular and unsound.

There are three distinct methods of making the moulds: —

1. In green sand; 2. In baked sand; 3. In loam.

To enumerate the different means employed to make every sort of mould exceeds the limits prescribed to this work. I shall merely indicate for each species of moulding, what is common to all the operations; and I shall then describe the fabrication of a few such moulds as appear most proper to give general views of this peculiar art.

Moulding in green sand. — The name green is given to a mixture of the sand as it comes from its native bed, with about one twelfth its bulk of coal reduced to powder, and damped in such a manner as to form a porous compound, capable of preserving the forms of the objects impressed upon it. This sand ought to be slightly argillaceous, with particles not exceeding a pin's head in size. When this mixture has once served for a mould, and been filled with metal, it cannot be employed again except for the coarsest castings, and is generally used for filling up the bottoms of fresh moulds.

For moulding any piece in green sand, an exact pattern of the object must be pre-

pared in wood or metal; the latter being preferable, as not liable to warping, swelling, or shrinkage.

A couple of iron frames form a case or box, which serves as an envelope to the mould. Such boxes constitute an essential and very expensive part of the furniture of a foundry. It is a rectangular frame, without bottom or lid, whose two largest sides are united by a series of cross bars, parallel to each other, and placed from 6 to 8 inches apart.

The two halves of the box carry ears corresponding exactly with one another; of which one set is pierced with holes, but the other has points which enter truly into these holes, and may be made fast in them by cross pins or wedges, so that the pair becomes one solid body. Within this frame there is abundance of room for containing the pattern of the piece to be moulded with its encasing sand, which being rammed into the frame, is retained by friction against the lateral faces and cross bars of the mould.

When a mould is to be formed, a box of suitable dimensions is taken asunder, and each half, No. 1. and No. 2., is laid upon the floor of the foundry. Green sand is thrown with a shovel into No. 1. so as to fill it; when it is gently pressed in with a rammer. The object of this operation is to form a plane surface upon which to lay in the pattern with a slight degree of pressure, varying with its shape. No. 1. being covered with sand, the frame No. 2. is laid upon it, so as to form the box., No. 2. being now filled carefully with the green sand, the box is inverted, so as to place No. 1. uppermost, which is then detached and lifted off in a truly vertical position; carrying with it the body of sand formed at the commencement of the operation. The pattern remains imbedded in the sand of No. 2., which has been exactly moulded upon a great portion of its surface. The moulder condenses the sand in the parts nearest to the pattern, by sprinkling a little water upon it, and trimming the ill-shaped parts with small iron trowels of different kinds. He then dusts a little well-dried finely-sifted sand over all the visible surface of the pattern, and of the sand surrounding it; this is done to prevent adhesion when he replaces the frame No. 1.

He next destroys the preparatory smooth bed or area formed in this frame, covers the pattern with green sand, replaces the frame 1. upon 2. to reproduce the box, and proceeds to fill and ram No. 1., as he had previously done No. 2. The object of this operation is to obtain very exactly a concavity in the frame No. 1., having the shape of the part of the model impressed coarsely upon the surface formed at the beginning, and which was meant merely to support the pattern and the sand sprinkled over it, till it got imbedded in No. 2.

The two frames in their last position, along with their sand, may be compared to a box of which No. 1. is the lid, and whose interior is adjusted exactly upon the enclosed pattern.

If we open this box, and after taking out the pattern, close its two halves again, then pour in melted metal till it fill every void space, and become solid, we shall obviously attain the wished-for end, and produce a piece of cast iron similar to the pattern. But many precautions must still be taken before we can hit this point. We must first lead through the mass of sand in the frame No. 1., one or more channels for the introduction of the melted metal; and though one may suffice for this purpose, another must be made for letting the air escape. The metal is run in by several orifices at once, when the piece has considerable surface, but little thickness, so that it may reach the remotest points sufficiently hot and liquid

The parts of the mould near the pattern must likewise be pierced with small holes, by means of wires traversing the whole body of the sand, in order to render the mould more porous, and to facilitate the escape of the air and the gases. Then, before lifting off the frame No. 1., we must tap the pattern slightly, otherwise the sand enclosing it would stick to it in several points, and the operation would not succeed. These gentle jolts are given by means of one or more pieces of iron wire which have been screwed vertically into the pattern before finally ramming the sand into the frame No. 1., or which enter merely into holes in the pattern. These pieces are sufficiently long to pass out through the sand when the box is filled; and it is upon their upper ends that the horizontal blows of the hammer are given; their force being regulated by the weight and magnitude of the pattern. These rods are then removed by drawing them straight out; after which the frame No. 1. may be lifted off smoothly from the pattern.

The pattern itself is taken out, by lifting it in all its parts at once, by means of screw pins adjusted at the moment. This manœuvre is executed, for large pieces, almost always by several men, who while they lift the pattern with one hand, strike it with the other with small repeated blows to detach the sand entirely, in which it is generally more engaged than it was in that of the frame No. 1. But in spite of all these precautions, there are always some degradations in one or other of the two parts of the mould; which are immediately repaired by the workman with damp sand, which he applies and presses gently with his trowel, so as to restore the injured forms.

Hitherto I have supposed all the sand rammed into the box to be of one kind; but

from economy, the green sand is used only to form the portion of the mould next the pattern, in a stratum of about an inch thick; the rest of the surrounding space is filled with the sand of the floor which has been used in former castings. The interior layer round the pattern is called in this case, *new sand.*

It may happen that the pattern is too complex to be taken out without damaging the mould, by two frames alone; then 3 or more are mutually adjusted to form the box.

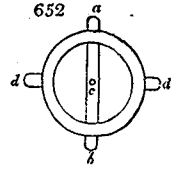
When the mould, taken asunder into two or more parts, has been properly repaired, its interior surface must be dusted over with wood charcoal reduced to a very fine powder, and tied up in a small linen bag, which is shaken by hand. The charcoal is thus sifted at the moment of application, and sticks to the whole surface which has been previously damped a little. It is afterwards polished with a fine trowel. Sometimes, in order to avoid using too much charcoal, the surfaces are finally dusted over with sand, very finely pulverized, from a bag like the charcoal. The two frames are now replaced with great exactness, made fast together by the ears, with wedged bolts laid truly level, or at the requisite slope, and loaded with considerable weights. When the casting is large, the charcoal dusting as well as that of fine sand, is suppressed. Every thing is now ready for the introduction of the fused metal.

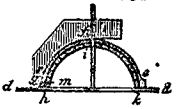
Moulding in baked or used sand. — The mechanical part of this process is the same as of the preceding. But when the castings are large, and especially if they are tall, the hydrostatic pressure of the melted metal upon the sides of the mould cannot be counteracted by the force of cohesion which the sand acquires by ramming. We must in that case adapt to each of these frames a solid side, pierced with numerous small holes to give issue to the gases. This does not form one body with the rest of the frame, but is attached extemporaneously to it by bars and wedged bolts. In general no ground coal is mixed with this sand. Whenever the mould is finished, it is transferred to the drying stove, where it may remain from 12 to 24 hours at most, till it be deprived of all its humidity. The sand is then said to be baked, or annealed. The experienced moulder knows how to mix the different sands placed at his disposal, so that the mass of the mould as it comes out of the stove, may preserve its form, and be sufficiently porous. Such moulds allow the gases to pass through them much more readily than those made of *green* sand; and in general the castings they turn out are less vesicular, and smoother upon the surface Sometimes in a large piece, the three kinds of moulding, that in green sand, in baked sand, and in loam, are combined to produce the best result.

Moulding in loam. — This kind of work is executed from drawings of the pieces to be moulded, without being at the expense of making patterns. The mould is formed of a pasty mixture of clay, water, sand, and cow's hair, or other cheap filamentous matter, kneaded together in what is called the loam mill. The proportions of the ingredients are varied to suit the nature of the casting. When the paste requires to be made very light, horse dung or chopped straw is added to it.

I shall illustrate the mode of fabricating loam moulds, by a simple case, such as that of a sugar pan. *Fig. 651.* is the pan. There is laid upon the floor of the foundry, an annular platform of cast-iron *a b, fig. 652.*; and upon its centre *c*, rests the lower extremity of a vertical shaft, adjusted so as to turn freely upon itself, while it makes a wooden pattern *e f, fig. 653.*, describe a surface of revolution identical with the internal surface reversed of the boiler intended to be made. The outline *e g*, of the pattern is fashioned so as to describe the surface of the edge of the vessel. Upon the part *a d b d, fig. 652.*, of the flat cast-iron ring, there must next be constructed, with bricks laid either flat or on their edge, and clay, a kind of dome, *h i k, fig. 653.*, from two to four inches

651





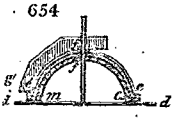
thick, according to the size and weight of the piece to be moulded. The external surface of the brick dome ought to be everywhere two inches distant at least, from the surface described by the arc *e, f.* Before building up the dome to the point *i*, coals are to be placed in its inside upon the floor, which may be afterwards kindled for drying the mould. The top is then formed, leaving at *i*, round the upright shaft of revolution, only a very small outlet. This aperture, as also some others left under the edges of the iron ring, enable the moulder to light the fire when it becomes necessary, and to graduate it so as to make it last long enough without needing more fuel, till the mould be quite finished and dry. The combustion should be always extremely slow.

Over the brick dome a pasty layer of loam is applied, and rounded with the mould

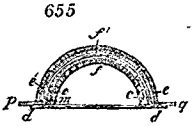
g e f; this surface is then coated with a much smoother loam, by means of the concave edge of the same mould. Upon the latter surface, the inside of the sugar pan is cast; the line *e g* having traced, in its revolution, a ledge *m*. The fire is now kindled, and as the surface of the mould becomes dry, it is painted over by a brush, with a mixture of water, charcoal powder, and a little clay, in order to prevent adhesion between the surface already dried and the coats of clay about to be applied to it. The board *g e f* is now removed, and replaced by another, *g' e' f'*, *fig.* 654., whose edge *e' f'* describes the outer surface of the pan. Over the surface *e, f*, a layer of loam is applied, which is turned and polished so as to produce the surface of revolution *e' f'*, as was done for the surface *e f*; only in the latter case, the line *e' g'* of the board does not form a new shoulder, but rubs lightly against *m*.

The layer of loam included between the two surfaces *e f*, *e' f'*, is an exact representation of the sugar pan. When this layer is well dried by the heat of the interior fire, it must be painted like the former. The upright shaft is now removed, leaving the small vent hole through which it passed to promote the complete combustion of the coal. There must be now laid horizontally upon the ears of the platform *d d*, *fig.* 652., another annular platform *p q*, like the former, but a little larger, and without any cross-bar.

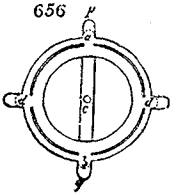
654



655



656



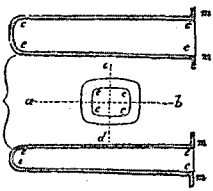
The relative position of these two platforms is shown in *fig.* 656. Upon the surface *e' f'*, *fig.* 655., a new layer of loam is laid, two inches thick, of which the surface is smoothed by hand. Then upon the platform *p q*, *fig.* 656., a brick vault is constructed, whose inner surface is applied to the layer of loam. This contracts a strong adherence with the bricks which absorb a part of its moisture, while the coat of paint spread over the surface *e' f'*, prevents it from sticking to the preceding layers of loam. The brick dome ought to be built solidly.

The whole mass is now to be thoroughly dried by the continuance of the fire, the draught of which is supported by a small vent left in the upper part of the new dome; and when all is properly dry, the two iron platforms are adjusted to each other by pin points, and *p q* is lifted off, taking care to keep it in a horizontal position. Upon this platform are removed the last brick dome, and the layer of loam which had been applied next to it; the latter of which represents exactly by its inside the mould of the surface *e' f'*, that is of the outside of the pan. The crust contained between *e f* and *e' f'* is broken away, an operation easily done without injury to the surface *e f*, which represents exactly the inner surface of the pan; or only to the shoulder *m*, corresponding to the edge of the vessel. The top aperture through which the upright shaft passed must be now closed; only the one is kept open in the portion of the mould lifted off upon *p q*; because through this opening the melted metal is to be poured in the process of casting. The two platforms being replaced above each other very exactly, by means of the adjusting pin-points, the mould is completely formed, and ready for the reception of the metal.

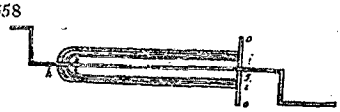
When the object to be moulded presents more complicated forms than the one now chosen for the sake of illustration, it is always by analogous processes that the workman constructs his loam moulds, but his sagacity must hit upon modes of executing many things which at first sight appear to be scarcely possible. Thus, when the forms of the interior and exterior do not permit the mould to be separated in two pieces, it is divided into several, which are nicely fitted with adjusting pins. More than two cast-iron rings or platforms are sometimes necessary. When ovals or angular surfaces must be traced instead of those of revolution, no upright shaft is used, but wooden or cast-iron guides made on purpose, along which the pattern cut-out board is slid according to the drawing of the piece. Iron wires and claws are often interspersed through the brick work to give it cohesion. The core, kernel, or inner mould of a hollow casting is frequently fitted in when the outer shell is moulded. I shall illustrate this matter in the case of a gas-light retort, *fig.* 657. The core of the retort ought to have the form *e e e e*, and be very solid, since it cannot be fixed in the outer mould, for the casting, except in the part standing out of the retort towards *m m*. It must be modelled in loam, upon a piece of cast-iron called a *lantern*, made expressly for this purpose. The lantern is a cylinder or a truncated hollow cone of cast iron, about half an inch thick; and differently shaped for every different core. The surface is perforated with holes of about half an inch in diameter. It is mounted by means of iron cross bars, upon an iron axis,

which traverses it in the direction of its length. *Fig.* 658 represents a horizontal section through the axis of the core; *g h* is the axis of the lantern, figured itself at *i k*

657



658



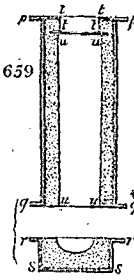
k i; *o i i o* is a kind of disc or dish, perpendicular to the axis, open at *i i*, forming one piece with the lantern, whose circumference *o o* presents a curve similar to the section of the core, made at right angles to its axis. We shall see presently the two uses for which this dish is intended. The axis *g h* is laid upon two gudgeons, and handles are placed at each of its extremities, to facilitate the operation in making the core. Upon the whole surface of the lantern, from the point *h* to the collet formed by the dish, a hay cord as thick as the finger is wound. Even two or more coils may be applied, as occasion requires, over which loam is spread to the exact form of the core, by applying with the hand a board, against the dish *o*, *o*, with its edge cut out to the desired shape; as also against another dish, adjusted at the time towards *h*; while by means of the handles a rotatory movement is given to the whole apparatus.

The hay interposed between the lantern and the loam, which represents the crust of the core, aids the adhesion of the clay with the cast iron of the lantern, and gives passage to the holes in its surface, for the air to escape through in the casting.

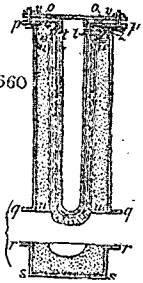
When the core is finished, and has been put into the drying stove, the axis *g h* is taken out, then the small opening which it leaves at the point *h*, is plugged with clay. This is done by supporting the core by the edges of the dish, in a vertical position. It is now ready to be introduced into the hollow mould of the piece.

This mould executed in baked sand consists of three pieces, two of which absolutely similar, are represented, *fig.* 659., at *p q*, the third is shown at *r s*. The two similar parts *p q*, present each the longitudinal half of the nearly cylindrical portion of the outer surface of the gas retort; so that when they are brought together, the cylinder is formed; *r s* contains in its cavity the kind of hemisphere which forms the bottom of the retort. Hence, by adding this part of the mould to the end of the two others, the resulting apparatus presents in its interior, the exact mould of the outside of the retort; an empty cylindrical portion *t t*, whose axis is the same as that of the cylinder *u u*, and whose surface, if prolonged, would be every where distant from the surface *u u*, by a quantity equal to the desired thickness of the retort. The diameter of the cylinder *t t* is precisely equal to that of the core, which is slightly conical, in order that it may enter easily into this aperture *t t*, and close it very exactly when it is introduced to the collet or neck.

659



660



The three parts of the mould and the core being prepared, the two pieces *p q*, must first be united, and supported in an upright position; then the core must be let down into the opening *t t*, *fig.* 660. When the plate or disc *o o* of the core is supported upon the mould, we must see that the end of the core is every where equally distant from the edge of the external surface *u u*, and that it does not go too far beyond the line *q q*. Should there be an inaccuracy, we must correct it by slender iron slips placed under the edge of the disc *o o*; then by means of a cast iron cross, and screw bolts *v v*, we fix the core immovably. The whole apparatus is now set down upon *r s*, and we fix with screw bolts the plane surface *q q* upon *r r*; then introduce the melted metal by an aperture *z*, which has been left at the upper part of the mould.

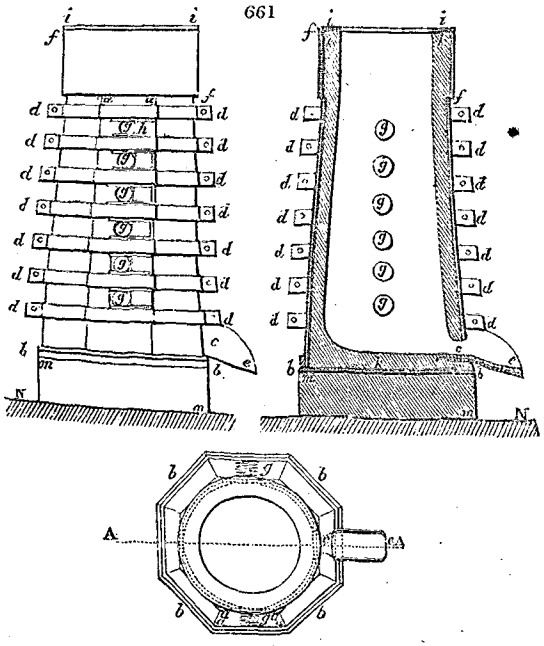
When, instead of the example now selected, the core of the piece to be cast must go beyond the mould of the external surface, as is the case with a pipe open at each end, the thing is more simple, because we may easily adjust and fix the core by its two ends.

In casting a retort, the metal is poured into the mould set upright. It is important to maintain this position in the two last examples of casting; for all the foreign matters which may soil the metal during its flow, as the sand, the charcoal, gases, scoriæ, being less dense than it, rise constantly to the surface. The hydrostatic pressure produced by a high gate, or filling-in aperture, contributes much to secure the soundness and solidity of the casting. This gate piece being superfluous, is knocked off almost immediately

after, or even before the casting cools. Very long, and somewhat slender pieces, are usually cast in moulds set up obliquely to the horizon. As the metal shrinks in cooling, the mould should always be somewhat larger than the object intended to be cast. The iron founder reckons in general upon a linear shrinkage of a ninety-sixth part; that is one-eighth of an inch per foot.

Melting of the cast-iron. — The metal is usually melted in a cupola furnace, of which the dimensions are very various. *Fig.* 661. represents in plan, section, and elevation, one of these furnaces of the largest size; being capable of founding 5 tons of cast-iron at a time. It is kindled by laying a few chips of wood upon its bottom, leaving the orifice *c* open, and it is then filled up to the throat with coke. The fire is lit at *c*, and in a quarter or half an hour, when the body of fuel is sufficiently kindled, the tuyère blast is set in action. The flame issues then by the mouth as well as the orifice *c*, which has been left open on purpose to consolidate it by the heat. Without this precaution, the sides which are made up in argillaceous sand after each day's work, would not present the necessary resistance. A quarter of an hour afterwards, the orifice *c* is closed with a lump of moist clay, and sometimes, when the furnace is to contain a great body of melted metal, the clay is supported by means of a small plate of cast-iron fixed against the furnace. Before the blowing machine is set a going, the openings *g g g* had been kept shut. Those of them wanted for the tuyères are opened in succession, beginning at the lowest, the tuyères being raised according as the level of the fused iron stands higher in the furnace. The same cupola may receive at a time from one to six tuyères, through which the wind is propelled by the centrifugal action of an excentric fan or ventilator. It does not appear to be ascertained whether there be any advantage in placing more than two tuyères facing each other upon opposite sides of the furnace. Their diameter at the nozzle varies from 3 to 5 inches. They are either cylindrical or slightly conical. A few minutes after the tuyères have begun to blow, when the coke sinks in the furnace, alternate charges of coke and pig iron must be thrown in. The metal begins to melt in about 20 minutes after its introduction; and successive charges are then made every 10 minutes nearly; each charge containing from 2 cwt. to 5 cwt. of iron, and a quantity proportional to the estimate given below. The amount of the charges varies of course with the size of the furnace, and the speed required for the operation. The pigs must be previously broken into pieces weighing at most 14 or 16 pounds. The vanes of the blowing fan make from 625 to 650 turns per minute. The two cupolas represented *fig.* 661., and another alongside in the plan, may easily melt $6\frac{1}{2}$ tons of metal in $2\frac{3}{4}$ hours;

661



that is $2\frac{1}{3}$ tons per hour. This result is three or four times greater than what was

formerly obtained in similar cupolas, when the blast was thrown in from small nozzles with cylinder bellows, moved by a steam engine of 10 horses power.

In the course of a year, a considerable foundry like that represented in the plan, *fig.* 650., will consume about 300 tons of coke in melting 1240 tons of cast iron; consisting of 940 tons of pigs of different qualities, and 300 tons of broken castings, gate-pieces, &c. Thus, it appears that 48 pounds of coke are consumed for melting every 2 cwt. of metal.

Somewhat less coke is consumed when the fusion is pushed more rapidly to collect a great body of melted metal, for casting heavy articles; and more is consumed when, as in making many small castings, the progress of the founding has to be slackened from time to time; otherwise, the metal would remain too long in a state of fusion, and probably become too cold to afford sharp impressions of the moulds.

It sometimes happens that in the same day, with the same furnace, pieces are to be cast containing several proportions of different kinds of iron; in which case, to prevent an intermixture with the preceding or following charges, a considerable bed of coke is interposed. Though there be thus a little waste of fuel, it is compensated by the improved adaptation of the castings to their specific objects. The founding generally begins at about 3 o'clock, P. M., and goes on till 6 or 8 o'clock. One founder, aided by four labourers for charging, &c., can manage two furnaces.

The following is the work of a well-managed foundry in Derby.

200 lbs. of coke are requisite to melt, or bring down (in the language of the founders), 1 ton of cast-iron, after the cupola has been brought to its proper heat, by the combustion in it of 9 baskets of coak, weighing by my trials, 40 pounds each, = 360 lbs.

The chief talent of the founder consists in discovering the most economical mixtures, and so compounding them as to produce the desired properties in the castings. One piece, for example, may be required to have great strength and tenacity to bear heavy weights or strains; another must yield readily to the chisel or the file; a third must resist sudden alternations of temperature; and a fourth must be pretty hard.

The filling in of the melted metal is managed in two ways. For strong pieces, whose moulds can be buried in the ground at 7 or 8 yards distance from the furnace, the metal may be run in gutters, formed in the sand of the floor, sustained by plates or stones. The clay plug is pierced with an iron rod, when all is ready.

When from the smaller size, or greater distance of the moulds, the melted metal cannot be run along the floor from the furnace, it is received in cast-iron pots or ladles, lined with a coat of loam. These are either carried by the hands of two or more men, or transported by the crane. Between the successive castings, the discharge hole of the furnace is closed with a lump of clay, applied by means of a stick, having a small disc of iron fixed at its end.

After the metal is somewhat cooled, the moulds are taken asunder, and the excrescences upon the edges of the castings are broken off with a hammer. They are afterwards more carefully trimmed or chipped by a chisel when quite cold. The loss of weight in founding is about 6¼ per cent. upon the pig iron employed. Each casting always requires the melting of considerably more than its own weight of iron. This excess forms the gates, false seams, &c.; the whole of which being deducted, shows that 1 cwt. of coke is consumed for every 3 cwt. of iron put into the furnace; for every 138 cwt. of crude metal, there will be 100 cwt. of castings, 32 of refuse pieces, and 6 of waste.

Explanation of the plates.

Manner of constructing the Mould of a Sugar-pan.

Fig. 651. View of the pan.
— 652. Flat ring of cast-iron for supporting the inner mould.
— 653. Construction of the inner mould.
— 654. Formation of the outer surface of the pan.
— 655. Finished mould.
— 656. Position of the two flat cast-iron rings, destined to sustain the moulds of the inner and the outer surface.

Gas-retort Moulding.

— 657. Vertical projection, perpendicular to the axis of the retort; and two sections, the one upright, the other horizontal.
— 658. Construction of the core of the retort.
— 659. Disposition of the outer mould.
— 660. Adjustment of the core in the mould.
— 661. *Cupola furnace.* It is 3 feet wide within, and 13½ high.
m m, solid body of masonry, as a basis to the furnace.

b b, octagonal platform of cast iron, with a ledge in which the plates *a a a a* are engaged.

a a, eight plates of cast iron, 1 inch thick, absolutely similar; only one of them is notched at its lower part in *c*, to allow the melted metal to run out, and two of the others have six apertures *g g g*, &c. to admit the tuyères.

c, orifice for letting the metal flow out. A kind of cast iron gutter, *e*, lined with loam is fitted to the orifice.

d, hoops of hammered iron, 4¼ inches broad; one half of an inch thick for the bottom ones; and a quarter of an inch for the upper ones. The intermediate hoops decrease in thickness from below upwards between these limits.

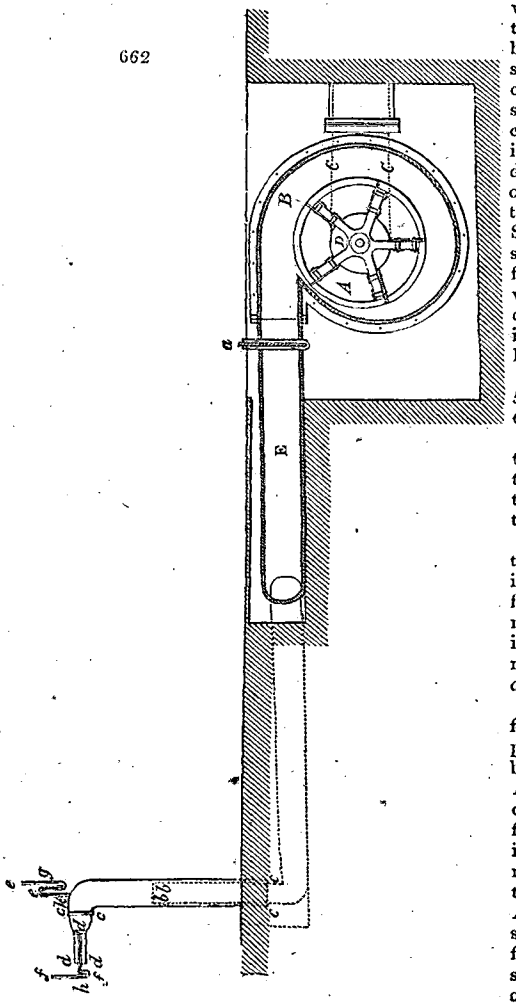
e, cast iron gutter or spout, lined with loam, for running off the metal.

f f, cylindrical piece of cast iron, for increasing the height and draught of the furnace.

g, side openings for receiving the tuyères, of which there are six upon each side of the furnace. Each of them may be shut at pleasure, by means of a small cast iron plate *h*, made to slide horizontally in grooves sunk in the main plate, pierced with the holes *g g*.

k k, interior lining of the surface, made of sand, somewhat argillaceous, in the following way. After having laid at the bottom of the furnace a bed of sand a few inches thick, slightly sloped towards the orifice of discharge, there is set upright, in the axis of the cupola, a wooden cylinder of its whole height, and of a diameter a little less than that of the vacant space belonging to the top of the furnace. Sand is to be then rammed in so as to fill the whole of the furnace; after which the wooden cylinder is withdrawn, and the lining of sand is cut or shaved away, till it has received the proper form.

662



This lining lasts generally 5 or 6 weeks, when there are 6 meltings weekly.

i i, cast iron circular plate, through which the mouth of the furnace passes, for protecting the lining in *k* during the introduction of the charges.

N N, level of the floor of the foundry. The portion of it below the running out orifice consists of sand, so that it may be readily sunk when it is wished to receive the melted metal in ladles or pots of large dimensions.

The fan distributes the blast from the main pipe to three principal points, by three branch tubes of distribution. A register, consisting of a cast-iron plate sliding with friction in a frame, serves to intercept the blast at any moment, when it is not desirable to stop the moving power. A large main pipe of zinc or sheet iron is fitted to the orifice of the slide valve. It is square at the beginning, or only rounded at the angles;

but at a little distance it becomes cylindrical, and conducts the blast to the divaricating points. There, each of the branches turns up vertically, and terminates at *b b*, *fig.* 662., where it presents a circular orifice of 7½ inches. Upon each of the upright pipes *b*, the one end of an elbow-tube of zinc *c c c c*, *fig.* 662., is adjusted rather loosely, and the other end receives a tuyère of wrought iron *d d*, through the intervention of a shifting hose or collar of leather *c c d*, hooped with iron wire to both the tube and the tuyère. The portion *c c c c* may be raised or lowered, by sliding upon the pipe *b*, in order to bring the nozzle of the tuyère *d d*, to the requisite point of the furnace. The portion *c c c c* may be made also of wrought iron. A power of 4 horses is adequate to drive this fan, for supplying blast to 3 furnaces.

The founders have observed the efflux of air was not the same when blown into the atmosphere, as it was when blown into the furnaces; the velocity of the fan, with the same impulsive power, being considerably increased in the latter case. They imagine that this circumstance arises from the blast being sucked in, so to speak, by the draught of the furnace, and that the fan then supplied a greater quantity of air.

The following experimental researches show the fallacy of this opinion. Two water syphons, *e e e*, *f f f*, made of glass tubes, one-fifth of an inch in the bore, were inserted into the tuyère, containing water in the portions *g g g*, *h h h*. The one of these *manometers* for measuring the pressure of the air was inserted at *k*, the other in the centre of the nozzle. The size of this glass tube was too small to obstruct in any sensible degree the outlet of the air. It was found that when the tuyères of the fan discharged into the open air, the expenditure by a nozzle of a constant diameter was proportional to the number of the revolutions of the vanes. It was further found, that when the speed of the vanes was constant, the expenditure by one or by two nozzles was proportional to the total area of these nozzles. The following formulæ give the volume of air furnished by the fan, when the number of turns and the area of the nozzles are known.

$$\text{Volume} = \frac{25{\cdot}32\ S\,n}{1{\cdot}000{,}000} \qquad (1)$$

$$\text{Volume} = \frac{0{\cdot}86'6'7\ S\,n}{1{,}000{,}000} \qquad (2)$$

The volume is measured at 32° Fahr., under a pressure of 29·6 inches barom.

S = is the total area of the orifices of the tuyères in square inches.

n = the number of turns of the vanes in a minute.

After measuring the speed of the vanes blowing into the atmosphere, if we introduce the nozzle of discharge into the orifice of the furnace, we shall find that their speed immediately augments in a notable degree. We might, therefore, naturally suppose that the fan furnishes more air in the second case than in the first; but a little reflection will show that it is not so. In fact, the air which issues in a cold state from the tuyère encounters instantly in the furnace a very high temperature, which expands it, and contributes, along with the solid matters with which the furnace is filled, to diminish the facility of the discharge, and consequently to retard the efflux by the nozzles. The oxygen gas consumed is replaced by a like volume of carbonic acid gas, equally expansible by heat. Reason leads us to conclude that less air flows from the nozzles into the furnace than into the open atmosphere.

The increase in the velocity of the vanes takes place precisely in the same manner, when after having made the nozzles blow into the atmosphere, we substitute for these nozzles others of a smaller diameter, instead of directing the larger ones into the furnace. Hence we may conceive that the proximity of the charged furnace acts upon the blast like the contraction of the nozzles. When the moving power is uniform, and the velocity of the vanes remains the same, the quantity of air discharged must also be the same in the two cases.

Two tuyères, one 5 inches in diameter, the other 4⅛, and which, consequently, presented a total area of 35½ square inches, discharged air into one of the furnaces, from a fan whose vanes performed 654 turns in the minute. These two nozzles being briskly withdrawn from the furnace, and turned round to the free air, while a truncated pasteboard cone of 3½ inches diameter was substituted for the nozzle of 4⅛ inches, whereby the area of efflux was reduced to 29·3 square inches, the velocity of the vanes continued exactly the same. The inverse operation having been performed, that is to say, the two original nozzles having been smartly replaced in the furnace, to discover whether or not the moving power had changed in the interval of the experiment, they betrayed no perceptible alteration of speed. From the measures taken to count the speed, the error could not exceed 3 revolutions per minute, which is altogether unimportant upon the number 654.

It follows, therefore, that when the vanes of the fan have the velocity of 654 turns per minute, the expenditure by two nozzles, whose joint area is $35\frac{1}{2}$ square inches, both blowing into a furnace, is to the expenditure which takes place, when the same nozzles blow into the air, as 35·5 is to 29·3; that is, a little more than 4-fifths.

If this be, as is probable, a general rule for areas and speeds considerably different from the above, to find the quantity of air blown into one or more furnaces by the fan, we should calculate the volume by one of the above formulæ (1) or (2), and take 4-fifths of the result, as the true quantity.

The fan A C here represented is of the best excentric form, as constructed by Messrs. Braithwaite and Ericsson. D is the circular orifice round the axis by which the air is admitted; and C C B is the excentric channel through which the air is wafted towards the main discharge pipe E.

FOUNTAIN; a stream of water rising up through the superficial strata of the earth. See ARTESIAN WELLS.

FOXING, is a term employed by brewers to characterize the souring of beer, in the process of its fermentation or ripening.

FRANKFORT BLACK; is made by calcining vine branches, and the other refuse lees of the vinegar vats in Germany. They must be previously washed.

FREEZING. (*Congelation*, Fr.; *Gefrierung*, Germ.) The three general forms, solid, liquid, and gaseous, under one or other of which all kinds of matter exist, seem to be immediately referrible to the influence of heat; modifying, balancing, or subduing the attraction of cohesion. Every solid may be liquefied, and every liquid may be vaporized, by a certain infusion of caloric, whether this be regarded as a moving power, or an elastic essence. The converse of this proposition is equally true; for many gases, till lately styled permanent, may be liquefied, nay, even solidified, by diminution of their temperature, either alone, or aided by a condensing force, to bring their particles within the sphere of aggregative attraction. When a solid is transformed into a liquid, and a liquid into a gas or vapour, a quantity more or less considerable of heat is absorbed, or becomes latent, to use the term of Dr. Black, the celebrated discoverer of this great law of nature. When the opposite transformation takes place, the heat absorbed is again emitted, or what was latent becomes sensible caloric. Upon the first principle, or the absorption of heat, are founded the various artificial methods of producing cold and congelation.

Tables, exhibiting a collective view of all the Frigorific Mixtures contained in Mr. Walker's publication,

I. — Table consisting of Frigorific Mixtures, composed of ice, with chemical salts and acids.

Frigorific Mixtures with Ice.

MIXTURES.		Thermometer sinks.	Deg. of cold produced.
Snow, or pounded ice - 2 parts Muriate of soda - 1	From any temperature	to − 5°	*
Snow, or pounded ice - 5 parts Muriate of soda - - 2 Muriate of ammonia - 1		to − 12°	*
Snow, or pounded ice - 24 parts Muriate of soda - - 10 Muriate of ammonia - 5 Nitrate of potash - - 5		to − 18°	*
Snow, or pounded ice - 12 parts Muriate of soda - - 5 Nitrate of ammonia - 5		to − 25°	*
Snow - - - 3 parts Diluted sulphuric acid - 2		From + 32° to − 23°	55
Snow - - - 8 parts Muriatic acid - - 5		From + 32° to − 27°	59
Snow - - - 7 parts Diluted nitric acid - 4		From + 32° to − 30°	62
Snow - - - 4 parts Muriate of lime - - 5		From + 32° to − 40°	72
Snow - - - 2 parts Cryst. muriate of lime - 3		From + 32° to − 50°	82
Snow - - - 3 parts Potash - - 4		From + 32° to − 51°	83

N. B. — The reason for the omissions in the last column of the preceding table is, the thermometer sinking in these mixtures to the degree mentioned in the preceding column, and never lower, whatever may be the temperature of the materials at mixing.

II. — Table, consisting of Frigorific Mixtures, having the power of generating or creating cold, without the aid of ice, sufficient for all useful and philosophical purposes, in any part of the world at any season.

Frigorific Mixtures without Ice.

MIXTURES.	Thermometer sinks.	Deg. of cold produced.
Muriate of ammonia - 5 parts Nitrate of potash 5 Water - - - 16	From + 50° to + 10°	40°
Muriate of ammonia - 5 parts Nitrate of potash - 5 Sulphate of soda - - 8 Water - - - 16	From + 50° to + 4°	46
Nitrate of ammonia - 1 part Water - - - 1	From + 50° to + 4°	46
Nitrate of ammonia - 1 part Carbonate of soda - 1 Water - - - 1	From + 50° to − 7°	57
Sulphate of soda - 3 parts Diluted nitric acid - 2	From + 50° to − 3°	53
Sulphate of soda - - 6 parts Muriate of ammonia - 4 Nitrate of potash - 2 Diluted nitric acid - 4	From + 50° to − 10°	60
Sulphate of soda - - 6 parts Nitrate of ammonia - 5 Diluted nitric acid - 4	From + 50° to − 14°	64
Phosphate of soda - 9 parts Diluted nitric acid - 4	From + 50° to − 12°	62
Phosphate of soda - 9 parts Nitrate of ammonia - 6 Diluted nitric acid - 4	From + 50° to − 21°	71
Sulphate of soda - - 8 parts Muriatic acid - - 5	From + 50° to 0°	50
Sulphate of soda - 5 parts Diluted sulphuric acid - 4	From + 50° to + 3°	47

N. B. — If the materials are mixed at a warmer temperature than that expressed in the table, the effect will be proportionably greater; thus, if the most powerful of these mixtures be made when the air is + 85°, it will sink the thermometer to + 2°.

III. — Table consisting of Frigorific Mixtures selected from the foregoing Tables, and combined so as to increase or extend cold to the extremest degrees.

Combinations of Frigorific Mixtures.

MIXTURES.	Thermometer sinks.	Deg. of cold produced.
Phosphate of soda - - 5 parts Nitrate of ammonia - - 3 Diluted nitric acid - 4	From 0° to − 34°	34
Phosphate of soda - - 3 parts Nitrate of ammonia - 2 Diluted mixed acids - 4	From − 34° to − 50°	16
Snow - - - 3 parts Diluted nitric acid - 2	From 0° to − 46°	46

TABLE III. — *continued.*

MIXTURES.	Thermometer sinks.	Deg. of cold produced.
Snow - - - 8 parts Diluted sulphuric acid - 3 Diluted nitric acid - - 3	From — 10° to — 56°	46
Snow - - - 1 part Diluted sulphuric acid - 1	From — 20° to — 60°	40
Snow - - - 3 parts Muriate of lime - - 4	From + 20° to — 48°	68
Snow - - - 3 parts Muriate of lime - 4	From + 10° to — 54°	64
Snow - - - 2 parts Muriate of lime - 3	From — 15° to — 68°	53
Snow - - - 1 part Cryst. muriate of lime - 2	From 0° to — 66°	66
Snow - - - 1 part Cryst. muriate of lime - 3	From — 40° to — 73°	33
Snow - - - 8 parts Diluted sulphuric acid - 10	From — 68° to — 91°	23

N. B. — The materials in the first column are to be cooled, previously to mixing, to the temperature required, by mixtures taken from either of the preceding tables.

Water absorbs 1000 degrees of heat in becoming vapour; whence, if placed in a saucer within an exhausted receiver, over a basin containing strong sulphuric acid, it will freeze by the rapid absorption of its heat into the vapour so copiously formed under these circumstances.

But the most powerful means of artificial refrigeration is afforded by the evaporation of liquefied carbonic acid gas; for the frozen carbonic acid thus obtained, has probably a temperature 100° under zero; so that when a piece of it is laid upon quicksilver, it instantly congeals this metal. The more copious discussion of this subject belongs to chemical science.

FRENCH BERRIES; Berries of Avignon.

FRICTION, counteraction of; see LUBRICATION.

FRIT; see ENAMEL and GLASS.

FUEL (*Combustible*, Fr; *Brennstoff*, Germ.).

Such combustibles as are used for fires or furnaces are called fuel, as wood, turf, pit-coal. These differ in their nature, and in their power of giving heat.

I. Wood, which is divided into hard and soft. To the former belong the oak, the beech, the alder, the birch, and the elm; to the latter, the fir, the pine of different sorts, the larch, the linden, the willow, and the poplar.

Under like dryness and weight, different woods are found to afford equal degrees of heat in combustion Moisture diminishes the heating power in three ways; by diminishing the relative weight of the ligneous matter, by wasting heat in its evaporation, and by causing slow and imperfect combustion. If a piece of wood contain, for example, 25 per cent. of water, then it contains only 75 per cent. of fuel, and the evaporation of that water will require $\frac{1}{3}$ part of the weight of the wood. Hence the damp wood is of less value in combustion by $\frac{8}{23}$ or $\frac{2}{7}$ than the dry. The quantity of moisture in newly felled wood amounts to from 20 to 50 per cent.; birch contains 30, oak 35, beech and pine 39, alder 41, fir 45. According to their different natures, woods which have been felled and cleft for 12 months contain still from 20 to 25 per cent. of water. There is never less than 10 per cent. present, even when it has been kept long in a dry place, and though it be dried in a strong heat, it will afterwards absorb 10 or 12 per cent. of water. If it be too strongly kiln dried, its heating powers are impaired by the commencement of carbonization, as if some of its hydrogen were destroyed. It may be assumed as a mean of many experimental results, that 1 pound of artificially dried wood will heat 35 pounds of water from the freezing to the boiling point; and that a pound of such wood as contains from 20 to 25 per cent. of water will heat 26 pounds of ice-cold water to the same degree. It is better to buy wood by measure than by weight, as the bulk is very little increased by moisture. The value of different woods for fuel is inversely as their moisture, and this may easily be ascertained by taking their shavings, drying them in a heat of 140° F., and seeing how much weight they lose.

From every combustible the heat is diffused either by radiation or by direct communication to bodies in contact with the flame. In a wood fire the quantity of radiating heat is to that diffused by the air, as 1 to 3; or it is one fourth of the whole heating power

II. *Charcoal.* The different charcoals afford, under equal weights, equal quantities of heat. We may reckon, upon an average, that a pound of dry charcoal is capable of heating 73 pounds of water from the freezing to the boiling point; but when it has been for some time exposed to the air, it contains at least 10 per cent. of water, which is partially decomposed in the combustion into carburetted hydrogen, which causes flame, whereas pure dry charcoal emits none.

A cubic foot of charcoal from soft wood weighs upon an average from 8 to 9 pounds, and from hard wood 12 to 13 pounds; and hence the latter are best adapted to maintain a high heat in a small compass. The radiating heat from charcoal fires constitutes one third of the whole emitted.

III. *Pitcoal.* The varieties of this coal are almost indefinite, and give out very various quantities of heat in their combustion. The carbon is the heat-giving constituent, and it amounts, in different coals, to from 75 to 95 per cent. One pound of good pitcoal will, upon an average, heat 60 pounds of water from the freezing to the boiling point. Small coal gives out three-fourths of the heat of the larger lumps. The radiating heat emitted by burning pitcoal is greater than that by charcoal.

IV. *The coke of pitcoal.* — The heating power of good coke is to that of pitcoal as 75 to 69. One pound of the former will heat 65 pounds of water from 32° to 212°; so that its power is equal to nine-tenths of that of wood charcoal.

V. *Turf or peat.* — One pound of this fuel will heat from 25 to 30 pounds of water from freezing to boiling. Its value depends upon its compactness and freedom from earthy particles; and its radiating power is to the whole heat it emits in burning, as 1 to 3.

VI. *Carburetted hydrogen or coal gas.* — One pound of this gas, equal to about 24 cubic feet, disengages in burning, as much heat as will raise 76 pounds of water from the freezing to the boiling temperature.

In the following table the fourth column contains the weight of atmospherical air, whose oxygen is required for the complete combustion of a pound of each particular substance.

Species of combustible.	Pounds of water which a pound can heat from 0° to 212°.	Pounds of boiling water evaporated by 1 pound.	Weight of atmospheric air at 32°, to burn 1 pound.
Perfectly dry wood -	35·00	6·36	5·96
Wood in its ordinary state -	26·00	4·72	4·47
Wood charcoal - -	73·00	13·27	11·46
Pitcoal - -	60·00	10·90	9·26
Coke - - -	65·00	11·81	11·46
Turf - - -	30·00	5·45	4·60
Turf charcoal - -	64·00	11·63	9·86
Carburetted hydrogen gas -	76·00	13·81	14·58
Oil, Wax, Tallow - - - -	78·00	14·18	15·00
Alcohol of the shops -	52·60	9·56	11·60

The quantity of air stated in the fourth column, is the smallest possible required to burn the combustible, and is greatly less than would be necessary in practice, where much of the air never comes into contact with the burning body, and where it consequently never has its whole oxygen consumed. The heating power stated in the second column is also the maximum effect, and can seldom be realized with ordinary boilers. The draught of air usually carries off at least $\frac{1}{7}$ of the heat, and more if its temperature be very high when it leaves the vessel. In this case it may amount to one half of the whole heat or more; without reckoning the loss by radiation and conduction, which however may be rendered very small by enclosing the fire and flues within proper non-conducting and non-radiating materials.

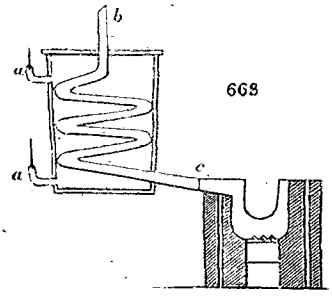
It appears that in practice, the quantity of heat which may be obtained from any combustible in a properly mounted apparatus, must vary with the nature of the object to be heated. In heating chambers by stoves, and water boilers by furnaces, the effluent heat in the chimney which constitutes the principal waste, may be reduced to a very moderate quantity, in comparison of that which escapes from the best constructed reverberatory hearth. In heating the boilers of steam engines, one pound of coal is reckoned adequate to convert $7\frac{1}{2}$ pounds of boiling water into vapour; or to heat $41\frac{1}{4}$ pounds of water from the freezing to the boiling point. One pound of fir of the usual dryness will evaporate 4 pounds of water, or heat 22 pounds to the boiling temperature; which is about two-thirds of the maximum effect of this combustible. According to Watt's experiments upon the great scale, one pound of coal can boil off with the best built boiler, 9 pounds of water; the deficiency from the maximum effect being here $\frac{10}{54}$ or nearly one-sixth.

In many cases the hot air which passes into the flues or chimneys may be bene-

ficially applied to the heating, drying, or roasting of objects; but care ought to be taken that the draught of the fire be not thereby impaired, and an imperfect combustion of the fuel produced. For at a low smothering temperature both carbonic oxide and carburetted hydrogen may be generated from coal, without the production of much heat in the fireplace.

To determine exactly the quantity of heat disengaged by any combustible in the act of burning, three different systems of apparatus have been employed: 1. the calorimeter of Lavoisier and Laplace, in which the substance is burned in the centre of a vessel, whose walls are lined with ice; and the amount of ice melted, measures the heat evolved; 2. the calorimeter of Watt and Rumford, in which the degree of heat communicated to a given body of water affords the measure of temperature; and 3. by the quantity of water evaporated by different kinds of fuel in similar circumstances.

If our object be to ascertain the relative heating powers of different kinds of fuel, we need not care so much about the total waste of heat in the experiments, provided it be the same in all; and therefore they should be burned in the same furnace, and in the same way. But the more economically the heat is applied, the greater certainty will there be in the results. The apparatus, *fig.* 663., is simple and well adapted to make such comparative trials of fuel. The little furnace is covered at top, and transmits its burned air by *c*, through a spiral tube immersed in a cistern of water, having a thermometer inserted near its top, and another near its bottom, into little side orifices *a a*, while the effluent air escapes from the upright end of the tube *b*. Here also a thermometer bulb may be placed. The average indication of the two thermometers gives the mean temperature of the water. As the water evaporates from the cistern, it is supplied from a vessel placed alongside of it. The experiment should be begun when the furnace has acquired an equability of temperature. A throttle valve at *c* serves to regulate the draught, and to equalise it in the different experiments by means of the temperature of the effluent air. When the water has been heated the given number of degrees, which should be the same in the different experiments, the fire may be extinguished, the remaining fuel weighed, and compared with the original quantity. Care should be taken to make the combustion as vivid and free from smoke as possible.



663

On the measurement of heat, and the qualities of different kinds of coal, I made an elaborate series of experiments, a few years ago, of which the following is an outline.

The first and most celebrated, though probably not the most accurate apparatus for measuring the quantity of heat transferable from a hotter to a colder body, was the calorimeter of Lavoisier and Laplace. It consisted of three concentric cylinders of tin plate, placed at certain distances asunder; the two outer interstitial spaces being filled with ice, while the innermost cylinder received the hot body, the subject of experiment. The quantity of water discharged from the middle space by the melting of the ice in it, served to measure the quantity of heat given out by the body in the central cylinder. A simpler and better instrument on this principle would be a hollow cylinder of ice of proper thickness, into whose interior the hot body would be introduced, and which would indicate by the quantity of water found melted within it the quantity of heat absorbed by the ice. In this case, the errors occasioned by the retention of water among the fragments of ice packed into the cylindric cell of the tin calorimeter, would be avoided. One pound of water at 172° Fahr., introduced into the hollow cylinder described, will melt exactly one pound of ice; and one pound of oil heated to 172° will melt half a pound.

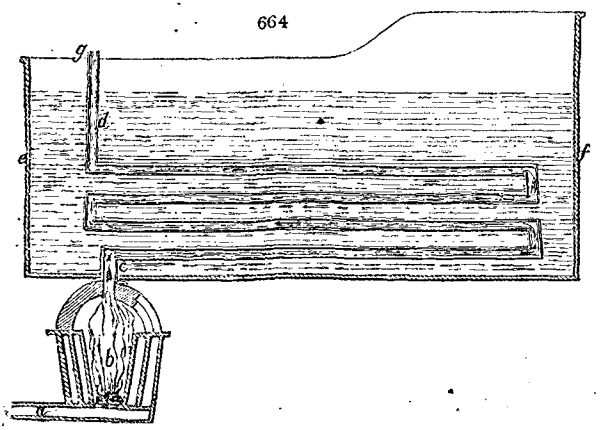
The method of refrigeration, contrived at first by Meyer, has been in modern times brought to great perfection by Dulong and Petit. It rests on the principle, that two surfaces of like size, and of equal radiating force, lose in like times the same quantity of heat when they are at the same temperature. Suppose, for example, that a vessel of polished silver, of small size, and very thin in the metal, is successively filled with different pulverized substances, and that it is allowed to cool from the same elevation of temperature; the quantities of heat lost in the first instant of cooling will be always equal to each other; and if for one of the substances, the velocity of cooling is double of that for another, we may conclude that its capacity for heat is one half, when its weight is the same; since by losing the same quantity of heat, it sinks in temperature double the number of degrees.

The method of mixtures.—In this method two bodies are always employed; a hot body, which becomes cool, and a cold body, which becomes hot, in such manner that all

the caloric which goes out of the former is expended in heating the latter. Suppose, for example, that we pour a pound of quicksilver at 212° F., into a pound of water at 32°; the quicksilver will cool and the water will heat, till the mixture by stirring acquires a common temperature. If this temperature was 122°, the water and mercury would have equal capacities, since the same quantity of heat would produce in an equal mass of these two substances equal changes of temperature, viz., an elevation of 90° in the water and a depression of 90° in the mercury. But in reality, the mixture is found to have a temperature of only 37½°, showing that while the mercury loses 174½° the water gains only 5½°; two numbers in the ratio of about 32 to 1; whence it is concluded, that the capacity of mercury is $\frac{1}{32}$ of that of water. Corrections must be made for the influence of the vessel and for the heat dissipated during the time of the experiment.

The following calorimeter, founded upon the same principle as that of Count Rumford, but with certain improvements, may be considered as an equally correct instrument for measuring heat, with any of the preceding, but one of much more general application, since it can determine the quantity of heat disengaged in combustion, as well as the latent heat of steam and other vapours.

664



(Scale about ½ inch to the foot.

It consists of a large copper bath, *e*, *f*, (*fig.* 664.) capable of holding 100 gallons of water. It is traversed four times, backwards and forwards, in four different levels, by a zig-zag horizontal flue or flat pipe *d*, *c*, nine inches broad and one deep, ending below in a round pipe at *c*, which passes through the bottom of the copper bath *e*, *f*, and receives there into it the top of a small black lead furnace *b*. The innermost crucible contains the fuel. It is surrounded at the distance of one inch by a second crucible, which is enclosed at the same time by the sides of the outermost furnace; the strata of stagnant air between the crucibles serving to prevent the heat from beimg dissipated into the atmosphere round the body of the furnace. A pipe *a*, from a pair of cylinder double bellows, enters the ash-pit of the furnace at one side, and supplies a steady but gentle blast, to carry on the combustion, kindled at first by half an ounce of red-hot charcoal. So completely is the heat which is disengaged by the burning fuel absorbed by the water in the bath, that the air discharged at the top orifice *g* has usually the same temperature as the atmosphere.

The vessel is made of copper, weighing two pounds per square foot; it is 5½ feet long, 1½ wide, 2 deep, with a bottom 5½ feet long, and 1¾ broad, upon an average. Including the zig-zag tin plate flue, and a rim of wrought iron, it weighs altogether 85 pounds. Since the specific heat of copper is to that of water as 94 to 1,000; the specific heat of the vessel is equal to that of 8 pounds of water, for which, therefore, the exact correction is made by leaving 8 pounds of water out of the 600 or 1,000 pounds used in each experiment.

In the experiments made with former calorimeters of this kind, the combustion was maintained by the current or draft of a chimney, open at bottom, which carried off at the top orifice of the flue a variable quantity of heat, very difficult to estimate.

When the object is to determine the latent heat of steam and other vapours, they may be introduced through a tube into the top orifice *g*, the latent heat being deduced from the elevation of temperature in the water of the bath, and the volume of vapour ex-

pended from the quantity of liquid discharged into a measure glass from the bottom outlet c. In this case, the furnace is of course removed.

The heating power of the fuel is measured by the number of degrees of temperature which the combustion of one pound of it, raises 600 or 1,000 pounds of water in the bath, — the copper substance of the vessel being taken into account. One pound of dry wood charcoal by its combustion causes 6,000 pounds of water to become 20° hotter. For the sake of brevity, we shall call this calorific energy 12,000 unities. In like circumstances, one pound of Llangennoek coal will yield by combustion 11,500 unities of caloric. One pound of charcoal after exposure to the air gives out in burning only 10,500 unities; but when previously deprived of the moisture which it so greedily imbibes from the atmosphere, it affords the above quantity. One pound of Lambton's Wall's-end coals affords 8,500 unities; and one of anthracite 11,000.

It must be borne in mind that a coal which gives off much unburnt carburetted hydrogen gas does not afford so much heat, since in the production of the gas a great deal of heat is carried off in the latent state. I have no doubt, that by this distillatory process, from one-third to one-fourth of the total calorific effect of many coals is dissipated in the air. But by means of such a furnace as the patent Argand invention of Mr. C. W. Williams, the whole heat producible by the hydrogen as well as the carbon is obtained; and it should be borne it mind that a pound of hydrogen in burning generates as much heat as three pounds of carbon.

M. Berthier proposes to determine the proportion of carbon in coals and other kinds of fuel, by igniting in a crucible a mixture of the carbonaceous matter with litharge, both finely comminuted, and observing the quantity of lead which is reduced. For every 34 parts of lead, he estimates 1 part of carbon, apparently on the principle that when carbon is ignited in contact with abundance of litharge, it is converted into carbonic acid. Each atom of the carbon is therefore supposed to seize two atoms of oxygen, for which it must decompose two atoms of litharge, and revive two atoms of lead. Calling the atom of carbon 6, and that of lead 104, we shall have the following ratio:—6 : (104 × 2) :: 1 : 34·66, being Berthier's proportion, very nearly.

On subjecting this theory to the touchstone of experiment, I have found it to be entirely fallacious. Having mixed very intimately 10 grains of recently calcined charcoal with 1,000 grains of litharge, both in fine powder, I placed the mixture in a crucible, which was so carefully covered as to be protected from all fuliginous fumes, and exposed it to distinct ignition. No less than 603 grains of lead were obtained; whereas by Berthier's rule, only 340 or 346·6 were possible. On igniting a mixture of 10 grains of pulverized anthracite from Merthyr Tydfil, with 500 grains of pure litharge (previously fused and pulverized), I obtained 380 grains of metallic lead. In a second similar experiment, with the same anthracite and litharge, I obtained 450 grains of lead; and in a third only 350 grains. It is therefore obvious that this method of Berthier is altogether nugatory for ascertaining the quantity of carbon in coals, and is worse than useless for judging of the calorific qualities of different kinds of fuel.

In my researches upon coals, I have also made it one of my principal objects to determine the quantity of sulphur which they may contain, — a point which has been hitherto very little investigated in this country at least, but which is of great consequence, not only in reference to their domestic combustion, but to their employment by manufacturers of iron and gas. That good iron cannot be produced with a sulphureous coal, however well coked, has been proved in France by a very costly experience. The presence of a notable proportion of sulphur in a gas coal is most injurious to the gaseous products, because so much sulphuretted hydrogen is generated as to require an operose process of washing or purification, which impoverishes the gas, and impairs its illuminating powers by the abstraction of its olefiant gas, or bicarburetted hydrogen. In proof of this proposition, I have only to state the fact, that I found in a specimen of coal gas, as delivered from the retorts of one of the metropolitan companies, no less than 18 per cent. of olefiant gas, while in the same gas, after being passed through the purifiers, there remained only 11 per cent. of that richly-illuminating gas. By using a gas-coal, nearly free from sulphur, such as No. 4. in the subjoined list, I think it probable that 10 per cent. of more light may be realised than with the common more sulphureous coal. This is an important circumstance which the directors of gas-works have hitherto neglected to investigate with analytical precision, though it is one upon which their success and profits mainly depend.

How little attention indeed has been bestowed upon the sulphureous impregnation of pit-coal may be inferred from the fact that one of our professional chemists of note, in a public report, upon a great commercial enterprise, stated that a certain coal analyzed by him was free from sulphur, which coal I found by infallible chemical evidence to contain no less than 7 per cent. of sulphur, being about double of what is contained in English coals of average quality. The proportion of sulphur may in general be inferred from the appearance and quantity of the ashes. If these be of a red or ochrey colour, and amount to above 10 per cent., we may be sure that the coal is eminently

sulphureous. The coal above referred to afforded from 15 to 16 per cent. of ferruginous ashes. I believe that sulphur exists in coal generally, though not always in the state of pyrites, either in manifest particles, or invisibly disseminated through their substance.

The readiest method of determining rigidly the quantity of sulphur in any compound is to mix a given weight of it with a proper weight of carbonate of potassa, nitre, and common salt, each chemically pure, and to ignite the mixture in a platinum crucible. A whitish mass is obtained, in which all the sulphur has been converted into sulphate of potassa. By determining with nitrate of baryta the amount of sulphuric acid produced, that of the sulphur becomes known. By means of this process applied to different samples of coals, I obtained the following results:

Gas Coals.	Sulphur in 100 parts.	Gas Coals.	Sulphur in 100 parts.
No. 1	3·00	No. 5	2·50
2	3·90	6	5·20
3	2·42	7	3·40
4	3·80	8	3·50

Coals for puddling cast iron, to be converted into steel,		Sulphur in 100 parts.
No. 1, hard foliated or splent coal, specific gravity	2·258	0·80
2, ditto	1·290	0·96
3, ditto	1·273	3·10
4, cubical and rather soft	1·267	0·89

The last coal being rich in bitumen, would prove an excellent one for the production of a pure coal gas. See PITCOAL.

FUEL, ECONOMY OF. In the report of the Transactions of the Institution of Civil Engineers for February, 1838, the results of exact comparisons between the performance of different steam-engines exhibit this economy in a remarkable manner. It is there shown that a condensing engine of the most perfect construction, and in perfect condition, of the common low-pressure crank kind, not working expansively, performs a duty of not more than 20 or 21 millions of lbs. raised one foot high, by 90 or 94 lbs. of coal; or 10 lbs. of coal per horse power per hour.

The following table exhibits the relative value of different engines in lbs. of coal per horse power per hour: —

Cornish Pumping Engine	1·57
Bolton & Watt's Single Engine	4·82
Cornish Double Engine	3·25
Bolton & Watt's Double Engine	10·5

The greatest duty performed by the measured bushel of 84 lbs. was 86½ millions of lbs. There was raised by the Huel Towan engine in Cornwall 1,085 tons (of water) one foot high for one farthing. Hence the weight of a man (1½ cwt.) would be raised ten miles for one penny!

In order to raise steam with economy, the surface of water in the boiler, exposed to the fire, ought not to be less than 10 square feet per horse power; but the usual allowance in Lancashire is only 7½; and by Messrs. Boulton & Watt, 5 square feet.

The values of the mean of the Cornish, Warwick, London, Lancashire, and locomotive experiments, as reported by Mr. Josiah Parkes, were respectively 21, 18, 13½, and 10 cubic feet of water evaporated by 112 lbs. of coals, from water heated to 212° F. See COALS.

FUEL, GRANT'S PATENT. This fuel is composed of coal-dust and coal-tar pitch; these materials are mixed together, under the influence of heat, in the following proportions: — 20 lbs. of pitch to 1 cwt. of coal-dust, by appropriate machinery, consisting of crushing-rollers for breaking the coal in the first instance sufficiently small so that it may pass through a screen, the meshes of which do not exceed a quarter of an inch asunder; 2dly, of mixing-pans or cylinders, heated to the temperature of 220°, either by steam or heated air; and, 3dly, of moulding machines, by which the fuel is compressed, under a pressure equal to five tons, into the size of a common brick; the fuel bricks are then whitewashed, which prevents their sticking together, either in the coal bunkers or in hot climates. The advantages of Grant's fuel over even the best coal may be stated to consist, first, in its superior efficacy in generating steam, which may be thus stated: 200 tons of this fuel will perform the same work as 300 tons of coal, such as are generally used; secondly, it occupies less space; that is to say, 500 tons of it may be stowed in an area which will contain only 400 tons of coal; thirdly, it is used with much greater ease by the stokers or firemen than coal, and it creates little or no dirt or dust, considerations of some importance when the delicate machinery of a steam-engine is considered; fourthly, it produces a very small proportion of clinkers, and thus it is far less liable to choke and destroy the furnace bars and

boilers than coal; fifthly, the ignition is so complete that comparatively little smoke, and only a small quantity of ashes, are produced by it; sixthly, from the mixture of the patent fuel, and the manner of its manufacture, it is not liable to enter into spontaneous ignition.

Fuel chiefly Pit Coal. "Considering the vast importance of the subject, it is somewhat remarkable that no exact mode of determining the true value of coal as a fuel has ever yet been invented. Of the methods hitherto in use there is not one which deserves the title even of an approximation to the truth. The plan of Berthier, as has been well shown by Dr. Ure, is beyond all things fallacious, though this very plan is that most relied on by the experimenters connected with the late Admiralty investigation respecting the coals best suited for the steam navy. It needs, however, but a moment's reflection to see that this process of Berthier can never afford a correct result, for the agent employed is litharge, a substance not acted on at all until exposed to heat more than sufficient for the expulsion of the volatile constituents of coal, and moreover a substance capable of being reduced at high temperatures by the carbonic oxide gas of the fire employed to effect the assay. Here then are two enormous sources of error; for in the first place the hydrogenous constituents of the coal can never be estimated at all, and in the second the litharge by mere exposure in a crucible to the action of the fire will give metallic lead exactly the same as if coal existed in it, so that not the least dependence in the world can be placed in this method. Numerous and carefully conducted experiments have fully confirmed the original observations of Dr. Ure upon this matter, and, in fact, the results from four crucibles, each charged with the same quantities of coal and litharge, taken from the same massive powder, and placed side by side in the same furnace, and treated in all respects exactly alike, have shown a discordance equal to the numbers 117, 142, 156, and 163. To think of attaching any value to any of these, or to the average which they present, is to lose sight of the most important province of chemistry in its relation to the arts.

"Another, and certainly a preferable method, is to consume a given amount of each coal in a calorimeter, so as to measure the total heat disengaged during combustion. But here, again, we meet with difficulties more than enough to destroy all confidence in the results. Thus it is not possible thoroughly to consume the whole of the fuel in this way. Of the volatile constituents of the coal, a portion always passes off unburnt in the shape of carburetted hydrogen, tar, and soot, whilst, of the carbon or fixed constituents, part is constantly lost in the form of carbonic oxide gas. So that no real estimate of the calorific value of a coal can be arrived at in this way, and even comparative experiments are worthless from the great inequalities which prevail in the ratio of the volatile and fixed ingredients in different coals, as well as from the changes induced by accidental variations of draught through the body of the fuel. Of course the same objections apply to what are called practical experiments, conducted with any one particular form of furnace or setting of a boiler. The form of furnace, as is well known, requires to be adapted to the fuel, and not the fuel to the furnace: nevertheless, in the Admiralty experiments already alluded to, the only form of furnace and boiler employed was that called the Cornish setting, though this particular form was expressly invented for, and will, as is notorious, do justice to no other kind of coal than anthracite. Hence the parliamentary reports which chronicles the results of the Procrustean theorem, though yet almost wet from the press, is even now rapidly on its road to the butter-shop, there to expiate, by the humblest of services, its previous utter inutility to the public. To know the precise amount of heat evolved from coals during their combustion, must, as has been before remarked, be a subject of the greatest possible interest, for until the total calorific power be taken into account, it is impossible for us to appreciate the loss which ensues under the existing modes of consuming fuel. At present it seems generally agreed, that ordinary Newcastle coal will evaporate about 8 times its weight of water, or in other words, that a ton of such coal will boil off or convert into steam 17,920 lbs. of water. If, however, we proceed to a practical analysis of this very coal, by examining the heating power of its gaseous and fixed constituents, after these have been separated from each other, we shall find that the above is very far short of the most moderate estimate that can be formed of the heat which must be disengaged; and whether the difference be lost by imperfect combustion, or by the action of the chimney, or in what other way, remains still to be decided by those who seek to improve our present modes of consuming fuel. The following table represents the actual heat evolved, and of water evaporated, by the different constituents of one ton of the Newcastle coal called Pelton; and it must be remembered, that so far as chemical research has yet gone, the heat evolved from a combustible is in proportion to the amount of oxygen consumed, and has no connection with the particular mechanical state of the combustible. For instance, there is no reason to suppose that gaseous carbon, if we possessed such a substance, would evolve either more or less heat than its equivalent weight of solid carbon, in combining with the same quantity of oxygen gas. Whether, therefore, we regard the constituents of coal as existing in the solid or gaseous

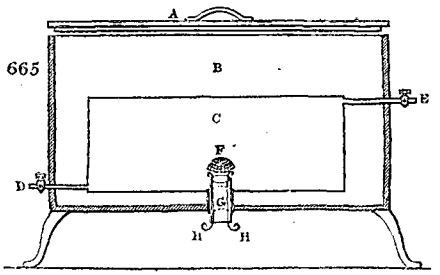
form, does not, according to our present knowledge, alter the proportion of heat which these constituents would give out during their perfect oxidation. Now one ton of Pelton coal affords

10,000 cubic feet of gaseous matters,
10 gallons or about 125 lbs. of tar,
and 41 bushels or 1680 lbs. of coke;

and, by experiment, it has been found that the above gas before purification will boil off for every cubic foot consumed 10½ ounces of water; that 3 gallons of tar are equal to about one bushel of coke; and that the coke will boil off 10 times its weight of water. Hence we have the total amount of water evaporated as under:

10,000 cubic feet of gas at 10½ ounces per foot	=	6537 lbs.
10 gallons of tar equal to 3·33 bushels of coke	=	1365 lbs.
1680 lbs. of coke at 10 lbs. per lb. - -	=	16800 lbs.
	Total	24702

or upwards of 11 lbs. of water for every lb. of coal. It happens, however, that even this estimate is too low, and that actual experiments on this very coal shows its true heating power to be not less than 12. To elucidate this it becomes necessary, however, to enter into an explanation of the means employed for ascertaining the precise amount of heat evolved by any combustible during its complete oxidation, and which is perhaps the only approach to accuracy that has yet been proposed with this view. A copper vessel, shaped like a parallelogram, and having in its ends two small openings provided with stop cocks, has also in its lower surface a large opening of two inches in diameter, terminating in a tube or neck of about two inches in length and fitted with an earthenware plug or stopper. This parallelogram is enclosed in another and larger one, capable of holding in addition 20 lbs. of water. The smaller vessel should have an internal capacity of about half a cubic foot, or 800 cubic inches, and the different openings must pass out of and through the larger vessel. The earthenware stopper is to be provided with two small openings, in which pass two insulated copper wires, and on the top of the stopper is a cavity capable of holding 50 grains of coal in coarse powder, through which a fine platinum wire passes connected with the terminal ends of the two copper wires, and over the whole a cage of stout platinum wire is placed so as to prevent the coal from being thrown out during the experiment, and also to insure the complete combustion of all the volatile and fuliginous matter. To use this apparatus, 50 grains of the coal in question are placed in the cavity of the stopper, and the necessary connections being made by means of a fine platinum wire, the cage is applied, and the whole inserted in the neck or opening left for it, and which it hermetically closes: as soon as this is completed, a current of oxygen gas is made to traverse the smaller vessel by means of the stop-cocks in the sides, and this is continued until the atmospheric air being almost wholly expelled, the vessel remains full of oxygen gas; when this is the case water must be poured into the larger vessel, and a piece of ice introduced into it until the temperature has fallen about 5° below that of the apartment, when the ice must be withdrawn, and the coal lighted by means of a small galvanic battery, the poles of which need be applied for but a moment to the copper wires which pass through the earthenware stopper. Ignition instantly ensues, and is finished in two or three seconds, when the heat of the water in the larger vessel must be ascertained by a delicate thermometer, after proper agitation. It is of course necessary to take the usual precautions followed in experiments of this kind, and to surround the whole of the larger vessel by non-conductors of caloric, having carefully determined beforehand the absorption of heat due to the apparatus, so that this may be added to that of the water; the water itself should either be actually weighed or measured with great accuracy at a mean temperature, and the ice must also be weighed before and after immersion. The accompaning sketch in section will perhaps facilitate the comprehension of this instrument.



"A, cover made of wood; B, larger vessel of copper; C, smaller vessel of copper; D, entrance for oxygen gas; E, exit for atmospheric air; F, platinum cage; G, earthenware stopper with cavity in top; H H, copper wires for conveying electricity, between the upper extremities of which a fine platinum wire is loosely stretched, which passes through the mass of powdered coal.

The results hitherto obtained by this apparatus are not very extensive, but nevertheless they embrace sub-

stantially many of the best established coals, and as might *à priori* be imagined, they moreover demonstrate in an undeniable manner the superiority of bituminous over anthracitic coals and coke, — a position directly the reverse of the absurd assumptions and foregone conclusions contained in the parliamentary report of Sir H. de la Beche and Dr. Playfair. The following is a tabular view of these results, with a column showing the evaporative power of each, deduced by assuming 980 as the latent heat of steam.

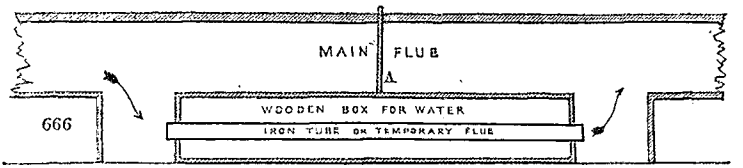
Comparing these results with the actual working of most of the above bituminous coals, it appears that very nearly one half of all the heat evolved is lost in practice, and either passes off in the shape of unconsumed fuel, or is wasted in the chimney. With a view to ascertain how much of the loss is due to this latter circumstance, Mr. F. J. Evans, the eminent engineer of the Westminster station of the Chartered Gas Company, made some time ago an experiment bearing upon this subject, and in which the loss of heat is necessarily very high, from the fact that the substance heated by the furnace was almost white hot, whereas in a steam boiler the temperature never exceeds 300° of Fahr. Mr. Evans's experiment, which shows no trifling amount of ingenuity, nevertheless demonstrates that not more than 3 per cent. of the fuel passes off by the heat of the chimney; consequently at least 15 times this amount must be lost by imperfect combustion, and fly away in the shape of carburetted hydrogen, tarry vapour, or carbonic oxide; thus leaving a wide field for improvement in burning and applying fuel. We give the following in Mr. Evans's own words.

"'Experiments on waste heat: to determine the quantity of heat going away to the chimney from a setting of 8 retorts. A deal box was constructed of the following dimensions; length 5 feet 6 inches, width 11 inches, and depth 7 inches, and quite water-tight. Within this box, and running through it, was placed an iron tube of the following dimensions; length 81 inches, width 9 inches, depth 3 inches. This tube formed by subsequent arrangement a portion of the flue through which the air from the furnace passed to the chimney, as is shown in the sketch below, where A represents an iron plate closing the main flue, and compelling the hot air to pass through the iron tube contained in the wooden box, into which water was ultimately placed, as will be explained.



"'Matters being thus arranged, and the iron plate at A securely fixed, it necessarily followed that all the heat from the setting of 8 retorts passed through the 81 inches of iron tube contained in the box, and would therefore impart heat to the water placed in that box, which was filled with this fluid at 71° Fahr. to the extent of 112 lbs. This water being kept in constant motion afforded the annexed thermometric indications.

	Temperature of Water.
Commenced experiment at 6·45 - - - - -	71°
Observation made at 6·48 - - - - -	82
" 6·51 - - - - -	94
" 6·54 - - - - -	110
" 6·57 - - - - -	114
" 7·01 - - - - -	132
" 7·06 - - - - -	148
" 7·07 - - - - -	150

Thus showing that 112 lbs. of water were raised 89° in 22 minutes, which is equal to 2·52 lbs. of water at 32° made to boil in each minute. Consequently in 24 hours 3628·8 lbs. of such water might be made to boil, or 604·1 lbs. of water be converted into steam in the same period of time, and as coke will evaporate, according to Lavoisier, more than 10 times its weight of water, this implies the consumption of nearly 60½ lbs. of coke, the heat of which is entirely lost in the chimney. And if this be compared with the total coke consumed for 24 hours in the same setting of retorts, it amounts to about 3 per cent. only, and is therefore under the circumstances remarkably trifling.' Hence it would appear, as has been before remarked, that some very considerable improvements are needed in the present mode of consuming bituminous coals. The probability is, that a flat boiler surface exposed freely to a single sheet of flame from such coals is the best form, for it is certain that long narrow flues act like the meshes of wire gauze upon the volatile constituents, and cool them down below the point at which ignition can go on. In support of this view we have only to recollect that though the gases from a blast furnace will burn freely when they first issue from the furnace and are white hot, yet after being once cooled down to the ordinary temperature they refuse altogether to burn or afford heat. The use of long and narrow flues, with combustibles of low accendibility, is therefore highly improper, and sufficiently explains the miserable results arrived at by the Admiralty coal investigators with a Cornish boiler." — *Mr. L. Thompson.*

FULGURATION; designates the sudden brightening of the melted gold and silver in the cupel of the assayer, when the last film of vitreous lead and copper leaves their surface.

FULLER'S EARTH, (*Terre à foulon, Argile Smectique*, Fr.; *Walkererde*, Germ.) is a soft, friable, coarse or fine grained mass of lithomarge clay. Its colour is greenish, or yellowish gray; it is dull, but assumes a fatty lustre upon pressure with the fingers, feels unctuous, does not adhere to the tongue, and has a specific gravity varying from 1·82 to 2·19. It falls down readily in water, into a fine powder, with extrication of air bubbles, and forms a non-plastic paste. It melts at a high heat into a brown slag. Its constituents are 53·0 silica; 10 0 alumina; 9·75 red oxide of iron; 1·25 magnesia; 0·5 lime; 24 water, with a trace of potash. Its cleansing action upon woollen stuffs depends upon its power of absorbing greasy matters. It should be neither tenacious nor sandy; for in the first case, it would not diffuse itself well

through water, and in the second it would abrade the cloth too much. The finely divided silica is one of its useful ingredients.

Fuller's earth is found in several counties of England; but in greatest abundance in Bedfordshire, Berkshire, Hampshire, and Surrey.

In the county of Surrey there are great quantities of fuller's earth found about Nutfield, Ryegate, and Blechingley, to the south of the Downs, and some, but of inferior quality, near Sutton and Croydon, to the north of them. The most considerable pits are near Nutfield, between which place and Ryegate, particularly on Redhill, about a mile to the east of Ryegate, it lies so near the surface as frequently to be turned up by the wheels of the waggons. The fuller's earth to the north of the road between Redhill and Nutfield, and about a quarter of a mile from the latter place, is very thin; the seam in general is thickest on the swell of the hill to the south of the road. It is not known how long this earth has been dug in Surrey; the oldest pit now wrought is said to have lasted between 50 and 60 years, but it is fast wearing out. The seam of fuller's earth dips in different directions. In one if not in more cases, it inclines to the west with a considerable angle. There are two kinds of it, the blue and the yellow; the former, on the eastern side of the pit, is frequently within a yard of the surface, being covered merely with the soil—a tough, wet, clayey loam. A few yards to the west, the blue kind appears with an irony sandstone, of nearly two yards in thickness, between it and the soil. The blue earth in this pit is nearly 16 feet deep. In some places the yellow kind is found lying upon the blue; there seems, indeed, to be no regularity either in the position or inclination of the strata where the fuller's earth is found, nor any mark by which its presence could be detected. It seems rather thrown in patches than laid in any continued or regular vein. In the midst of the fuller's earth are often found large pieces of stone of a yellow colour, translucent and remarkably heavy, which have been found to be sulphate of barytes, encrusted with quartzose crystals. These are carefully removed from the fuller's earth, as the workmen say they often spoil many tons of it which lie about them. There is also found with the yellow fuller's earth a dark brown crust, which the workmen consider as injurious also. In Surrey the price of fuller's earth seems to have varied very little, at least for these last 80 years. In 1730, the price at the pit was 6*d.* a sack, and 6*s.* per load or ton. In 1744, it was nearly the same. It is carried in waggons, each drawing from three to four tons, to the beginning of the iron railway near Westham, along which it is taken to the banks of the Thames, where it is sold at the different wharfs for about 25*s.* or 26*s.* per ton. It is then shipped off either to the north or west of England.

The next characteristic stratum, owing to its forming a ridge of conspicuous hills through the country, is the Woburn land, a thick ferruginous stratum, which below its middle contains a stratum of fuller's earth. This is thicker and more pure in Apsley and Hogstye-end, two miles north-west of Woburn, than in any known place.

Fuller's earth is found at Tillington, and consumed in the neighbouring fulling mills.

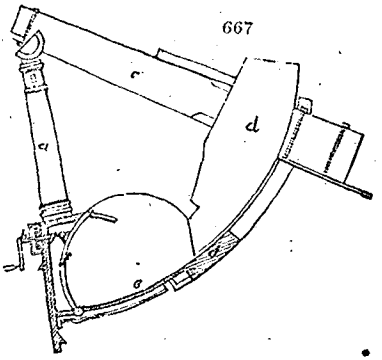
Mode of preparing Fuller's Earth.—After baking it is thrown into cold water, where it falls into powder, and the separation of the coarse from the fine is effectually accomplished, by a simple method used in the dry colour manufactories, called washing over. It is done in the following manner: Three or four tubs are connected on a line by spouts from their tops; in the first the earth is beat and stirred, and the water, which is continually running from the first to the last through intermediate ones, carries with it and deposits the fine, whilst the coarse settles in the first. The advantages to be derived from this operation are, that the two kinds will be much fitter for their respective purposes of cleansing coarse or fine cloth; for without baking the earth they would be unfit, as before noticed, to incorporate so minutely with the water in its native state; it would neither so readily fall down, nor so easily be divided into different qualities, without the process of washing over. When fuel is scarce for baking the earth, it is broken into pieces of the same size, as mentioned above, and then exposed to the heat of the sun.

The various uses of fuller's earth may be shortly explained. According to the above method, the coarse and fine of one pit being separated, the first is used for cloths of an inferior, and the second for those of a superior quality. The yellow and the blue earths of Surrey are of different qualities naturally, and are, like the above, obtained artificially, and used for different purposes. The former, which is deemed the best, is employed in fulling the kerseymeres and finer cloths of Wiltshire and Gloucestershire, whilst the blue is principally sent into Yorkshire for the coarser cloths. Its effects on these cloths is owing to the affinity which alumina has for greasy substances: it unites readily with them, and forms combinations which easily attach themselves to different stuffs, and thereby serve the purposes of mordants in some measure. The fullers generally apply it before they use the soap.

FULLING; for the theory of the process, see Felting, and Wool.

FULLING MILL. William & Ogle obtained a patent in 1825 for improved ful-

667



ling machinery, designed to act in a similar way to the ordinary stocks, in which cloths are beaten, for the purpose of washing and thickening them; but the standard and the bed of the stocks are made of iron instead of wood as heretofore; and a steam vessel is placed under the bed, for heating the cloths during the operation of fulling; whereby their appearance is said to be greatly improved.

Fig. 667. is a section of the fulling machine or stocks; *a*, is a cast-iron pillar, made hollow for the sake of lightness; *b*, is the bed of the stocks, made also of iron, and polished smooth, the side of the stock being removed to show the interior; *c*, is the lever that carries the beater *d*. The cloths are to be placed on the bed *b*, at bottom, and water allowed to pass through the stock, when by the repeated blows of the beater *d*, which is raised and let fall in the usual way, the cloths are beaten, and become cleansed and fulled.

A part of the bed at *e*, is made hollow, for the purpose of forming a steam box, into which steam from a boiler is introduced by a pipe with a stop-cock. This steam heats the bed of the stock, and greatly facilitates, as well as improves, the process of cleansing and fulling the cloths.

The smoothness of the surface of the polished metal, of which the bed of the stock is constituted, is said to be very much preferable to the roughness of the surface of wood of which ordinary fulling stocks are made, as by these iron stocks less of the nap or felt of the cloth is removed, and its appearance when finished is very much superior to cloths fulled in ordinary stocks.

In the operation of fulling, the cloths are turned over on the bed, by the falling of the beaters, but this turning over of the cloths will depend in a great measure upon the form of the front or breast of the stock. In these improved stocks therefore, there is a contrivance by which the form of the front may be varied at pleasure, in order to suit cloths of different qualities; *f*, is a movable curved plate, constituting the front of the stock; its lower part is a cylindrical rod, extending along the entire width of the bed, and being fitted into a recess, forms a hinge joint upon which the curved plate moves; *g*, is a rod attached to the back of the curved plate *f*, with a screw thread upon it; this rod passes through a nut *h*, and by turning this nut, the rod is moved backward or forward, and consequently, the position of the curved plate altered.

The nut *h*, is a wheel with teeth, taking into two other similar toothed wheels, one on each side of it, which are likewise the nuts of similar rods jointed to the back of the curved plate *f*; by turning the central wheel, therefore, which may be done by a winch, the other two wheels are turned also, and the curved plate moved backward or forward. At the upper part of the plate there are pins passing through curved slots, which act as guides when the plate is moved.

The patentees state in conclusion, that steam has been employed before for heating cloths while fulling them; they therefore do not exclusively claim its use, except in the particular way described; the advantages arising from the construction of iron stocks, with polished surfaces in place of wooden ones, together with the movable curved plates described, are in their opinion "sufficiently important to constitute a patent right."

FULMINATES, or *Fulminating Powders*. Of these explosive compounds, there are several species; such as fulminating gold, mercury, platinum, silver; besides the old fusible mixture of nitre, sulphur, and potash. The only kind at all interesting in a manufacturing point of view is the fulminate of mercury, now so extensively used as a priming to the caps of percussion locks. Having published a paper in the Journal of the Royal Institution for 1831, upon gunpowder (see GUNPOWDER), the result of an elaborate suite of experiments, I was soon afterwards requested by the Hon. the Board of Ordnance to make such researches as would enable me to answer, in a satisfactory practical manner, a series of questions upon fulminating powders, subservient to the future introduction of percussion musquets into the British army. The following is a verbatim copy of my report upon the subject:—

To the Secretary of the Board of Ordnance.

SIR,—I have the honour of informing you, for the instruction of the Honourable the Master General and the Board of Ordnance, that the researches on fulminating mercury, which I undertook by their desire, have been brought to a satisfactory conclu-

sion, after a numerous, diversified, and somewhat hazardous series of experiments. The following are the questions submitted to me, with their respective answers: —

Question 1. What proportions of mercury, with nitric acid and alcohol of certain strengths, will yield the greatest quantity of pure fulminate of mercury?

Answer. One hundred parts, by weight, of mercury, must be dissolved with a gentle heat, in 1000 parts (also by weight) of nitric acid, spec. gr. 1·4; and this solution, at the temperature of about 130° Fahr. must be poured into 830 parts by weight of alcohol, spec. gr. 0·830. — *Note.* 830 parts of such alcohol, by weight, constitute 1000 by measure; and 1000 parts of such nitric acid, by weight, constitute 740 by measure. Hence, in round numbers, one ounce weight of quicksilver must be dissolved in 7½ oz. measures of the above designated nitric acid, and the resulting solution must be poured into 10 oz. measures of the said alcohol.

Question 2. What is the most economical and safe process for conducting the manipulation, either as regards the loss of nitrous gas and residuum, or as respects danger to the operator; also, what is the readiest and safest mode of mixing the fulminate intimately with its due proportions of common gunpowder.

Answer. The mercury should be dissolved in the acid in a glass retort, the beak of which is loosely inserted into a large balloon or bottle of glass or earthenware, whereby the offensive fumes of the nitrous gas disengaged during the solution are, in a considerable measure, condensed into liquid acid, which should be returned into the retort. As soon as the mercury is all dissolved, and the solution has acquired the prescribed temperature of about 130°, it should be slowly poured, through a glass or porcelain funnel, into the alcohol contained in a glass matrass or bottle capable of holding fully 6 times the bulk of the mixed liquids. In a few minutes bubbles of gas will proceed from the bottom of the liquid; these will gradually increase in number and magnitude till a general fermentative commotion, of a very active kind, is generated, and the mixture assumes a somewhat frothy appearance. A white voluminous gas now issues from the orifice of the matrass, which is very combustible, and must be suffered to escape freely into the air, at a distance from any flame. These fumes consist of an ethereous gas, holding mercury in suspension or combination. I have made many experiments with the view of condensing this gas, or, at least, the mercury, but with manifest disadvantage to the perfection of the process of producing fulminate. When the said gas is transmitted, through a glass tube, into a watery solution of carbonate of soda, a little oxide of mercury is, no doubt, recovered; but the pressure on the fermentative mixture, though slight, necessary to the displacement of the soda solution, seems to obstruct or impair the generation of the fulminate; this effect is chiefly injurious towards the end of the operation when the gaseous fumes are strongly impregnated with nitrous gas. When this is not allowed freely to come off, a portion of subnitrate or nitrate of mercury is apt to be formed, to the injury of the general process and the product.

As soon as the effervescence and concomitant emission of gas are observed to cease, the contents of the matrass should be turned out upon a paper double filter, fitted into a glass or porcelain funnel, and washed by the effusion of cold water till the drainings no longer redden litmus paper. The powder adhering to the matrass should be washed out and thrown on the filter by the help of a little water. Whenever the filter is thoroughly drained, it is to be lifted out of the funnel, and opened out on plated copper or stone ware, heated to 212° Fahr. by steam or hot water. The fulminate being thus dried, is to be put up in paper parcels of about 100 grains each; the whole of which may be afterwards packed away in a tight box, or a bottle with a cork stopper. The excellence of the fulminate may be ascertained by the following characters. It consists of brownish-gray small crystals which sparkle in the sun, are transparent when applied to a slip of glass with a drop of water, and viewed by transmitted light. These minute spangles are entirely soluble in 130 times their weight of boiling water; that is to say, an imperial pint of boiling water will dissolve 67 grs. of pure fulminate. Whatever remains indicates impurity. From that solution beautiful pearly spangles of fulminate fall down as the liquid cools.

It may now be proper to show within what nice and narrow limits the best proportions of the ingredients used in making the fulminate of mercury lie. The following are selected from among many experiments instituted to determine that point, as well as the most economical process.

1. According to the formula given by the celebrated chemist Berzelius, in the 4th vol. of his "Traité de Chimie," the mercury should be dissolved in twelve times its weight of nitric acid sp. gr. 1·375; and alcohol of sp. gr. 0·850, amounting to 16·3 times the weight of the mercury, should be poured at intervals into the nitric solution. The mixture is then to be heated till effervescence with the characteristic cloud of gas appears. On the action becoming violent, alcohol is to be poured in from time to time to repress it, till additional 16·3 parts have been employed.

On this process I may remark, that it is expensive, troublesome, dangerous, and unproductive of genuine pure fulminate. One fifth more nitric acid is expended very

nearly than what is necessary, and almost four times the weight of alcohol which is beneficial. Of alcohol at 0·83, 8·3 parts by weight are sufficient; whereas Berzelius prescribes nearly 4 times this quantity in weight, though the alcohol is somewhat weaker, being of sp. gr. 0·850. By using such an excess of alcohol, much of the fulminate is apt to be revived into globules of quicksilver at the end of the process, as I showed in my paper on this subject published in the Journal of the Royal Institution 30 years ago. There is no little hazard in pouring the alcohol into the nitric solution; for at each effusion an explosive blast takes place, whereas by pouring the solution into the alcohol, as originally enjoined by the Hon. Mr. Howard, the inventor of the process, no danger whatever is incurred. 100 parts of mercury treated in the way recommended by Berzelius afforded me only 112 parts of fulminate, instead of the 130 obtained by my much more economical and safe proportions and process from the same weight of quicksilver.

2. If 10 parts of nitric acid of sp. gr. 1·375 be used for dissolving 1 of quicksilver, and if 14 parts of alcohol of sp. gr. 0·85 be afterwards mixed with the solution, the product of such proportions will either be not granular, and therefore not fulminating, or it will be partially granular and partially pulverulent, being a mixture of fulminate and subnitrate of mercury ill adapted for priming detonating caps. Instead of 130 parts of genuine fulminate, as I do obtain, probably not more than 10 parts of powder will be produced, and that of indifferent quality. In fact, whenever the ethereous fermentation is defective, or not vigorous, little true fulminate is generated; but much of the mercury remains in the acidulated alcoholic liquid.

3. If the alcohol be poured in successive portions, and of proper strength (sp. gr. 0·83) into a proper nitric solution of mercury, the explosive action which accompanies each effusion dissipates much of the alcohol, and probably impairs the acid, so that the subsequent etherous fermentation is defective, and little good fulminate is formed. From 100 parts of mercury submitted to this treatment, I obtained in one experiment carefully made, only 51 parts of a powder, which was impalpable, had a cream colour, and was not explosive either by heat or percussion.

4. When, with 100 parts of mercury, 800 of nitric acid of sp. gr. 1·375 are employed with 650 of alcohol of sp. gr. 846, no fulminate whatever is generated.

5. When with the proper proportions of mercury, acid, and alcohol, the process is advanced into a proper energy of fermentative commotion, if the matrass be immersed in cold water so as materially to repress that action, the process will be impaired, and will turn out ultimately defective both as to the quantity and quality of the fulminate. It is therefore evident that a certain energy or vivacity of etherization is essential to the full success of this curious process, and that any thing which checks it, or obstructs its taking place, is injurious and to be avoided.

When my proportions are observed in making fulminating mercury, somewhat less than one-fourth of the nitric acid used in making the solution remains in the alcoholic mixture along with the fulminate. When other proportions are taken, much more acid remains. This acid is not recoverable to any useful or economical purpose, nor is the alcohol that is associated with it. Many distillations with various reagents have led me to this practical conclusion. In fact, when the process is most complete, as described in the first paragraph, the alcohol is entirely and profitably employed in etherization, and generating fulminic acid.

I have made a series of analytical experiments on the pure fulminate of mercury, with the view of determining its composition, the quantity of quicksilver present in it, and consequently the loss of mercury in the operation. I have stated that my maximum product of fulminate from 100 grs. of quicksilver is 130 grs. Occasionally from slight differences in the temperature of the mixture, or the ambient atmosphere, 2 grs. less may be obtained.

A. I dissolved 130 grs. with a gentle heat in muriatic acid contained in a small matrass, adding a few drops of the nitric to quicken the solution. On evaporating it to dryness, with much care to avoid volatilization of the salt, I obtained 125 grs. of corrosive sublimate or bi-chloride of mercury. But 125 grs. of this bi-chloride contain only 91·1 grs. of quicksilver. Therefore, by this experiment, 130 grs. of fulminate contain no more than 91·1 of mercury, indicating an exhalation of 8·9 parts in the form of fumes, or a retention in the residuary liquid of some of these 8·9 parts, out of the 100 originally employed.

B. In another experiment for analysis, 130 grs. dissolved as above, were thrown down by carbonate of soda. 95 grs. of black oxide of mercury were obtained, which are equivalent to 91·2 grs. of quicksilver; affording a confirmation of the preceding result.

C. 130 grs. of fulminate were dissolved in strong muriatic acid, and the solution was decomposed by crystals of proto-muriate of tin at a boiling temperature. The mercury was precipitated in globules to such amount as to verify the two preceding experiments.

Regarding fulminate of mercury as a bi-cyanate, that is, as a compound of one atom

or one equivalent prime of deutoxide of mercury, and two primes of cyanic acid, we shall find its theoretical composition to be as follows, hydrogen being the radix, or 1.

2 Primes of Cyanic or fulminic Acid	= 34 × 2	= 68	24
1 Deutoxide of Mercury	=	216	76
		284	100

As these 284 parts of fulminate contain 200 of quicksilver, so 142 parts of fulminate will contain 100 of quicksilver. Whence it appears, that when only 130 parts of fulminate can be obtained in practice from 100 of quicksilver, 8½ parts of quicksilver out of the 100 are unproductive, that is, are expended in the etherized gas, or left in the residuary acidulous liquid. By the above experimental and theoretical analysis, 91·5 parts of quicksilver enter into the composition of 130 parts of true crystalline fulminate. The complete accordance here exhibited between theory and practice removes every shadow of doubt as to the accuracy of the statements. 100 parts of fulminate consist of—

Mercury	70·4	Peroxide	76·0
Oxygen	5·6		
Fulminic acid -	-	-	24
			100·0

Question 3. May the gas or vapour produced by the inflammation of the fulminate of mercury, when combined with a portion of gunpowder, be considered in its nature corrosive of iron or brass?

Answer. I have suggested to Mr. Lovell, of the Tower of London, that the fulminate may be probably diluted most advantageously with spirit varnish made of a proper consistence by dissolving sandarach in alcohol. When well mixed with this varnish, a small drop of the mixture will suffice for priming each copper cap or disc; and as the spirit evaporates immediately, the fulminate will be fixed to the copper beyond the risk of shaking or washing away. On the Continent, tincture of benjamin is used for the same purpose; but as that balsamic resin leaves in combustion a voluminous coal, which sandarach does not, the latter, which is the main constituent of spirit varnish, seems better adapted for this purpose. It is sufficiently combustible, and may be yet made by a due proportion, to soften the violence of the explosive mercury on the nipple of the touch-hole. Fulminate prepared by my formula has no corrosive influence whatsoever on iron or steel; and, therefore, if such a medium of applying it, as I have now taken leave to suggest, should be found to answer, all fears on the score of corrosion may for ever be set at rest.

Question 4. How far is the mixture (of fulminate and gunpowder) liable to be affected by the mixture of the atmosphere, or by the intrusion of water; and will such an accident affect its inflammability when dried again?

Answer. Well made fulminate, mixed with gunpowder and moistened, undergoes no change, nor is it apt to get deteriorated by keeping any length of time in a damp climate or a hazy atmosphere. Immersion in water would be apt to wash the nitre out of the pulverine; but this result would be prevented if the match or priming mixture were liquefied or brought to the pasty consistence not with water, but spirit varnish. Such detonating caps would be indestructible, and might be alternately moistened and dried without injury.

Question 5. Is it at all probable that the composition would be rendered more inflammable or dangerous of use, by the heat of tropical climates?

Answer. No elevation of temperature of an atmospheric kind compatible with human existence, could cause spontaneous combustion of the fulminating mercury, or the detonating matches made with it. In fact, its explosive temperature is so high as 367° of Fahrenheit's scale, and no inferior heat will cause its detonation.

Question 6. Is the mercurial vapour or gas arising from the ignition of a great number of primers, and combined with the smoke of gunpowder in a confined space (as in the case of troops in close bodies, squares, casemates, &c.) likely in its nature to be found prejudicial to human health?

Answer. I have exploded in rapid succession of portions, 100 grains of fulminate of mercury (equivalent to 300 or 400 primers), in a close chamber of small dimensions, without experiencing the slightest inconvenience at the period, or afterwards, though my head was surrounded by the vapours all the time of the operation. These vapours are, in fact, so heavy that they subside almost immediately. When the fulminate mixed with pulverine is exploded in the primers by condensed masses of troops, the mercury will cause no injury to their health, nor one 100th part of the deleterious impression on weak lungs which the gases of exploded gunpowder might by possibility inflict. These gases are all, *theoretically* speaking, noxious to respiration; such as carbonic acid gas, azote, carburetted hydrogen, and sulphuretted hydrogen, a deadly gas. Yet the soldier who should betray any fear of gunpowder smoke would be an object of just ridicule.

In the following September, I executed for the Board of Ordnance a set of experiments complementary to those of the memoir, with the view of ascertaining the best manner of protecting the fulminate when applied to the copper caps, from being detached by carriage, or altered by keeping. The following were my results and conclusions.

"1. Fulminate of mercury moistened upon copper is speedily decomposed by the superior affinity of the copper over mercury, for oxygen and fulminic acid. Dryness is, therefore, essential to the preservation of the fulminate; and hence charcoal, which is apt to become moist, should not be introduced into percussion caps destined for distant service.

"2. An alcoholic solution of sandarach, commonly called spirit varnish, acts powerfully on copper, with the production of a green efflorescence, which decomposes fulminate of mercury. Indeed, sandarach can decompose the salts of copper. It is therefore ill adapted for attaching the fulminate to copper caps.

"3. An alcoholic solution of shell-lac acts on copper, though more feebly than the sandarach.

"4. A solution of mastic in spirits of turpentine, when alone or mixed with fulminate, has no action whatever on bright copper, but protects it from being tarnished. Such a varnish is very cheap, dries readily, adheres strongly, screens the fulminate from damp, and does not impair or counteract its detonating powers. This, therefore, is in my opinion the fittest medium for attaching the fulminate, and for softening the force of its impulsion in any degree proportional to the thickness of the varnish."

Fulminate of mercury is obtained in white grains, or short needles, of a silky lustre, which become gray upon exposure to light, and detonate either by a blow or at a heat under 370° F.; with the disengagement of azote, carbonic acid, as also of aqueous and mercurial vapours; to the sudden formation of which gaseous products the report is due. It detonates even in a moist condition; and when dry it explodes readily when struck between two pieces of iron, less so between iron and bronze, with more difficulty between marble and glass, or between two surfaces of marble or glass. It is hardly possible to explode it by a blow with iron upon lead; and impossible by striking it with iron upon wood. It fulminates easily when rubbed between two wooden surfaces; less so between two of marble, two of iron, or one of iron against one of wood or marble. The larger its crystals, the more apt they are to explode. By damping it with 5 per cent. of water, it becomes less fulminating; the part of it struck still explodes with a proper blow, but will not kindle the adjoining portion. Though moistened with 30 per cent. of water, it will occasionally explode by trituration between a wooden muller and a marble slab, but only to a small extent, and never with any danger to the operator. When an ounce of it, laid upon the bottom of a cask, is kindled, it strikes a round hole down through it, as if it had been exposed to a four-pound shot, without splintering the wood. If a train of fulminate of mercury be spread upon a piece of paper, covered with some loose gunpowder, in exploding the former the latter will not be kindled, but merely scattered. When gunpowder, however, is packed in a cartridge, or otherwise, it may be certainly kindled by a percussion cap of the fulminate, and more completely than by a priming of gunpowder. 8½ parts of gunpowder exploded by a percussion cap, have an equal projectile force as 10 exploded by a flint lock. If we add to this economy in the charge of the barrel, the saving of the powder for priming, the advantage in military service of the percussion system will become conspicuous.

The French calculate that 1 kilogramme of mercury will furnish 1¼ kil. (2⅔ lbs. nearly) of fulminate, which will be sufficient to charge 40,000 percussion caps. For this purpose they grind the crystalline salt along with 30 per cent. of water upon a marble table with a wooden muller; mixing with every 10 parts of the fulminate 6 of gunpowder. A consistent dough is thus obtained, which, being dried in the air, is ready for introducing into the bottoms of the copper caps. One quarter of a grain of the fulminate is said to be fully sufficient for one priming.

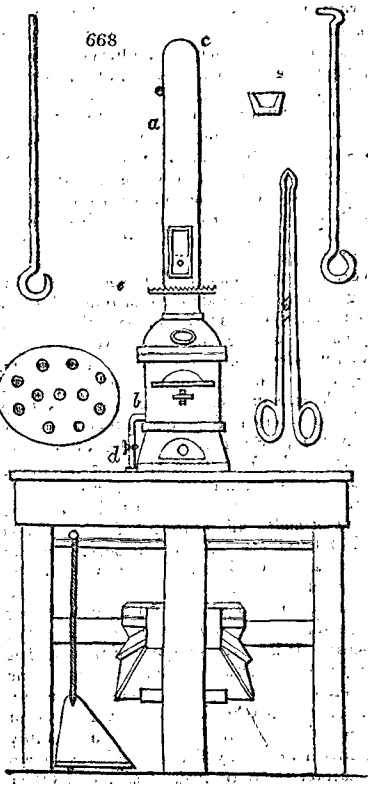
Mr. Lovell, of the Royal Manufactory of Arms, has lately executed a series of experiments upon priming powders. His trials, which occupied nearly 18 months, were made for the purpose of ascertaining what is the advantage in point of *force* obtained by using percussion primes. He had anticipated some extra energy would be imparted to the charge of powder in the barrel, because he had repeatedly proved that a good strong cap, exploded by itself on the nipple of the musquet (without any charge of gunpowder), will exert sufficient force upon the air within the barrel to blow a candle out at a distance of 12 feet from the muzzle. He concluded also that stopping the escape of fluid from the vent, as is done by the cap, would have some effect, but he attributed most to the quickness and energy with which the powder of the charge is ignited by the vivid stream of flame, generated by the percussion prime. The trials were made from one and the same barrel, having a percussion lock on one side and a flint lock on the other. The balls were fired against Austen's recoiling target, a very delicate *plegometer*, beginning with a charge of 150 grains (the present musquet charge), and

descending by 10 grains at a time (firing 30 rounds with each weight), down to 50 grains. The machine marked the decrease of force at each reduction in the charge very satisfactorily, and the result of the whole average was that 8·84 parts of gunpowder fired by percussion are equal to 10 parts fired by the flint.

To find out what sort of liberties might be taken with fulminate of mercury in handling it, he placed 3 grains on an anvil, putting the end of a steel punch gently on the top of it, and while so placed he covered the fulminate over with a drachm of dry gunpowder. He then ignited the fulminate by a blow on the punch with the hammer, but not a grain of the gunpowder was lighted, though it was blown about in all directions. He then placed a train of fulminate as thick as a quill, and about 3 feet long, on a table, and covered it over entirely with gunpowder except about an inch at one end; this he lighted with a hot iron, when the whole train went off without blazing a grain of the gunpowder, which he swept together and blew up afterwards with a match. He then took a tin box containing 500 copper caps, made a hole in the top of the box, and through this hole ignited one of the caps in the middle, by means of the punch and hammer on the outside; only two other caps besides the one struck exploded; no injury was sustained by the remainder, except being discoloured. This he tried repeatedly, and always with the same kind of result, never more than 3 or 4 caps exploding. He then made a steel rammer red hot, and passed it through the hole in the box right in amongst the caps, but it only ignited them where the iron came in actual contact with the priming composition; when, however, he placed a few grains of gunpowder loose among the caps, the hot iron lighted this, and produced a flame that blew off the whole of them.

The same thing has been tried at Woolwich, where large packages of percussion caps (some thousands) have been fired at with musquet balls, and only a few of the caps actually hit by the ball exploded; but when any cartridges were connected with the packages, the whole, caps and all, were blown up. The flame of the fulminate is therefore hazardous, but being so very ethereal, it requires for making primes an admixture of some combustible matter, as a little gunpowder, to condense or modify the flame.

FULMINIC ACID; (*Acid fulminique*, Fr.; *Knallsaure*, Germ.) is the explosive constituent of the fulminating mercury of Howard, and the fulminating silver of Brugnatelli, being generated by the reaction of alcohol and the acid nitrates of these metals. It is a remarkable chemical fact, that fulminic acid has exactly the same composition as cyanic acid; though the salts of the latter possess no detonating property, and afford, in their decomposition by an oxygen acid, ammonia with carbonic acid; while those of the former afford ammonia and prussic acid. All attempts to insulate fulminic acid have proved unsuccessful, as it explodes with the slightest decomposing force. It consists, by weight, of 2 primes of carbon, 1 of azote, and 1 of oxygen; or of two volumes of carbonic acid, and one of azote. When two different bodies, like the above, have the same composition, they are said to be *isomeric*.



FUMIGATION, is the employment of fumes or vapours to purify articles of apparel, and goods or apartments supposed to be imbued with some infectious or contagious poison or fumes. The vapours of vinegar, the fumes of burning sulphur, explosion of gunpowder, have been long prescribed and practised, but they have in all probability little or no efficacy. The diffusion of such powerful agents as chlorine gas, muriatic acid gas, or nitric acid vapour, should alone be trusted to for the destruction of morbific effluvia.

FUR; see PELTRY.

FURNACE OF ASSAY. Under ASSAY, I have referred to a furnace constructed by Messrs. Anfrye and d'Arcet

which gives some peculiar facilities and economy to the ancient process by fire. It had originally a small pair of bellows attached to it, for raising the heat rapidly to the proper vitrifying pitch. The furnace, 17½ inches high, and 7½ inches wide, made of pottery or fine clay, is represented *fig.* 481., supported upon a table, having a pair of bellows beneath it. The laboratory is at *b*, the blow-pipe of the bellows at *d*, with a stop-cock, and the dome is surmounted by a chimney *a*, *c*, in whose lower part there is an opening with a sliding door, for the introduction of the charcoal fuel. The furnace is formed in three pieces; a dome, a body, and an ash-pit. A pair of tongs, a stoking-hook, and cupel, are seen to the right hand, and the plan of the stone-ware grate, pierced with conical holes, and a poker, are seen to the left. This grate suits the furnace represented under ASSAY. The following are comparative experiments made by means of this furnace:

Numbers.	Silver employed.	Lead employed.	Time of Assay.	Standards.	Charcoal used.
1	1 Grain.	4 Grains.	12 minutes.	947 millièmes.	173 Grains.
2	—	—	11	950	86
3	—	—	13	949	93
4	—	—	10	949	60

Each assay was therefore performed at an average in 11½ minutes, and not much more than a quarter of a pound of charcoal was used. An experiment of verification in the ordinary assay furnace showed the standard to be 949 thousandths.

This furnace becomes a very convenient one for melting small quantities of metals in analyses, by removing the muffle, and closing the several apertures with their appropriate stoppers. A small pedestal may be then set in the middle of the grate, to support a crucible, which may be introduced through the opening *h*. Coke may also be used as fuel, either by itself or mixed with charcoal. For descriptions of various furnaces, see ASSAY; BEER; COPPER; EVAPORATION; IRON; METALLURGY; ORES; SILVER; TIN, &c.

FUR-SKIN DRESSING. Fur-skins are usually dressed by placing them in their dried state in tubs, where they undergo a treading operation with men's feet, until they are sufficiently soft and bend easily. The skins if large are sewn up, the fur being turned inwards; but if small skins, such as ermine, are being dressed, they require no sewing. This sewing is preparatory to the greasing with butter or lard, and is intended to protect the fur from the grease, and to promote the softening in the succeeding treading operation. The skins are next wetted, and their flesh is removed; or they are fleshed and then hung up to dry. They are again subjected to treading in tubs containing sawdust; and afterwards in tubs containing plaster of Paris, or whitening, sprinkled between the skins. They are then beaten with a stick, and combed; when the dressing is completed. M. Pierre Thirion proposes, in his patent of June, 1845, to soften the skins, not by treading, but by beating stocks, of a construction like the fulling mill. They are next sewn up, and again fulled in a strong vessel, where they are forced upwards by the beaters, turned over and over, and thus speedily softened. They are now fleshed, and then returned to the beating stocks, and mahogany or other sawdust is sprinkled upon the fur, before the beating is renewed. They are next placed in a heated barrel, furnished within with radial pins for turning the goods over and over, in order that they may be acted upon by various dry substances, which are thrown into the barrel, and absorb the fat from the skins. Through the hollow shaft of the barrel steam is introduced, which heats the skins, softening the fat, which is then absorbed by sand, flour, or any other desiccative powder. It is proper to take the skins out of the barrel from time to time, to comb them. Such as have been sufficiently acted upon may then be set aside. They are lastly freed from the dust by being subjected to a grated cylinder in a state of rotation, and then combed by hand.

FUSEL OIL is the German name of the offensive smelling oil which exists in alcohol, as distilled from the fermented infusions of malt, and corn meal of all kinds, as also from the fermented wash of potatoes, and of beets, &c. A like oil occurs in the alcohol distilled from the fermented must of grapes, and the juices of many sweet fruits. This oil is not, however, identical from these several sources; as may indeed be inferred from the diversity in the flavours of the different liquors. But they all agree in being somewhat less volatile than water, and therefore make their appearance chiefly in the spirits towards the end of the distillation process. It is to the presence of this oil that the milkiness of the last, and also sometimes of the first, portions of the spirit that come over, called feints, owe their opalescence and their penetrating odour. When the milky fluid is redistilled, alcohol and water first pass over with very little oil, but if the heat of the still be moderate, the oil may be made a residuum, and obtained in a tolerably concentrated state. The oil from potatoes was first analyzed by Dumas, and was shown by him to be composed of 68·2 per cent. of carbon, 13·6 of hydrogen, and 18·2 of oxygen; according to the formula $C_{10}H_{11}O, HO$. It belongs therefore to the class of

alcohols, one whose radical is $C_{10}H_{11}$, or *amyle*, and is an amyl oxyhydrate; just as common alcohol is an oxyhydrate of ethyle. The potato amyle spirit is a colourless fluid of an acrid burning taste, and of a most offensive, penetrating, durable smell. When the vapour of it is inhaled it produces an oppressive nausea, headache, giddiness, and retching. It has a poisonous action on the animal system. By oxydizing agents it is converted into valerianic (Baldrian) acid. According to Balard the amyle spirit occurs along with the ænanthic ether in the oil, which contaminates brandy, and is probably derived from the husks of the grapes. This noxious spirit exists most abundantly in the whisky of malt, and especially in that from raw grain; and is now an article of considerable sale, being used to burn in lamps, to dissolve copal and other resins for varnish making and other purposes.

Besides this liquid amyle spirit corn spirits contain a concrete fatty matter, of a brown colour, an acid reaction, and an offensive smell and taste. It has a green tinge, which I believe is derived from the copper worm of the still. Mulder has shown that this fatty product consists of an easily fusible and a difficultly fusible portion. The former he regards as the ether of ænanthic acid; consisting of 85 carbon, 10·3 hydrogen, and 4·8 oxygen, and is therefore quite different from the amyle spirit. Margaric acid is mixed with the less fusible portion. He says that one million parts of malt whisky contain 30 of ænanthic acid, 9 of ænanthic ether, and 5 of corn oil (amyle spirit). There are probably many varieties of these oils of crude alcohol.

FUSIBILITY. That property by which solids assume the fluid state.

Some chemists have asserted that fusion is simply a solution in caloric; but this opinion includes too many yet undecided questions, to be hastily adopted.

Fusibility of Metals, as given by M. Thenard.

		Centigr.	
1. Fusible below a red heat.	Mercury	—39°	
	Potassium	+ 58°	Gay Lussac and Thenard.
	Sodium	90	Gay Lussac and Thenard.
	Tin	210	Newton.
	Bismuth	256	Newton.
	Lead	260	Biot.
	Tellurium	A little less fusible than lead.—Klaproth.	
	Arsenic	Undetermined.	
	Zinc	370°	Brongniart.
	Antimony	A little below a red heat.	
	Cadmium		Stromeyer.
		Pyrometer of Wedgewood.	
2. Infusible below a red heat.	Silver	20°	Kennedy.
	Copper	27	Wedgewood.
	Gold	32	Wedgewood.
	Cobalt	A little less difficult to melt than iron.	
	Iron	130	Wedgewood.
		158	Sir G. M'Kenzie.
	Manganese	160	Guyton.
	Nickel		As manganese.—Richter.
	Palladium, Molybdenum, Uranium, Tungsten, Chromium, Titanium	Nearly infusible; and to be obtained at a forge heat only in small buttons.	
	Cerium, Osmium, Iridium, Rhodium, Platinum, Columbium	Infusible at the forge furnace. Fusible at the oxyhydrogen blowpipe. See BLOWPIPE.	

FUSIBLE METAL. See ALLOY.

FUSTET. (*Fustec*, Fr.) The wood of the *rhus cotinus*, a fugitive yellow dye.

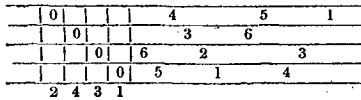
FUSTIAN, is a species of coarse thick tweeled cotton, and is generally dyed of an olive, leaden, or other dark colour. Besides the common fustian, which is known by the name of pillow (probably pilaw), the cotton stuffs called corduroy, velverett, velveteen, thicksett, used for men's wearing apparel, belong to the same fabric. The commonest kind is merely a tweel of four, or sometimes five leaves, of a very close stout texture, and very narrow, seldom exceeding 17 or 18 inches in breadth. It is cut from the loom in half pieces, or ends as they are usually termed, about 35 yards long, and after undergoing the subsequent operations of dyeing, dressing, and folding, is ready for the market.

The draught and cording of common fustian is very simple, being generally a regular or unbroken tweel of four or five leaves. Below are specimens of a few different kinds, selected from those most general in Lancashire.

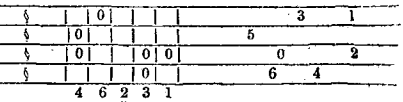
The number of leaves of heddles are represented by the lines across the paper, and the *cording* by the cyphers in the little squares, those which raise every leaf being distinguished by these marks, and those which sink them left blank, as more particularly explained in the article TEXTILE FABRIC.

Of velvet, there are properly only two kinds, that with a plain, and that with a tweeled, or, as it is here called, a Genoa ground, or back. When the material is silk, it is called velvet, when cotton, velveteen; and this is the sole difference. In the same way a common tweeled cloth, when composed of silk is called satin; when of cotton, fustian or jean; of woollen, plaiding, serge, or kerseymere; and in the linen trade is distinguished by a variety of names according to the quality or fineness, or the place where the article is manufactured.

No. 1.—Pillow Fustian.

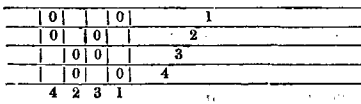


No. 2.—Plain Velveret.

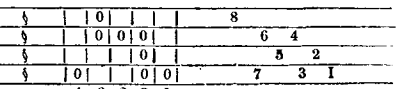


Of the above, each contains four leaves of heddles or healds; that represented by No. 1. is wrought by four treddles, and that which is distinguished by No. 2. by five; the succession of inserting the threads of warp into the heddles will be discovered by the figures between the lines, and the order in which the treddles are to be successively pressed down by the figures below.

No. 3.—Double Jean.

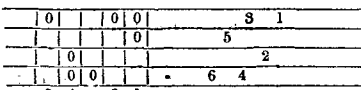


No. 4.—Plain Thicksett.

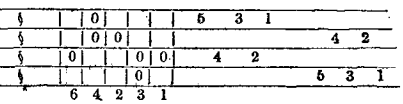


These, like the former, are wrought with leaves. No. 3. requires four, and No. 4. five treddles. The succession of inserting the threads of warp, and of working the treddles, are marked by the respective numbers between and under the lines, as in the former example. Both are fabrics of cloth in very general use and estimation as low priced articles.

No. 5.—Best Thicksett.

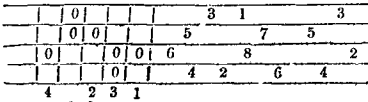


No. 6.—Velvet Tuft.

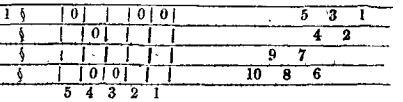


These are further specimens of what may be, and is, executed with four leaves, and in both examples five treddles are used. With two other specimens we shall conclude our examples of this description of work, and shall then add a very few specimens of the more extensive kinds.

No. 7.—Cord and Velveret.

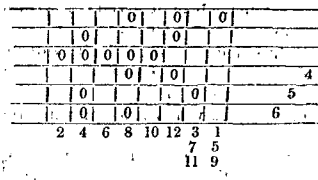


No. 8. Thicksett Cord.

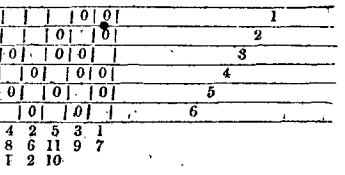


In these the succession of drawing and working are marked like the former. The next are examples of patterns wrought with six leaves. No. 9. has eight, and No. 10. five heddles.

No. 9.—Double Corduroy.

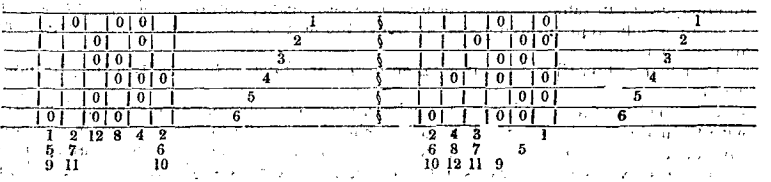


No. 10.—Genoa Thicksett.

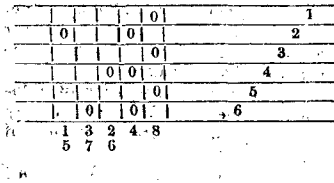


In both these the warp is inserted into the heddles the same way. The difference is entirely in the application of the cords, and in the succession of pressing down the treddles. We now give four specimens of the flushed and cut work, known by the name of velveteen. They are also upon six leaves, and the difference is solely in the cording and in the treading.

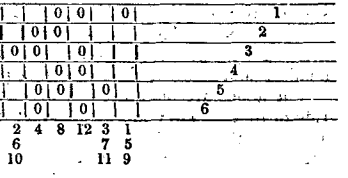
No. 11. Queen's Velveteens. No. 12.



No. 13.—Plain Velveteen.

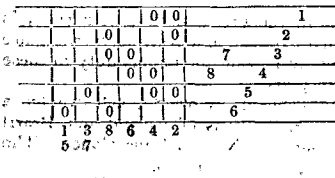


No. 14.—Genoa Velveteen.

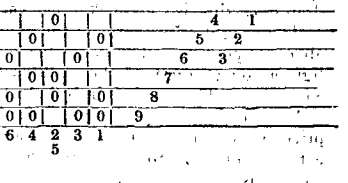


The additional varieties of figure which might be given are almost endless, but the limits of this article will not admit a further detail. Those already given are the articles in most general use. The varieties of fancy may be indulged to great extent, but it is univerally found, that the most simple patterns in every department of ornamental weaving, are those which attract attention and command purchasers. We shall therefore only add two examples of king's cord or corduroy, two of Genoa and common velvet, and two more of jean. These will be found below.

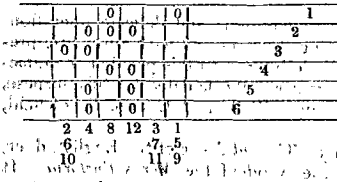
No. 15.—King's Cord.



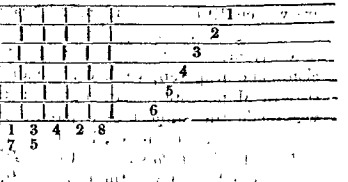
No. 16.—Dutch Cord.



No. 17.—Genoa Velvet.



No. 18.—Plain Velvet.



After the fustian cloth is taken from the loom-beam, it is carried to the cutter, who rips up the surface-threads of weft, and produces thereby a hairy-looking stuff.

Preparatory to its being cut, the cloth is spread evenly upon a table about six feet long, upon each end of which a roller mounted with a ratchet-wheel is fixed; the one to give off, and the other to wind up the piece, in the above six-feet lengths.

The knife is a steel rod about two feet long, and three-eighths of an inch square, having a square handle at the one end; the other end is tapered away to a blade, as thin as paper. To prevent this point from turning downwards and injuring the cloth, its under side is covered by a guide which serves to stiffen it, as well as to prevent its lower edge from cutting the fustian.

The operative (male or female) grasps the handle in the right hand, and insinuating the projecting point of the guide under the weft, pushes the knife smartly forward through the whole length of six feet, with a certain dexterous movement of the shoulder and right side, balancing the body meanwhile, like a fencer, upon the left foot. This process is repeated upon every adhesive line of the weft.

The next process to which fustians are exposed is steeping in hot water, to take out the dressing paste. They are then dried, reeled, and brushed by a machine, &c. From twenty to thirty pieces, each eighty yards long, may be brushed in an hour. The breadth of the cloth is twenty inches. The maceration is performed by immersing the bundled pieces in tanks of water, heated by waste steam; and the washing by means of a reel or winch, kept revolving rapidly under the action of a stream of cold water, for an hour or longer.

After being thus ripped up, it is taken to the brushing or teazling machine, to make it shaggy.

This consists of a series of wooden rollers, turning freely upon iron axles, and covered with tin-plate, rough with the burs of punched holes; and blocks of wood, whose concave under surfaces are covered with card-cloth or card-brushes, and which are made to traverse backwards and forwards in the direction of the axes of the revolving rollers, during the passage of the cloth over them.

After they are brushed in the machine, the goods are singed by passing their cut surface over a cylinder of iron, laid in a horizontal direction, and kept red hot by a flue. See SINGEING. They are now brushed again by the machine, and once more passed over the singeing surface. The brushing and singeing are repeated a third or even occasionally a fourth time, till the cord acquires a smooth polished appearance.

The goods are next steeped, washed, and bleached, by immersion in solution of chloride of lime. They are then dyed by appropriate chemical means. After which they are padded (imbued by the padding machine of the calico printers) with a solution of glue, and passed over steam cylinders to stiffen them.

Smooth fustians, when cropped or shorn before dyeing, are called moleskins; but when shorn after being dyed, are called beaverteen; they are both tweeled fabrics. Cantoon is a fustian with a fine cord visible upon the one side, and a satiny surface of yarns running at right angles to the cords upon the other side. The satiny side is sometimes smoothed by singeing. The stuff is strong, and has a very fine aspect. Its price is one shilling and sixpence a yard.

Common plain fustian, of a brown or drab colour, with satin top, is sold as low as sevenpence a yard.

A fustian, with a small cord running in an oblique direction, has a very agreeable appearance. It is called diagonal. Moleskin shorn, of a very strong texture, and a drab-dyed tint, is sold at 20*d.* per yard.

The weight of 90 yards of the narrow velveteen, in the green or undressed state, is about 24 pounds. The goods made for the German, Italian, and Russian markets are lighter, on account of the peculiarity in the mode of levying the import duty in these countries. These prices have been lowered of late years.

Velveteens as they come from the loom, are sold wholesale by weight, and average a price of 20*d.* per pound. They are usually woven with yarns of Upland and Brazil cotton wool, spun together for the warp; or, sometimes, New Orleans alone. The weft is usually Uplands, sometimes mixed with East India cotton wools.

Trowser velveteens are woven 19 inches wide, if they are to be cut up; if not, they are woven 30 inches, and called beaverteen.

Cutting or cropping fustians by hand is a very laborious and delicate operation. The invention of an improved apparatus for effecting the same end with automatic precision and despatch, was therefore an object of no little interest to this peculiar manufacture of Manchester. An ingenious machine, apparently well calculated for this purpose, was made the subject of a patent by Messrs. William Wells and George Scholefield, of Salford, in November, 1834.
